$$D_\mu F^{\mu\nu} + \frac{m}{2}\varepsilon^{\mu\alpha\beta}F_{\alpha\beta} = J^\nu \qquad [64a]$$

or, equivalently, in terms of the dual-field strength ${}^*F^\mu \equiv \frac{1}{2}\varepsilon^{\mu\alpha\beta}F_{\alpha\beta}$,

$$\varepsilon^{\mu\nu\alpha}D_\mu {}^*F_\alpha + m {}^*F^\nu = J^\nu \qquad [64b]$$

For dimensional balance, $m$ carries dimension of mass. Indeed, in the source-free case [64] implies

$$(D^\alpha D_\alpha + m^2){}^*F_\mu = \varepsilon_{\mu\alpha\beta}[{}^*F^\alpha, {}^*F^\beta] \qquad [65]$$

This shows that excitations are massive, even though local gauge invariance is preserved. Otherwise, as in the Dirac monopole case, the equations of motion are unexceptional.

However, for the quantum theory we need the action, whose variation produces the mass term in [64]. This is just the Chern–Simons term $W(A)$ in [37], multiplied by $-8\pi^2 m$ and now defined on $(2+1)$-dimensional spacetime:

$$I_{\mathrm{CS}} = 2m\int \mathrm{d}^3x\, \varepsilon^{\alpha\beta\gamma}\mathrm{tr}\left(\tfrac{1}{2}A_\alpha\partial_\beta A_\gamma + \tfrac{1}{3}A_\alpha A_\beta A_\gamma\right) \qquad [66]$$

Everything holds also in the abelian theory; the last term in [66] is then absent.

In this model, the mass is generated by a topological mechanism since $I_{CS}$ possesses the usual attributes for a topological entity: it is diffeomorphisms invariant without a metric tensor; when the potentials are appropriately parametrized, it is given by a surface term. (In the abelian case, the appropriate parametrization is in terms of Clebsch decomposition, $A_\mu = \partial_\mu\theta + \alpha\partial_\mu\beta$.) Most importantly, in the nonabelian theory [66] changes by $8\pi^2 mn$ with three-dimensional gauge transformations carrying winding number $n$. Hence, for consistency of the nonabelian quantum theory, $m$ must be quantized as $n/4\pi$ (in units of $\hbar$ and the coupling constant, which have been scaled to unity). All this is a clear field-theoretic analog to the quantum mechanics of the Dirac monopole, and just as for the magnetic monopole, a Hamiltonian argument for quantizing $m$ can be constructed, as an alternative to the above action-based derivation.

The time component of [64] relates the electric and magnetic fields to the charge density:

$$\boldsymbol{D}\cdot\boldsymbol{E} - mB = \rho \qquad [67]$$

In the abelian case, the first term involves a total derivative and its spatial integral vanishes, leaving a formula that identifies magnetic flux with a total charge. At low energy, the mass term dominates the conventional kinetic term in [64], and the flux–charge relation becomes a local field-current identity,

$$m^*F^\nu \approx J^\nu \qquad [68]$$

These formulas have made Chern–Simons-modified gauge theories relevant to issues in condensed matter physics, for example, the quantum Hall effect. In the abelian case, $m$ need not be quantized.

### Adding Fermions

Three-dimensional Dirac matrices are minimally realized by $2\times 2$ Pauli matrices. As a consequence, a mass term is not parity invariant; also, there is no $\gamma_5$ matrix, since the product of the three Dirac (= Pauli) matrices is proportional to $I$. While there are no chiral anomalies, there is the so-called parity anomaly: integrating a single doublet of massless SU(2) fermions one obtains $\Delta(\boldsymbol{A}) \equiv \det[\gamma^\mu(\mathrm{i}\partial_\mu + \boldsymbol{A}_\mu)]$, which should preserve parity and gauge invariance.

Since there are no anomalies in current divergences, $\Delta(\boldsymbol{A})$ is certainly invariant against infinitesimal gauge transformations. But for finite gauge transformations (categorized by $\Pi^3(\mathrm{SU}(2) = Z)$ one finds that $\Delta(\boldsymbol{A})$ is not invariant: when the gauge transformation belongs to an odd-numbered homotopy class, $\Delta(\boldsymbol{A})$ changes sign. To regain gauge invariance, one must either work with an even number of fermion doublets or, if only one doublet (more generally, odd number) is to be used, one must add to the gauge Lagrangian a parity-violating Chern–Simons term with half the correctly quantized coefficient, to neutralize the gauge non-invariance of $\Delta(\boldsymbol{A})$.

Alternatively, $\Delta(\boldsymbol{A})$ can be regularized in a gauge-invariant manner. But this requires massive, Pauli–Villars regulator fields, which produce a parity-violating expression for $\Delta(A)$. One cannot avoid the parity anomaly.

### Adding Bosons

There are a variety of bosonic field models that one may consider: Abelian or nonabelian; with conventional kinetic term or supplemented by the Chern–Simons topological mass; or, for low energy, no kinetic term but only the Chern–Simons term, as in [68]. Abelian charged Bose fields in a Maxwell theory lead to vortex solitons, based on $\Pi^1(\mathrm{U}(1)) = Z$. These are just the instantons of the $(1+1)$-dimensional bosonic gauge theory discussed previously. With Maxwell kinematics there are no charged vortices, but these appear when the Chen–Simons mass is added; see [67]. Pure Chern–Simons kinematics, with no Maxwell term, can produce completely integrable soliton equations (Liouville, Toda) when the Bose field dynamics is appropriately chosen.

## Conclusion

Topological effects in field theory are associated with the infinities and regularization that beset quantum field theories. These give rise to the chiral anomaly, parity anomaly (and scale symmetry anomalies, not discussed here). Yet the anomalies themselves are finite quantities that have topological significance (Atiyah–Singer, Chern–Pontryagin, Chern–Simons). This paradoxical pairing has not been understood. Nor can we explain why the anomalies interfere in a topological manner with symmetries associated with masslessness.

Although the range of topological effects in gauge theory is large, and even larger in non-gauge theories (sigma models, Skyrme models) the relevance to actual fundamental physics is confined to the $\theta$-angle phenomenon, which is analyzed accurately and abstractly by reference to $\Pi^3(G)$ and to the interplay with fermions through the chiral anomaly. Instantons are relevant only to an approximate, semiclassical discussion. Although after much mathematical work, general instanton configurations are well understood, only the 1-instanton solution enjoys physical significance.

Other topological entities that fascinate are either nonexistent in fundamental physics or are relevant to

condensed matter physics (vortices, Chern–Simons effects). But here too, we note that the fundamental equation of condensed matter physics – the many-body Schrödinger equation – carries no evident topological structure. Only the phenomenological equations, which replace the fundamental one, give rise to topological intricacies.

# Normal Forms and Semiclassical Approximation

**D Bambusi**, Universitá di Milano, Milan, Italy

## Introduction

Quantum mechanics was born at the beginning of the twentieth century with the quantization rules for the harmonic oscillator and for the hydrogen atom. Such rules were almost immediately extended to more general systems by the so-called Bohr–Sommerfeld quantization rule: "the actions of the classical system can assume only those values which are integer multiples of $\hbar$." However, the actions are defined only in some special situations and, moreover, at the present time the Schrödinger equation is the paradigm of quantum mechanics. A question naturally arises: is there any relation between the eigenvalues of the Schrödinger operator and the numbers obtained by Bohr–Sommerfeld quantization rule (when available)?

According to common wisdom, the "Bohr–Sommerfeld numbers" are a first approximation to the eigenvalues of the Schrödinger operator in the so-called semiclassical limit. However, precise mathematical results on the subject were obtained only in the 1980s and a good understanding of the problem has been achieved only recently. In particular it is now clear how to compute higher-order corrections to the eigenvalues: this is done through suitable normal form procedures.

In the present article we will discuss the above questions for the case of perturbed harmonic oscillators, a case which, on the one hand, is physically relevant and, on the other, is well understood. We will only briefly discuss the quantization of perturbations of integrable systems.

## A Statement

On $L^2(\mathbb{R}^n)$, consider the Schrödinger operator

$$\hat{H} = -\frac{\hbar^2}{2}\Delta + V \qquad [1]$$

where $\Delta$ is the $n$-dimensional Laplacian and $V$ is a smooth real potential having an absolute nondegenerate minimum at the origin. We are interested in

the eigenvalues of [1] close to zero. Introduce coordinates adapted to the normal modes, namely such that

$$V(x) = \sum_{i=1}^{n} \frac{\omega_i^2 x_i^2}{2} + O(\|x\|^3)$$

Assume

(H1) *Nonresonance*: There exist $\gamma > 0$ and $\tau \in \mathbb{R}$ such that, for any $k \in \mathbb{Z}^n - \{0\}$ one has

$$|\omega \cdot k| \geq \frac{\gamma}{|k|^\tau} \qquad [2]$$

(H2) $V(x) > 0$ for $x \neq 0$, and

$$\liminf_{|x|\to\infty} V(x) > 0$$

(H3) $V \in C^\infty(\mathbb{R}^n)$ and for any $r \geq 0$ there exists $C_r$ such that

$$\left|\frac{\partial^{|\alpha|} V}{\partial x^\alpha}(x)\right| \leq C_{|\alpha|}\langle x\rangle^m, \quad \forall \alpha \in \mathbb{N}^n$$

where we used the notation $\langle x\rangle := (1 + \|x\|^2)^{1/2}$.

**Theorem 1** *Assume that* (H1)–(H3) *hold. Then, for any positive N, M there exist positive constants* $\hbar_{N,M}, \epsilon_{N,M}, C^1_{N,M}, C^2_{N,M}$, *and a smooth function*

$$\mathcal{Z}_{N,M}(I_1, \ldots, I_n; \hbar)$$

*such that,* $\forall 0 < \epsilon \leq \epsilon_{N,M}$ *and* $0 < \hbar \leq \hbar_{N,M}\epsilon$, *the eigenvalues of* [1] *in* $[0, \epsilon)$ *have the representation*

$$\lambda_k = \left(k + \tfrac{1}{2}\right) \cdot \omega\hbar + \mathcal{Z}_{N,M}\left(\left(k + \tfrac{1}{2}\right)\hbar; \hbar\right) + R_{NM}(k, \hbar), \quad k \in \mathbb{N}^n,\ k_j \geq 1 \qquad [3]$$

*where*

$$|R_{NM}(k, \hbar)| \leq C^1_{N,M}\epsilon^N + C^2_{N,M}\left(\frac{\hbar}{\epsilon}\right)^M$$

*More precisely, for any* $k \in \mathbb{N}^n$ *such that*

$$\left(k + \tfrac{1}{2}\right) \cdot \omega\hbar + \mathcal{Z}_{N,M}\left(\left(k + \tfrac{1}{2}\right)\hbar; \hbar\right) \in [0, \epsilon) \qquad [4]$$

*there exists an eigenvalue* $\lambda_k \in [0, \epsilon)$ *for which* [3] *holds, and vice versa, for any eigenvalue in* $[0, \epsilon)$ *there exists a k satisfying* [3] *and* [4]. *The function* $\mathcal{Z}_{N,M}(I_1, \ldots, I_n; 0)$ *coincides with the classical Birkhoff normal form of the system computed up to order N.*

The proof of the theorem is constructive, in the sense that it provides an algorithm allowing to construct explicitly, by elementary operations, the function $\mathcal{Z}_{N,M}$. One could choose $\epsilon = \epsilon(\hbar) = \hbar^\delta$ with some positive $\delta < 1$, obtaining a simpler statement valid for the eigenvalues in $[0, \hbar^\delta)$. It is also possible to weaken the nonresonance condition (H1) to the condition $\omega \cdot k \neq 0$ for $k \in \mathbb{Z}^n - \{0\}$.

A theorem very close to [1] was proved by Sjöstrand (1992) by a method different from the one that will be presented here (see also Graffi and Paul (1987)). In the analytic or Gevrey case (recall that a $C^\infty$ function $f(x)$ is Gevrey in some domain if there exist constants $C, \sigma$ such that, for all multi-indexes $\alpha \in \mathbb{N}^n$ one has

$$\left|\frac{\partial^{|\alpha|} f}{\partial x^\alpha}\right| \leq C^{|\alpha|}(\alpha!)^\sigma$$

in the whole domain), the error can be reduced to be exponentially small with the parameters (Bambusi *et al.* 1999). Previous results dealing with compact perturbations of the harmonic oscillator were obtained by Bellissard and Vittot (1990). It is possible to deal also with the resonant case in which (H1) is violated. In this case the spectrum of the complete system is qualitatively different from the spectrum of the harmonic one. As discussed later, the normal form allows one to compute the main qualitative differences.

## Birkhoff Normal Form

In this section we recall the procedure leading to classical Birkhoff normal form, whose quantization leads to the proof of Theorem 5.

### Birkhoff's Theorem

The operator [1] is the quantization of the classical Hamiltonian

$$\sum_{i=1}^{n} \frac{\xi_i^2}{2} + V(x) \qquad [5]$$

Denote

$$H_0(\xi, x) := \sum_{j=1}^{n} \omega_j I_j, \quad I_j := \frac{\xi_j^2 + \omega_j^2 x_j^2}{2\omega_j} \qquad [6]$$

then we have

**Theorem 2** *For any positive integer* $N \geq 2$ *there exist a neighborhood* $\mathcal{U}_N$ *of the origin and a canonical transformation* $\mathcal{T}_N : \mathbb{R}^{2n} \supset \mathcal{U}_N \to \mathbb{R}^{2n}$ *which puts the system* [5] *in Birkhoff normal form up to order N, namely such that*

$$H \circ \mathcal{T}_N = H_0 + Z^N + R_N \qquad [7]$$

*where* $Z^N$ *Poisson-commutes with* $H_0$, *namely* $\{H_0; Z^N\} \equiv 0$ *and* $R_N$ *is small*, *that is*,

$$|R_N(\xi, x)| \leq C_N \|(\xi, x)\|^{N+1} \quad [8]$$

*Moreover*, *if the frequencies are nonresonant*, *namely*

$$\omega \cdot k \neq 0, \quad \forall k \in \mathbb{Z}^n \backslash \{0\} \quad [9]$$

*the function* $Z^N$ *depends on the actions* $I_j$ *only*. We recall that the Poisson bracket of two functions $f$ and $g$ is defined by

$$\{f; g\} := \sum_{j=1}^{n} \left( \frac{\partial f}{\partial \xi_j} \frac{\partial g}{\partial x_j} - \frac{\partial f}{\partial x_j} \frac{\partial g}{\partial \xi_j} \right) = -\{g; f\}$$

and coincides with the Lie derivative of $g$ with respect to the Hamiltonian vector field of $f$.

**Remark 1** In the case where the frequencies fulfill (H1) and the potential $V$ is analytic (or of Gevrey class) the remainder can be reduced to be exponentially small with $\|(\xi, x)\|$.

### Scheme of the Proof

Make the rescaling $\xi = \epsilon \xi'$, $x = \epsilon x'$. In terms of the primed variables, the Hamiltonian of the system [5] takes the form

$$H_\epsilon(\xi', x') = H_0(\xi', x') + \epsilon W(x') \quad [10]$$

with

$$W(x') := \frac{V(\epsilon x') - \epsilon^2 \sum_{j=1}^{n} \omega_j^2 (x_j')^2 / 2}{\epsilon^3} = W_3(x') + \epsilon W_4(x') + \cdots \quad [11]$$

and $W_l$ is the Taylor polynomial of order $l$ of $V$. In what follows we will omit primes from the scaled variables.

Given an auxiliary Hamiltonian $\chi_3$, denote by $\Phi_t^3$ the flow of the corresponding Hamiltonian vector field. We construct $\chi_3$ so that $H_\epsilon \circ \Phi_\epsilon^3$ is in normal form up to order $\epsilon^2$.

**Remark 2** Given a $C^\infty$ function $g$ one has $g \circ \Phi_\epsilon^3 \sim \sum_{l=0}^{\infty} \epsilon^l g_l$, with

$$g_0 := g, \qquad g_l = \frac{1}{l} \{\chi_3; g_{l-1}\}, \quad l \geq 1 \quad [12]$$

where $\sim$ denotes the fact that the left-hand side is asymptotic to the right-hand side (a precise definition appears later in the article). If both $g$ and $\chi_3$ are analytic then the series of $g \circ \Phi_\epsilon^3$ can be shown to converge in a neighborhood of the origin. Using [12] to compute $H_\epsilon \circ \Phi_\epsilon^3$, we get

$$H_\epsilon \circ \Phi_\epsilon^3 = H_0 + \epsilon[W_3 + \{\chi_3; H_0\}] + O(\epsilon^2)$$

So $H_\epsilon \circ \Phi_\epsilon^3$ is in normal form up to $O(\epsilon^2)$ provided $\chi_3$ fulfills the so-called homological equation:

$$W_3 + \{\chi_3; H_0\} = Z_3 \quad [13]$$

where the unknown function $Z_3$ has to be in normal form. Note that, since the operator

$$\chi \mapsto \{\chi; H_0\}$$

maps linearly polynomials of degree $l$ into polynomials of degree $l$, eqn [13] can be interpreted as a linear equation in the finite-dimensional space of polynomials of degree 3 in the phase-space variables.

**Lemma 1** *The homological equation* [13] *admits a solution* $(\chi_3, Z_3)$.

**Proof** Introduce the canonical coordinates $(\zeta, \eta)$ by

$$\zeta_j := \frac{1}{\sqrt{2}} \left( \frac{\xi_j}{\sqrt{\omega_j}} + \mathrm{i} x_j \sqrt{\omega_j} \right)$$
$$\eta_j := \frac{1}{\mathrm{i}\sqrt{2}} \left( \frac{\xi_j}{\sqrt{\omega_j}} - \mathrm{i} x_j \sqrt{\omega_j} \right) \quad [14]$$

In these variables the unperturbed Hamiltonian $H_0$ reads $H_0 = \sum_{j \geq 1} \mathrm{i}\omega_j \zeta_j \eta_j$ and $W_3$ is transformed in a different polynomial, again of third order. The important fact is that in these coordinates the eigenvectors of the linear operator $\{H_0; .\}$ are the monomials

$$\zeta^k \eta^l \equiv \zeta_1^{k_1} \cdots \zeta_n^{k_n} \eta_1^{l_1} \cdots \eta_n^{l_n}$$

Indeed, one has $\{H_0; \zeta^k \eta^l\} = \mathrm{i}\omega \cdot (k - l) \zeta^k \eta^l$. As a consequence, writing

$$W_3(\zeta, \eta) = \sum_{k,l} C_{k,l} \zeta^k \eta^l$$

one can define the resonant set

$$\mathcal{R} := \{(k, l) : \omega \cdot (k - l) = 0\}$$

and

$$Z_3(\zeta, \eta) := \sum_{k,l \in \mathcal{R}} C_{k,l} \zeta^k \eta^l$$
$$\chi_3(\zeta, \eta) := \sum_{k,l \notin \mathcal{R}} \frac{C_{k,l}}{\mathrm{i}\omega \cdot (k - l)} \zeta^k \eta^l \quad [15]$$

Going back to the original variables, one has the solution of the homological equation. □

**Definition 1** The function $Z_3$ solving [13] will be called the resonant part of $W_3$ and will be denoted by $\langle W_3 \rangle$.

Using the function $\chi_3$, one can transform the Hamiltonian to the form

$$H_0 + \epsilon Z_3 + \epsilon^2 R_3$$

**Remark 3** Equation [12] allows to construct directly the Taylor expansion of $R_3$ in terms of the Taylor expansion of $W$ and of its Poisson brackets with $\chi_3$.

Iterating the construction (which however slightly changes due to the presence of $Z_3$), one gets the proof of Theorem 2.

**Remark 4** In the nonresonant case $\omega \cdot (k - l) = 0$ implies that $k = l$; therefore, the resonant part of a polynomial is the sum of monomials of the form

$$\zeta^k \eta^k = I_1^{k_1} \cdots I_n^{k_n}$$

that is, it is a function of the actions only. Moreover, in this case one has $Z_3 = 0$, while in general $Z_4 \neq 0$.

## Some Symbolic Calculus

To understand how to quantize the procedure of Birkhoff normal form, we consider the classical–quantum correspondence. It is well known that there are different procedures in order to associate an operator with a classical observable. Here we concentrate on the Weyl quantization rule.

To a function $f \in \mathcal{S}(\mathbb{R}^{2n})$ (Schwartz class), we associate an operator $\hat{f}$ acting on functions $\psi \in \mathcal{S}(\mathbb{R}^n)$, which is defined by

$$[\hat{f}\psi](x) := \frac{1}{(2\pi\hbar)^n} \int_{\mathbb{R}^n \times \mathbb{R}^n} f\left(\frac{x+y}{2}, \xi\right) \times e^{\frac{i(x-y)\cdot\xi}{\hbar}} \psi(y)\, dy\, d\xi \qquad [16]$$

**Definition 2** The operator [16] is called the Weyl quantization of $f$ and in turn $f$ is called the symbol of $\hat{f}$.

Using the method of oscillatory integrals, the Weyl quantization rule can be extended to much more general observables $f$. We recall that, roughly speaking, the method of oscillatory integrals consists in giving meaning to a formal expression of the form [16] by using successive integration by parts (see, e.g., Martinez (2001)).

**Definition 3** A function $f \in C^\infty(\mathbb{R}^{2n})$ will be called a smooth symbol of class $S(\langle z \rangle^m)$ if, for any $r \geq 0$, there exists $C_r$ such that

$$\left| \frac{\partial^{|\alpha|} f}{\partial z^\alpha}(z) \right| \leq C_{|\alpha|} \langle z \rangle^m, \quad \forall \alpha \in \mathbb{N}^{2n}$$

Where $\langle z \rangle$ is as defined earlier.

It is useful to extend such a definition to functions explicitly depending also on $\hbar$. This can be done in a straightforward way by asking the constants $C_r$ to be independent of $\hbar$ in a neighborhood of the origin. Different classes of symbols can also be defined, but for our purpose this class is enough.

**Theorem 3** *Let $f \in S(\langle z \rangle^m)$, $m \in \mathbb{R}$, and $\psi \in \mathcal{S}(\mathbb{R}^n)$; then the formal expression [16] is a well-defined oscillatory integral.*

**Example 1** Under Weyl quantization rule, one has

$$\hat{\xi}_j = i\hbar\partial_{x_j}, \quad \hat{x}_j = x_j \quad \text{(multiplication operator)}$$
$$\widehat{\xi_j x_j} = \tfrac{1}{2}(\hat{\xi}_j \hat{x}_j + \hat{x}_j \hat{\xi}_j)$$

**Definition 4** A sequence $(f_j)_{j\geq 0}$ with $f_j \in S(\langle z \rangle^m)$ will be called the asymptotic expansion of $f \in S(\langle z \rangle^m)$ if, for any integer $N$, there exist two positive constants $C_N, \hbar_N$ such that

$$f = \sum_{j=0}^{N} \hbar^j f_j + R_N$$

with $|R_N(z, \hbar)| \leq C_N \hbar^{N+1} \langle z \rangle^m$, and $\hbar \in (0, \hbar_N)$.

The key point for the quantization of the normal form procedure is the following.

**Theorem 4** *Let $f \in S(\langle z \rangle^{m_1})$ and $g \in S(\langle z \rangle^{m_2})$; then there exists a unique $F \in S(\langle z \rangle^{m_1+m_2})$ such that*

$$\hat{F} = \hat{f}\hat{g} \quad (\textit{operator product!})$$

*moreover, one has*

$$F = \exp\left(\frac{i\hbar}{2}(\partial_x \cdot \partial_\eta - \partial_y \cdot \partial_\xi)\right) \times (f(x,\xi) g(y,\eta))|_{y=x,\, \eta=\xi} \qquad [17]$$

*Finally, $F$ admits an asymptotic expansion in $\hbar$ which coincides with the formal expansion of* [17].

The proof is obtained by using eqn [16] to write down an expression for $\hat{f}\hat{g}\psi$ and obtain a formula for $F$. Then, one shows that the formula is well defined and therefore the result is not formal.

**Definition 5** In the above context, the symbol $G$ of

$$\frac{i}{\hbar}\left[\hat{f}; \hat{g}\right] =: \hat{G}$$

will be called the "Moyal bracket" of $f$ and $g$ and will be denoted by $\{f; g\}_M$.

By formula [17], one has in particular

$$\{f; g\}_M = \{f; g\} + \hbar^2 \Delta_1(f, g) + O(\hbar^4) \qquad [18]$$

where

$$\Delta_1(f,g) = -\frac{1}{24}\left(\frac{\partial^3 f}{\partial\xi^3}\frac{\partial^3 g}{\partial x^3} - 3\frac{\partial^3 f}{\partial\xi^2\partial x}\frac{\partial^3 g}{\partial x^2\partial\xi} + 3\frac{\partial^3 f}{\partial\xi\partial x^2}\frac{\partial^3 g}{\partial x\partial\xi^2} - \frac{\partial^3 f}{\partial x^3}\frac{\partial^3 g}{\partial\xi^3}\right)$$

where we used a vector notation for the derivatives. If either $f$ or $g$ are polynomials of degree $\leq 2$, then

$$\{f;g\}_{\mathrm{M}} = \{f;g\} \qquad [19]$$

Given a self-adjoint operator $A$ and a smooth function $G:\mathbb{R}\to\mathbb{R}$, it is well known how to define by spectral theorem the operator $G(A)$. Suppose now that $A=\hat{f}$ for some symbol $f$. In general, one has $G(\hat{f})\neq\widehat{G\circ f}$. However, by symbolic calculus (i.e., using eqn [17]), one has:

**Lemma 2** *Denote* $I_j(x,\xi)=(\omega_j^2 x_j^2+\xi_j^2)/2\omega_j$. *Then, for any positive integer* $k$ *there exists a function* $F_k(I_j,\hbar)$ *such that*

$$\widehat{(I_j)^k} = F_k(\hat{I}_j,\hbar)$$

*where the right-hand side is defined by spectral calculus. Moreover,* $F_k$ *can be computed explicitly by the recursion formula* $F_{k+1}=I_jF_k+F_{k-1}\hbar^2(k^2-k+1)/4$.

As a consequence of this fact and of the fact that $[\hat{I}_j,\hat{I}_l]=0$, one has that the Weyl quantization of a polynomial function of the actions is a function of the action operators.

## Semiclassical Normal Form

Let $\chi$ be a smooth symbol such that $\hat{\chi}$ is self-adjoint, and consider the group of unitary operators $X_\epsilon := \exp((\mathrm{i}\epsilon/\hbar)\hat{\chi})$. Let $g$ be a smooth symbol; apply the unitary transformation $X_\epsilon$ to $\hat{g}$, namely compute $X_\epsilon\hat{g}X_\epsilon^{-1}$. Noting that (on a suitable domain)

$$\frac{\mathrm{d}}{\mathrm{d}\epsilon}(X_\epsilon\hat{g}X_\epsilon^{-1}) = X_\epsilon\frac{\mathrm{i}}{\hbar}[\hat{\chi};\hat{g}]X_\epsilon^{-1}$$

one has (formally!) the expansion of $X_\epsilon\hat{g}X_\epsilon^{-1}$ in $\epsilon$:

$$X_\epsilon\hat{g}X_\epsilon^{-1} = \sum_{l\geq 0}\epsilon^l\widehat{g_{q,l}}$$

where

$$\widehat{g_{q,0}} := \hat{g}, \quad \widehat{g_{q,l}} = \frac{1}{l}\frac{\mathrm{i}}{\hbar}[\hat{\chi};\widehat{g_{q,l-1}}],\ l\geq 1 \qquad [20]$$

(Such a series can be interpreted as an asymptotic expansion provided one restricts the domain at each step of the approximation.) Equivalently, the symbol of $X_\epsilon\hat{g}X_\epsilon^{-1}$ is formally given by $\sum_l \epsilon_l g_{q,l}$ with

$$g_{q,0} := g, \quad g_{q,l} := \frac{1}{l}\{\chi; g_{q,l-1}\}_{\mathrm{M}},\ l\geq 1 \qquad [21]$$

from which one sees a remarkable similitude with the classical equation. Moreover, [21] converges to [12] when $\hbar\to 0$.

Applying the unitary transformation generated by $\hat{\chi}$ to the Hamiltonian operator $\hat{H}_\epsilon$ (cf. eqn [10]), one has $X_\epsilon\hat{H}_\epsilon X_\epsilon^{-1}=\widehat{H_q^1}$ with

$$H_q^1 = H_0 + \epsilon[W_3 + \{\chi;H_0\}_{\mathrm{M}}] + O(\epsilon^2) \qquad [22]$$

$$\equiv H_0 + \epsilon[W_3 + \{\chi;H_0\}] + O(\epsilon^2) \qquad [23]$$

where we used the fact that $H_0$ is a quadratic polynomial, so that [19] holds. It is thus clear that Lemma 1 allows to solve also the quantum homological equation appearing in this context and to determine the symbol of the operator generating the unitary transformation putting the Hamiltonian operator in normal form up to corrections of order $\epsilon^2$. Moreover, one can compute in terms of Moyal brackets (of polynomials!) the expansion of the symbol of the new remainder and of the normal form. Iterating the construction, one generates a well-defined semiclassical normal form of the quantum system.

**Example 2** Denote by $Z_{q,l}, l=1,2\ldots,$ the term added to the semiclassical normal form at the $l$th step of the iterative construction. Explicitly, the first terms are given by

$$Z_{q,1} = \langle W_3\rangle = Z_3 \qquad [24]$$

$$Z_{q,2} = \langle W_4\rangle + \tfrac{1}{2}\langle\{\chi_3;W_3\}_{\mathrm{M}}\rangle + \tfrac{1}{2}\langle\{\chi_3;Z_3\}_{\mathrm{M}}\rangle \qquad [25]$$

$$Z_{q,3} = \langle W_5\rangle + \langle\{\chi_4;Z_3\}_{\mathrm{M}}\rangle + \tfrac{1}{3}\langle\{\chi_3;H_2\}_{\mathrm{M}}\rangle + \tfrac{1}{2}\langle\{\chi_3;W_{3,1}\}_{\mathrm{M}}\rangle + \langle\{\chi_3;W_4\}_{\mathrm{M}}\rangle \qquad [26]$$

where, according to Definition 1, $\langle\,.\,\rangle$ is the resonant part of its argument, $\chi_j$ is (formally) the symbol of the operator generating the $j$th unitary transformation, and

$$H_2 := \tfrac{1}{2}\{\chi_3;Z_3-W_3\}_{\mathrm{M}}, \quad W_{3,1} := \{\chi_3;W_3\}_{\mathrm{M}}$$

Note that all the Moyal brackets involved contain polynomials of degree at most 4, so that they can be computed exactly using formula [18] which in this case does not contain corrections of order $\hbar^4$.

The problem in making previous construction rigorous is that all the series involved are in general

divergent. Moreover, it is not possible to show that the remainders appearing when truncating such series are small in a reasonable sense. Nevertheless, it is possible, using the tools of microlocal analysis, to show that the semiclassical normal form contains essentially all the information on the part of the spectrum close to zero.

The precise relation between the spectrum of the original Hamiltonian and the spectrum of the semiclassical normal form is captured by the following definition.

Let $H_1(\epsilon, \hbar), H_2(\epsilon, \hbar)$ be two families of self-adjoint operators; set $\mathrm{Spec}_\epsilon(H_{1,2}) := \mathrm{Spec}(H_{1,2}) \cap [0, \epsilon)$.

**Definition 6** We say that

$$\mathrm{Spec}_\epsilon(H_1) = \mathrm{Spec}_\epsilon(H_2) \bmod (\epsilon^\infty + (\hbar/\epsilon)^\infty)$$

if for any $N, M > 0$ there exist $C^1_{N,M}$ and $C^2_{N,M}$ such that for any $\lambda_1 \in \mathrm{Spec}_\epsilon(H_1)$ there exists $\lambda_2 \in \mathrm{Spec}_\epsilon(H_2)$ such that $\lambda_1 = \lambda_2 + R_{N,M}$ with

$$|R_N| \le C^1_{N,M}\epsilon^N + C^2_{N,M}(\hbar/\epsilon)^M \qquad [27]$$

and conversely. Equation [27] has to hold for any couple $(\hbar, \epsilon)$ with $\epsilon$ and $(\hbar/\epsilon)$ small enough.

**Theorem 5** *Assume* (H2) *and* (H3); *assume also*: (H1′) *There exist* $\gamma > 0$ *and* $\tau \in \mathbb{R}$ *such that, for any* $k \in \mathbb{Z}^n$, *one has*

$$\text{either } \omega \cdot k = 0 \quad \text{or } |\omega \cdot k| \ge \frac{\gamma}{|k|^\tau} \qquad [28]$$

*Then there exists a polynomial function* $\mathcal{Z}_q$ *such that one has*

$$\mathrm{Spec}_\epsilon(\hat{H}) = \mathrm{Spec}_\epsilon(\hat{H}_0 + \widehat{\mathcal{Z}_q}) \bmod \left(\epsilon^\infty + \left(\frac{\hbar}{\epsilon}\right)^\infty\right) \qquad [29]$$

*The polynomial* $\mathcal{Z}_q$ *coincides with the semiclassical normal form defined at the beginning of the section.*

**Scheme of the proof** It consists of six steps. (1) Make the unitary transformation $(U\psi)(x) := \epsilon^{n/4}\psi(\epsilon^{1/2}x)$ which transforms the Hamiltonian operator [1] into the Weyl quantized of $\epsilon H_\epsilon := \epsilon(H_0 + \epsilon^{1/2}W)$, but a Weyl quantization where $\hbar$ is substituted by $\hbar' := \hbar/\epsilon$. (2) Make a cutoff of $H_\epsilon$, namely, fix $R$ and consider a smooth function $t$ such that $t(s) \equiv 1$ for $|s| \le R$, $t(s) \equiv 0$ for $|s| \ge 2R$, define $a(x, \xi) := W(x)t(\|(\xi, x)\|)$. (3) Compare the spectrum of the Hamiltonian $\hat{H}_\epsilon$ with the spectrum of $H^t := H_0 + \epsilon a$. By microlocal analysis, one has that, in any fixed bounded interval such spectra coincide modulo $\hbar^\infty$ (see, e.g., Martinez (2001)). (4) Rescale back the variables, namely apply the transformation $U^{-1}_\epsilon$ to $H^t$. (5) Apply the normal form algorithm to the so-obtained Hamiltonian showing that all the series involved are convergent in suitable norms. (6) Use again microlocal analysis to show that the spectrum of the semiclassical normal form coincides with the spectrum of the normalized operator with compactly supported symbol. □

**Remark 5** Fix an arbitrary $1 > \delta > 0$ and link $\epsilon$ to $\hbar$ by $\epsilon := \hbar^\delta$. Then one obtains a simplified statement according to which the spectrum of [1] in $[0, \hbar^\delta]$ coincides modulo $\hbar^\infty$ with the spectrum of $\hat{H}_0 + \widehat{\mathcal{Z}}_q$ in the same interval.

**Remark 6** In the case where the frequencies are nonresonant one has that the symbol of the normal form depends on the actions only. By Lemma 2 one has that also the quantization of the normal form is a function of the action operators only (explicitly computable), and therefore the spectrum of the normal form is given by a quantization formula as claimed in Theorem 1.

## The Resonant Case

In the case where the frequencies are nonresonant, due to the particular structure of the normal form, one obtains a very precise information on the spectrum. In the case where there are some resonances, the situation is more difficult. In order to illustrate what happens we concentrate on the completely resonant case, that is, the case where all the frequencies are integer multiples of a single fundamental frequency $\nu$.

In this case, the eigenvalues of $\hat{H}_0$ form a subset of $\mathbb{N}\hbar\nu + (1/2)|\omega|\hbar$ and are degenerate. One expects the nonlinear part to break such a degeneracy and to transform each eigenvalue in a small band. One can use the normal form to study the structure of the so-obtained band. To this end, the most relevant contribution is due to the first nonvanishing term of the normal form. For the sake of definiteness, we assume that this is the term of order 4, namely $\mathcal{Z}_4$. Denote

$$N := \mathcal{Z}_4\big|_{H_0^{-1}(1)}, \qquad B(E) \equiv \left[E - \tfrac{1}{3}\nu\hbar, E + \tfrac{1}{3}\nu\hbar\right]$$

**Theorem 6** *Fix* $1 > \gamma_1 > 1/2$, *then, provided* $\hbar$ *is small enough, one has*

$$\mathrm{Spec}(\hat{H}) \cap (\hbar, \hbar^{\gamma_1}) \subset \bigcup_{E \in \mathrm{Spec}(\hat{H}_0)} B(E) \qquad [30]$$

*Moreover, denote by*

$$E + \lambda_1(E, \hbar) \le \cdots \le E + \lambda_m(E, \hbar) \qquad [31]$$

*the eigenvalues of $\hat{H}$ in $B(E)$ counted with multiplicity, then*

$$\lambda_1(E,\hbar) = E^2 \mathrm{Min}\, N + E^2(O(\hbar/E) + O(E^{1/2})) \quad [32]$$

*and similarly*

$$E^2\lambda_m(E,\hbar) = \mathrm{Max}\ N + E^2(O(\hbar/E) + O(E^{1/2})) \quad [33]$$

This statement is due to Bambusi, Charles, and Tagliaferro (see Bambusi 2004); for previous results, see Vũ Ngọc (1998).

Equation [30] shows that the spectrum has a band structure, while eqns [32] and [33] allow one to compute the minimum and the maximum of each band.

The idea of the proof is as follows. First forget high-order terms of the normal form, whose effect is included in the error terms. Then, due to the commutation property of the normal form with $\hat{H}_0$, one has that $\mathcal{Z}_4$ restricts to an operator acting on the eigenspaces of $\hat{H}_0$. On the classical side, one has that by Marsden–Weinstein procedure $\mathcal{Z}_4$ defines a classical Hamiltonian system on the manifold obtained by symplectic reduction of the original phase space. By the methods of geometric quantization, it turns out that the quantum operator acting on an eigenspace of $\hat{H}_0$ is a Toeplitz operator whose principal symbol is exactly the above reduced classical Hamiltonian. Then, the proof follows by classical properties of Toeplitz operators.

We point out that results of this kind are useful in the computation of the molecular spectra (Michel and Zhilinskii 2001, Zhilinskii 2001).

## Quantization of KAM Tori

In this section we present a result on the quantization of KAM tori. It allows one to construct part of the spectrum of a close-to-integrable system.

We recall that a classical Hamiltonian system with $n$ degrees of freedom is said to be integrable if it has $n$ integrals of motion independent and in involution. If the energy surface is compact, then, by Arnol'd–Liouville theorem there exists a canonical transformation $\mathcal{T}_0 : \mathbb{R}^n \times \mathbb{T}^n \supset D \times \mathbb{T}^n \to \mathbb{R}^{2n}$ introducing action-angle variables, namely such that, denoting by $K_0$ the original integrable Hamiltonian, $K_0 \circ \mathcal{T}_0$ is independent of the angles $\phi \in \mathbb{T}^n$. Here, $D$ is an open bounded domain.

Consider now a close-to-integrable analytic Hamiltonian system, namely a Hamiltonian system with Hamiltonian

$$K = K_0 + \epsilon K_1$$

where $\epsilon$ is a small parameter. We assume that, denoting again by $\mathcal{T}_0$ the canonical transformation introducing action-angle variables for the system $K_0$, one has that both $K_0 \circ \mathcal{T}_0$ and $K_1 \circ \mathcal{T}_0$ are real analytic on $D \times \mathbb{T}^n$. Then, the KAM theory applies. To state the corresponding result, denote by $D_0 \subset D$ a domain whose closure is contained in $D$.

**Theorem 7** *Assume that $\forall I \in D$ one has*

$$\det\left(\frac{\partial^2 (K_0 \circ \mathcal{T}_0)}{\partial I^2}\right) \neq 0 \quad [34]$$

*then there exists a positive constant $\epsilon_*$ and, for any $\epsilon$ with $|\epsilon| < \epsilon_*$, there exists a Gevrey canonical transformation $\mathcal{T}_\epsilon : D_0 \times \mathbb{T}^n \to \mathbb{R}^{2n}$ and a Cantor set $D_\epsilon \subset D_0$ with the following properties:*

$$K \circ \mathcal{T}_\epsilon = Z(I) + R(I,\phi,\epsilon) \quad [35]$$

*where $R(I,\phi,\epsilon)$ vanishes at infinite order on $D_\epsilon$, that is, for any multi-index $\alpha$ there exists $C_{|\alpha|}$ such that one has*

$$\left|\frac{\partial^{|\alpha|} R}{\partial (I,\phi)^\alpha}(I,\phi,\epsilon)\right| \leq C_{|\alpha|} \exp\left(-\frac{c}{|I - D_\epsilon|^\rho}\right) \quad [36]$$

*with a suitable $\rho > 0$ and $|I - D_\epsilon|$ denoting the distance from $D_\epsilon$. Moreover, as $\epsilon$ tends to zero, the measure of $D_\epsilon$ tends to the measure of $D_0$.*

A particular consequence is that the set $D_\epsilon$ is foliated in invariant tori. From the proof, it also turns out that the motion on each torus is quasiperiodic with frequencies fulfilling the assumption (H1) stated earlier. Moreover, the tori are linearly stable and even more: they are stable in an exponential sense (namely, a solution starting $O(\mu)$ close to a torus takes at least a time $O(\exp(c/\mu^\rho))$ to double its distance from the torus).

Quantizing the normalizing transformation $\mathcal{T}_\epsilon$ by using the theory of Fourier integral operators, one can also put the quantum Hamiltonian in a suitable normal form which allows to deduce some spectral information on the system.

To fix ideas we restrict to the case where $K$ is a natural system, namely it has the form (3.1), and is close to integrable in the above sense. Fix two parameters $E_1 < E_2$; assume (1) that $K^{-1}([-\infty, E_2 + \delta])$ is compact for some positive $\delta$ and (2) that the domain $D_0$ can be constructed in such a way that $\mathcal{T}_0 : D_0 \times \mathbb{T}^n \to K_0^{-1}([E_0, E_1])$ is a bijection and, moreover, the KAM condition [34] holds. Denote by $\theta \in \mathbb{Z}^n$ the Maslov class of the tori of $K_0$ (see, e.g., Lazutkin (1993)) and, having fixed some $0 < \sigma < 1$, define the set of indexes

$$\mathcal{I} := \{k \in \mathbb{Z}^n : |D_\epsilon - \hbar(k + \theta/4)| \leq \hbar^\sigma\} \quad [37]$$

**Theorem 8** *There exist positive constants $\hbar_*$, $c$, $C$, and $\sigma < 1$, and a function $K_q : D_0 \times (0, \hbar_*) \to \mathbb{R}$ with the following property: for any $k \in \mathcal{I}$ there exists at least one eigenvalue of $\hat{K}$ in the interval*

$$\left[Z_q(\hbar(k+\theta/4),\hbar) - \mathrm{C}e^{-c/\hbar^\rho},\right.$$
$$\left. Z_q(\hbar(k+\theta/4),\hbar) + \mathrm{C}e^{-c/\hbar^\rho}\right] \quad [38]$$

One can also show that a large part of the spectrum is constructed in this way. This is obtained by comparing the semiclassical estimate of the number of eigenvalues in $[E_1, E_2]$ to the number of eigenvalues thus constructed.

Theorem 8 is due to Popov (2000); the quantization of KAM tori was initiated by Lazutkin and widely developed by Colin de Verdière, who obtained a result similar to Theorem 8 for the case where $K$ is $C^\infty$ and describes the geodesic flow on a compact Riemannian manifold (Colin de Verdière 1977).

# *N*-Particle Quantum Scattering

**D R Yafaev**, Université de Rennes, Rennes, France

## Introduction

The present article relies heavily on Quantum Mechanical Scattering Theory in this Encyclopedia and can be considered as its continuation. We use here freely the notation and results discussed in this article.

An important problem of scattering theory concerns the Schrödinger $H$ operator of $N$, $N \geq 3$, interacting particles. Since the potential energy of pair interactions between particles depends on their relative positions only, it does not tend to zero at infinity in the configuration space of a system, even if the center-of-mass motion is removed. This is qualitatively different from the two-particle case. It turns out that asymptotically (for large times $t \to +\infty$ or $t \to -\infty$) an $N$-particle system splits up into clusters,

$$\mathcal{C}_1 \cup \cdots \cup \mathcal{C}_n = \{1, \ldots, N\}, \quad \mathcal{C}_k \cap \mathcal{C}_l = \emptyset \text{ if } k \neq l \quad [1]$$

Particles from the same cluster $\mathcal{C}_k$, $k = 1, \ldots, n$, form a bound state, and different clusters do not interact with each other. In particular, if $n = 1$ and $\mathcal{C}_1 = \{1, 2, \ldots, N\}$, then we have a bound state of the system. In another extreme case $n = N$, all particles are free. The asymptotic evolution determined by clusters $\mathcal{C}_1, \ldots, \mathcal{C}_n$ where $n \geq 2$, and bound states of all these clusters is called a scattering channel. Physically it is natural to expect that the list of all such channels is exhaustive, that is, no other scattering process is possible. This statement is called asymptotic completeness.

We emphasize that an $N$-particle system may be in different scattering states as $t \to +\infty$ and $t \to -\infty$ and different rearrangement processes are possible. For example, a three-particle system may asymptotically consist of free particles or a pair of particles may be in a bound state, whereas the third particle may be asymptotically free. If particles are free at both $-\infty$ and $+\infty$, then one speaks about elastic scattering; we have a capture if particles free at $-\infty$ form a bound state of a couple after the interaction; an opposite process, when a bound state at $-\infty$ gives three free particles, is known as a breakup. It is also possible that a bound state of one couple yields a bound state of

another pair (a rearrangement) or a bound state of a couple transforms into another bound state of the same couple (an excitation). All these processes are described by the scattering operator. On the contrary, if the whole system forms a bound state at $-\infty$ (i.e., $n=1$), then it remains in the same state for all $t$.

As far as monographic literature on $N$-particle scattering is concerned, we mention Dereziński and Gérard (1997), Faddeev (1965), Reed and Simon (1979), and Yafaev (2000).

## Setting the Scattering Problem

Let us recall the definition of the $N$-particle Schrödinger operator (Hamiltonian)

$$\boldsymbol{H} = \boldsymbol{H}_0 + \boldsymbol{V} \qquad [2]$$

If the configuration space of each particle is $\mathbb{R}^d$, then the operator $\boldsymbol{H}$ acts in the space $L_2(\mathbb{R}^{dN})$. The operator of kinetic energy (the "unperturbed" Hamiltonian) is

$$\boldsymbol{H}_0 = -\sum_{j=1}^{N}(2m_j)^{-1}\Delta_{x_j} \qquad [3]$$

where $x_j$ and $m_j$ are the position and mass of the particle labeled by $j$. The operator of potential energy of pair interactions of particles (the perturbation) $\boldsymbol{V}$ is the operator of multiplication by the function

$$V(x) = \sum_{i<j} V^{ij}(x_j - x_i), \quad i,j = 1,\ldots,N \qquad [4]$$

Set $\alpha=(ij)$, $x^\alpha = x_j - x_i$. It is assumed that the functions $V^\alpha(x^\alpha)$ tend to zero sufficiently rapidly as $|x^\alpha|\to\infty$ in $\mathbb{R}^d$. However, the function $V(x)\not\to 0$ as $|x|\to\infty$ in $\mathbb{R}^{dN}$ if at least one of the distances $|x_i - x_j|$ between particles remains bounded. This difficulty is manifest even for two particles ($N=2$), but in this case it disappears if the motion of the center of mass of the system is removed.

This means the following. Let the subspace $X^{\mathrm{cm}}$ of $\mathbb{R}^{dN}$ be distinguished by the condition

$$\sum_{j=1}^{N} m_j x_j = 0 \qquad [5]$$

and let $X_{\mathrm{cm}}$ be the orthogonal complement to $X^{\mathrm{cm}}$ in the space $\mathbb{R}^{dN}$ endowed with the scalar product

$$\langle x, y\rangle = 2\sum_{j=1}^{N} m_j \langle x_j, y_j\rangle_{\mathbb{R}^d} \qquad [6]$$

Then

$$L_2(\mathbb{R}^{dN}) = L_2(X_{\mathrm{cm}}) \otimes L_2(X^{\mathrm{cm}})$$

Denote by $x_{\mathrm{cm}}$, $x^{\mathrm{cm}}$ the orthogonal projections of $x\in\mathbb{R}^{dN}$ on the subspaces $X_{\mathrm{cm}}$, $X^{\mathrm{cm}}$, respectively, so that $x=(x_{\mathrm{cm}}, x^{\mathrm{cm}})$. Clearly, the vector $x_{\mathrm{cm}}$ has components

$$x_{\mathrm{cm}} = M^{-1}\sum_{j=1}^{N} m_j x_j, \quad M = \sum_{j=1}^{N} m_j$$

Let $T(p)$, $(T(p)f)(x_1,\ldots,x_N) = f(x_1+p,\ldots,x_N+p)$, be the operator of common translations of particles. The operator $\boldsymbol{H}$ commutes with $T(p)$, that is, $T(p)\boldsymbol{H} = \boldsymbol{H}T(p)$, for all $p\in\mathbb{R}^d$. It follows that

$$\boldsymbol{H} = K\otimes I + I\otimes H, \quad K = -(2M)^{-1}\Delta_{x_{\mathrm{cm}}} \qquad [7]$$

where $K$ is the kinetic energy operator of the center-of-mass motion.

The operator

$$H = H_0 + V \qquad [8]$$

acts in the space $\mathcal{H} = L_2(X^{\mathrm{cm}})$. Here $V$ is again the operator of multiplication by function [4]. The precise form of the differential operator $H_0$ depends on the choice of coordinates in $X^{\mathrm{cm}}$. For example, if $N=2$ and $x = x_2 - x_1$, then $H_0 = -(2m)^{-1}\Delta_x$ where $m = m_1 m_2 (m_1+m_2)^{-1}$. In the case $N=3$, a natural choice of coordinates in $X^{\mathrm{cm}}$ is given by one of the three sets of Jacobi variables:

$$x^{12} = x_2 - x_1$$

$$x_{12} = x_3 - (m_1+m_2)^{-1}(m_1x_1 + m_2x_2)$$

and similarly for $x^{13}, x_{13}$ and $x^{23}, x_{23}$. In coordinates $x^\alpha, x_\alpha$ the operator of kinetic energy is determined by the formula

$$H_0 = -(2m_\alpha)^{-1}\Delta_{x_\alpha} - (2m^\alpha)^{-1}\Delta_{x^\alpha}$$

where, for example,

$$(m^{12})^{-1} = m_1^{-1} + m_2^{-1}, \quad m_{12}^{-1} = (m_1+m_2)^{-1} + m_3^{-1}$$

If $N=2$, then $V(x)\to 0$ as $|x|\to\infty, x\in X^{\mathrm{cm}}$, but this is no longer true for $N\geq 3$. According to eqn [7] the spectral and scattering theories for the operator $\boldsymbol{H}$ reduce to those for the operator $H$. However, for $N\geq 3$, this reduction is not really helpful.

Let us now consider a breakup $a = \{\mathcal{C}_1,\ldots,\mathcal{C}_n\}$ of an $N$-particle system into clusters $\mathcal{C}_1,\ldots,\mathcal{C}_n$, $1\leq n =: \#(a)\leq N$ satisfying conditions [1]. If interactions between different clusters are neglected, we obtain the operator

$$H_a = H_0 + V^a, \quad V^a = \sum_{l=1}^{n}\sum_{\alpha\in\mathcal{C}_l} V^\alpha \qquad [9]$$

In particular, $H_a = H_0$ if $\#(a) = N$ and $H_a = H$ if $\#(a)=1$. Let the operator of common translations

of particles from the same cluster be defined by the equation

$$(T_a(p_1,\ldots,p_n)f)(x_1,\ldots,x_N) = f(x'_1,\ldots,x'_N)$$

where $x'_j = x_j + p_l$ if $j \in \mathcal{C}_l$. The operator $H_a$ commutes with the operators $T_a(p_1,\ldots,p_n)$ for all vectors $p_1,\ldots,p_n \in \mathbb{R}^d$. Let the subspace $X^a$ be determined by the condition

$$\sum_{j\in\mathcal{C}_l} m_j x_j = 0, \quad l = 1,\ldots,n$$

and let $X_a$ be the orthogonal complement to $X^a$ in $X^{\text{cm}}$ with respect to scalar product [6]. Clearly, $\dim X^a = (N - \#(a))d$, $\dim X_a = (\#(a) - 1)d$. Then the space $\mathcal{H}$ splits into the tensor product

$$L_2(X^{\text{cm}}) = L_2(X_a) \otimes L_2(X^a) \qquad [10]$$

In what follows, $x_a$ and $x^a$ are the orthogonal projections of $x \in X^{\text{cm}}$ on the subspaces $X_a$ and $X^a$, respectively. The "external" variable $x_a = (\boldsymbol{x}_1, \boldsymbol{x}_2, \ldots, \boldsymbol{x}_n)$, where

$$\boldsymbol{x}_l = M_l^{-1} \sum_{j\in\mathcal{C}_l} m_j x_j, \quad M_l = \sum_{j\in\mathcal{C}_l} m_j$$

describes positions of centers of masses of the clusters. The "internal" variable $x^a$ is the set of numbers $x_j - \boldsymbol{x}_l$ for all $j \in \mathcal{C}_l$ and all $l = 1,\ldots,n$. Of course, for each $l$ only $|\mathcal{C}_l| - 1$ ($|\mathcal{C}_l|$ is the number of particles in a cluster $\mathcal{C}_l$) of variables $x_j - \boldsymbol{x}_l$ are independent. Set

$$K_a = -\Delta_{x_a} = -\sum_{l=1}^{n} (2M_l)^{-1} \Delta_{\boldsymbol{x}_l}$$

and

$$H^a = -\Delta_{x^a} + V^a$$

Then

$$H_a = K_a \otimes I + I \otimes H^a$$

Note that eigenvalues $\lambda^{a,n}$ of the operator $H^a$ are sums over $l = 1,\ldots,n$ of eigenvalues of the operators

$$H(\mathcal{C}_l) = H_0(\mathcal{C}_l) + \sum_{\alpha\in\mathcal{C}_l} V^\alpha$$

describing each cluster. Similarly, eigenfunctions $\psi^{a,n}$ of $H^a$ are products of eigenfunctions of these operators. We usually write $\boldsymbol{a}$ instead of a couple $\{a, n\}$. In the following, the index $\boldsymbol{a}$ labels all cluster decompositions with $\#(a) \geq 2$. The eigenvalues $\lambda^{\boldsymbol{a}}$ of the operators $H^a$ ($\lambda^a = 0$ if $\#(a) = N$) are called thresholds of the Schrödinger operator [8]. If all functions $V^\alpha(x^\alpha) \to 0$ as $|x^\alpha| \to \infty$, then the essential spectrum of the operator $H$ consists of the interval $[\lambda_0, \infty)$, where

$$\lambda_0 = \min_{\boldsymbol{a}} \lambda^{\boldsymbol{a}}$$

(the Hunziker–Van Winter–Zhislin theorem). Moreover, the eigenvalues of the operator $H$ may accumulate at its thresholds only.

The fundamental result of scattering theory for the $N$-particle Schrödinger operator can be formulated as follows. Let $\mathsf{P}^{\boldsymbol{a}}$ be the orthogonal projection in $L_2(X^a)$ on the subspace $\mathcal{H}_a^{(p)}$ spanned by all eigenvectors $\psi^{a,n}$ of $H^a$, and let $\mathsf{P}_{\boldsymbol{a}} = I \otimes \mathsf{P}^{\boldsymbol{a}}$, where the tensor product is defined by eqn [10]. Then $\mathsf{P}_{\boldsymbol{a}}$ commutes with the operator $H_a$. Set also $K_0 = H_0$, $\mathsf{P}_0 = I$. Suppose that for all $\alpha$

$$|V^\alpha(x^\alpha)| \leq C(1 + |x^\alpha|)^{-\rho}, \quad \rho > 1 \qquad [11]$$

(the short-range assumption). Then, for all $\boldsymbol{a}$, the wave operators

$$W_{\boldsymbol{a}}^{\pm} = W^{\pm}(H, H_a; \mathsf{P}_{\boldsymbol{a}}) = \operatorname*{s-lim}_{t\to\pm\infty} e^{iHt} e^{-iH_a t} \mathsf{P}_{\boldsymbol{a}}$$

exist and are isometric on the ranges $\operatorname{Ran} \mathsf{P}_{\boldsymbol{a}}$ of projections $\mathsf{P}_{\boldsymbol{a}}$. The subspaces $\operatorname{Ran} W_{\boldsymbol{a}}^{\pm}$ are mutually orthogonal, and scattering is asymptotically complete:

$$\bigoplus_{\boldsymbol{a}} \operatorname{Ran} W_{\boldsymbol{a}}^{\pm} = \mathcal{H}^{(\text{ac})}$$

The singular continuous spectrum of $H$ is empty, so the absolutely continuous subspace $\mathcal{H}^{(\text{ac})}$ of the operator $H$ can be replaced by $\mathcal{H} \ominus \mathcal{H}^{(p)}$, where $\mathcal{H}^{(p)}$ is spanned by all eigenvectors of $H$.

These results can be reformulated in terms of scattering theory in a couple of spaces. Suppose that, for every $a$, eigenvectors $\psi^{a,n}$ are normalized and orthogonal if the corresponding eigenvalues $\lambda^{a,n}$ coincide. Let us introduce an auxiliary space

$$\hat{\mathcal{H}} = \bigoplus_{\boldsymbol{a}} \mathcal{H}_{\boldsymbol{a}}, \quad \mathcal{H}_{\boldsymbol{a}} = \mathcal{H}_a = L_2(X_a) \qquad [12]$$

and an auxiliary operator

$$\hat{H} = \bigoplus_{\boldsymbol{a}} K_{\boldsymbol{a}}, \quad K_{\boldsymbol{a}} = K_a + \lambda^{\boldsymbol{a}} \qquad [13]$$

in this space. Here and below, the sums are taken over all $\boldsymbol{a}$. We define an identification $\hat{J} : \hat{\mathcal{H}} \to \mathcal{H}$ by the relations

$$\hat{J} = \sum_{\boldsymbol{a}} J^{\boldsymbol{a}}, \quad J^{\boldsymbol{a}} f_{\boldsymbol{a}} = f_{\boldsymbol{a}} \otimes \psi^{\boldsymbol{a}} \qquad [14]$$

where the tensor product is the same as in [10]. In particular, $J^0 = I$. Since $H_a J^{\boldsymbol{a}} = J^{\boldsymbol{a}} K_{\boldsymbol{a}}$, the wave operators $W^{\pm}(H, \hat{H}; \hat{J})$ exist and are isometric and complete, that is,

$$\operatorname{Ran} W^{\pm}(H, \hat{H}; \hat{J}) = \mathcal{H}^{(\text{ac})}$$

Thus, for states orthogonal to eigenvectors of $H$, evolution of an $N$-particle system decomposes

asymptotically into a sum of evolutions which are "free" in external variables $x_a$ and are determined by eigenvalues and eigenfunctions of the Hamiltonians $H^a$ in internal variables $x^a$. To be more precise, we have that, for all $f \in \mathcal{H}^{(\mathrm{ac})}$ and $t \to \pm\infty$,

$$\exp(-\mathrm{i}Ht)f = \sum_a \exp(-\mathrm{i}K_a t) f_a^{\pm} \otimes \psi^a + o(1) \qquad [15]$$

where

$$f_a^{\pm} = W^{\pm}(H, K_a; J^a)^* f$$

and the term $o(1)$ tends to zero in $\mathcal{H}$. The wave operator $W^{\pm}(H, K_a; J^a)$ describes the scattering channel where a system of $N$ interacting particles splits up asymptotically (for $t \to \pm\infty$) into noninteracting clusters $\mathcal{C}_1, \ldots, \mathcal{C}_n$, $n \geq 2$, and particles from the same cluster $\mathcal{C}_l$ are in the bound state (if there are more than one particle in $\mathcal{C}_l$) given by the function $\psi^a(x^a)$. Somewhat loosely speaking, this implies that the continuous spectrum of the operator $H$ consists of branches starting from all its thresholds.

Note that the scattering problem can equivalently be formulated without the separation of center-of-mass motion. In this case, a trivial decomposition with $\#(a) = 1$ should be added, and the set of thresholds of the operator $\boldsymbol{H}$ includes eigenvalues of the operator $H$.

The existence of the wave operators and their isometricity can be obtained by the Cook method. Only the asymptotic completeness is a difficult mathematical problem. It can be solved within the framework of the smooth method, which requires a study of boundary values of resolvents as the spectral parameter $z$ approaches the continuous spectrum or, equivalently, a study of a large-time behavior of evolution operators.

The scattering operator

$$\boldsymbol{S} = W^+(H, \hat{H}; \hat{J})^* W^-(H, \hat{H}; \hat{J})$$

is unitary on the space $\hat{\mathcal{H}}$ and commutes with the operator $\hat{H}$. Its component $\boldsymbol{S}_{ab} : \mathcal{H}_b \to \mathcal{H}_a$ describes a process where a system in a state $\boldsymbol{b}$ as $t \to -\infty$ goes over in a state $\boldsymbol{a}$ as $t \to +\infty$. Diagonalizing the operator $\hat{H}$ by a unitary operator $\hat{F}, (\hat{F}\hat{H}f)(\lambda) = \lambda(\hat{F}f)(\lambda), \lambda > \lambda_0$, we obtain the scattering matrix $S(\lambda)$ defined by the equation $(\hat{F}\boldsymbol{S}f)(\lambda) = S(\lambda)(\hat{F}f)(\lambda)$. In its turn, the scattering matrix is also a matrix operator with components $S_{ab}(\lambda)$. For $N \geq 3$, the structure of the scattering matrix is essentially more complicated than for $N = 2$. This is discussed in some detail in the next section.

## Resolvent Equations for Three-Particle Systems

Let the Hamiltonian $\boldsymbol{H}$ be defined by eqns [2]–[4], where $N = 3$, and let the configuration space of each particle be $\mathbb{R}^d$, $d \geq 3$. The operator $H$ acts in the space $\mathcal{H} = L_2(X^{\mathrm{cm}})$, where the subspace $X^{\mathrm{cm}} \subset \mathbb{R}^{3d}$ is distinguished by condition [5]. Let $R_0(z) = (H_0 - z)^{-1}, R(z) = (H - z)^{-1}$. Since $V(x)$ does not tend to 0 as $|x| \to \infty, x \in X^{\mathrm{cm}}$, in the three-particle case, the resolvent equation

$$R(z) = R_0(z) - R_0(z) V R(z) \qquad [16]$$

is not Fredholm even for $\operatorname{Im} z \neq 0$.

To overcome this difficulty, Faddeev (1965) derived a system of equations for components of the resolvent. The entries of this system are constructed in terms of three Hamiltonians

$$H_\alpha = H_0 + V^\alpha$$

$\alpha = (12), (13), (23)$, containing only one pair interaction each, and their resolvents $R_\alpha(z) = (H_\alpha - z)^{-1}$. Let us write down the resolvent equation for each pair $H_\alpha, H$

$$R(z) = R_\alpha(z) - R_\alpha(z) \sum_{\beta \neq \alpha} V^\beta R(z)$$

We multiply it by $|V^\alpha|^{1/2}$ and set

$$\boldsymbol{r}_\alpha^0(z) = |V^\alpha|^{1/2} R_\alpha(z), \quad \boldsymbol{r}_\alpha(z) = |V^\alpha|^{1/2} R(z)$$
$$\boldsymbol{t}_{\alpha,\alpha}(z) = 0, \quad \boldsymbol{t}_{\alpha,\beta}(z) = |V^\alpha|^{1/2} R_\alpha(z) (V^\beta)^{1/2}$$

where $(V^\beta)^{1/2} = V^\beta |V^\beta|^{-1/2}$. This yields a system of equations

$$\boldsymbol{r}_\alpha(z) = \boldsymbol{r}_\alpha^0(z) - \sum_{\beta \neq \alpha} \boldsymbol{t}_{\alpha,\beta}(z) \boldsymbol{r}_\beta(z) \qquad [17]$$

for the operators $\boldsymbol{r}_\alpha(z)$. Note that the resolvent $R(z)$ can be recovered from its components $\boldsymbol{r}_\alpha(z)$ by the formula

$$R(z) = R_0(z) - R_0(z) \sum_\alpha (V^\alpha)^{1/2} \boldsymbol{r}_\alpha(z)$$

It is convenient to rewrite eqn [17] in the matrix notation

$$\boldsymbol{r}(z) = \boldsymbol{r}^0(z) - \boldsymbol{t}(z) \boldsymbol{r}(z) \qquad [18]$$

where $\boldsymbol{r}^0(z) = \{\boldsymbol{r}_\alpha^0(z)\}, \boldsymbol{r}(z) = \{\boldsymbol{r}_\alpha(z)\}$ are the "vector" operators in the three-component space $L_2^{(3)}(X^{\mathrm{cm}})$ and $\boldsymbol{t}(z) = \{\boldsymbol{t}_{\alpha,\beta}(z)\}$ is the "matrix" operator in this space.

The advantage of eqn [17] compared to [16] is that the operators $\boldsymbol{t}_{\alpha,\beta}(z)$ are compact for $\operatorname{Im} z \neq 0$. This can be deduced from the fact that the product $V^\alpha(x^\alpha) V^\beta(x^\beta)$, where $\alpha \neq \beta$ tends to 0 as

$|x| \to \infty, x \in X^{cm}$, provided that $V^\alpha(x^\alpha) \to 0$ as $|x^\alpha| \to \infty$ for all $\alpha$. Moreover, the homogeneous equation [17] has only a trivial solution. Indeed, if for some $z$ with $\mathrm{Im}\, z \neq 0$

$$f_\alpha = -\sum_{\beta \neq \alpha} \boldsymbol{t}_{\alpha,\beta}(z) f_\beta \qquad [19]$$

then the function

$$u = \sum_\alpha (V^\alpha)^{1/2} f_\alpha$$

satisfies the equation $u = -R_0(z)Vu$. Since the operator $H$ is self-adjoint, this implies that $u = 0$ and hence $f_\alpha = 0$ for all $\alpha$. According to the Fredholm alternative, eqns [17] for $\boldsymbol{r}_\alpha(z)$ or [18] for $\boldsymbol{r}(z)$ can be solved if $\mathrm{Im}\, z \neq 0$, that is,

$$\boldsymbol{r}(z) = (I + \boldsymbol{t}(z))^{-1} \boldsymbol{r}^0(z) \qquad [20]$$

This equation allows one to deduce the existence of necessary boundary values of the "sandwiched" resolvent $R(z)$ from similar results for the resolvents $R_\alpha(z)$ of the "two-particle" operators $H_\alpha$. In its turn, $R_\alpha(z)$ can be expressed in terms of the resolvent $R^\alpha(z)$ of the operator $H^\alpha$ acting in the space $L_2(\mathbb{R}^d)$. Indeed, in the "mixed" representation $(\xi_\alpha, x^\alpha)$, where the Fourier transform in the variable $x_\alpha$ is performed and the variable $\xi_\alpha$ is dual to $x_\alpha$, we have

$$(R_\alpha(z)f)(\xi_\alpha, x^\alpha) = (R^\alpha(z - (2m_\alpha)^{-1}|\xi_\alpha|^2)f) \times (\xi_\alpha, x^\alpha) \qquad [21]$$

The passage to the limit $\mathrm{Im}\, z \to 0$ requires that assumption [11] be satisfied for $\rho > 2$. Moreover, we have to suppose that the operators $H^\alpha$ do not have the so-called zero-energy resonances as well as eigenvalues embedded in the continuous spectrum. Then the operator functions $\langle x^\alpha \rangle^{-l} R^\alpha(z) \langle x^\alpha \rangle^{-l}, l > 1$, $\langle x^\alpha \rangle = (1 + |x^\alpha|^2)^{1/2}$, are analytic in the complex plane cut along $[0, \infty)$, they have poles only at the points $\lambda^{\alpha,n}$, and are continuous up to the cut, the point $z = 0$ included. In particular, it follows from eqn [21] that, if the operators $H^\alpha$ do not have negative eigenvalues, then the operator functions $\langle x^\alpha \rangle^{-l} R_\alpha(z) \langle x^\alpha \rangle^{-l}, l > 1$, are also analytic in the complex plane cut along $[0, \infty)$ and are continuous up to the cut.

The next result is of genuinely three-particle nature and is crucial for the study of the operator $\boldsymbol{t}(z)$. The operator functions $\langle x^\alpha \rangle^{-l} R_0(z) \langle x^\beta \rangle^{-l}, \alpha \neq \beta, l > 1$, are continuous in norm up to the cut along $[0, \infty)$.

Now it follows from eqn [20] that the operator-valued functions $\boldsymbol{r}_\alpha(z)|V^\alpha|^{1/2}$ are continuous up to the cut $(0, \infty)$ except points $\lambda \in (0, \infty)$, where the homogeneous equation [19] for $z = \lambda \pm \mathrm{i}0$ has a nontrivial solution. The set $\mathcal{N} = \mathcal{N}_+ \cup \mathcal{N}_-$ of such points $\lambda \in (0, \infty)$ is closed and has Lebesgue measure zero. In particular, the operators $\langle x^\alpha \rangle^{-l}$, $l > 1$, are $H$-smooth on any compact subinterval of $\Lambda = (0, \infty) \backslash \mathcal{N}$. Therefore, the smooth method of scattering theory can be directly applied. It yields the existence and completeness of the wave operators $W_\pm(H, H_0)$. In this case, three-particles are necessarily asymptotically free.

"Two-particle" channels of scattering arise if the operators $H^\alpha$ have negative eigenvalues. To simplify notation, we assume that every $H^\alpha$ has exactly one eigenvalue $\lambda^\alpha < 0$. Moreover, it is supposed that the corresponding eigenfunction $\psi^\alpha(x^\alpha)$ tends to zero sufficiently rapidly as $|x^\alpha| \to \infty$. Analytically, the appearance of new channels is due to new singularities of the resolvents. Indeed, in this case

$$R^\alpha(z) = (\lambda^\alpha - z)^{-1} P^\alpha + \hat{R}^\alpha(z)$$

where the function $\hat{R}^\alpha(z)$ is analytic and continuous up to the cut in the complex plane cut along $[0, \infty)$. It follows from eqn [21] that in this case the resolvent $R_\alpha(z)$ contains the additional term

$$((2m_\alpha)^{-1}|\xi_\alpha|^2 + \lambda^\alpha - z)^{-1} \otimes P^\alpha$$

which is analytic only in the complex plane cut along $[\lambda^\alpha, \infty)$. To take these terms into account, system [17] should be further rearranged. This yields the following result. Let us set

$$\mathsf{G}_{\alpha 0} = \langle x^\alpha \rangle^{-l}(I - P_\alpha), \quad \mathsf{G}_{\alpha 1} = \langle x_\alpha \rangle^{l} (J^\alpha)^* \sum_{\beta \neq \alpha} V^\beta \qquad [22]$$

Then, for all $\alpha, \beta, i, j = 0, 1$, a suitable $l > 1$ and $\lambda_0 = \min\{\lambda^\alpha\}$, the operator functions $\mathsf{G}_{\alpha i} R(z) \mathsf{G}^*_{\beta j}$ are norm continuous as $z$ approaches the cut $(\lambda_0, \infty)$ at the points of $\Lambda = (\lambda_0, \infty) \backslash \mathcal{N}$, where $\mathcal{N}$ is again a closed set of measure zero. In particular, the operators $\mathsf{G}_{\alpha 0}$ and $\mathsf{G}_{\alpha 1}$ are $H$-smooth on any compact subinterval of $\Lambda$.

In the multichannel case, to fit scattering for the Hamiltonian $H$ into the framework of smooth theory, it is convenient to reformulate the result in terms of scattering theory in a couple of spaces. Let the space $\hat{\mathcal{H}}$, the operator $\hat{H}$, and the identification $\hat{J}$ be defined by eqns [12], [13], and [14], respectively, where the index $\boldsymbol{a}$ takes four values $\boldsymbol{a} = 0, \alpha$ and $\alpha = (12), (13), (23)$. One, further, needs to introduce auxiliary identifications

$$J^0 = I - \sum_\alpha P_\alpha$$

and

$$\hat{J} = J^0 \oplus \bigoplus_\alpha J^\alpha$$

The $H$- (and $\hat{H}$-) smoothness of operators [22] imply that the wave operators

$$W^{\pm}(H, \hat{H}; \hat{\boldsymbol{J}}) \quad \text{and} \quad W^{\pm}(\hat{H}, H; \hat{\boldsymbol{J}}^*)$$

exist.

The operators $W^{\pm}(H, \hat{H}; \hat{\boldsymbol{J}})$ are isometric because

$$\operatorname*{s-lim}_{|t| \to \infty} P_\alpha \exp(-\mathrm{i}H_0 t) = 0 \qquad [23]$$

and the operators $P_\alpha P_\beta$ are compact for $\alpha \neq \beta$. Using that the operator

$$\hat{\boldsymbol{J}}\hat{\boldsymbol{J}}^* - I = \sum_{\alpha \neq \beta} P_\alpha P_\beta$$

is compact (whereas $\hat{J}\hat{J}^* - I$ is not), we see that the operators $W^{\pm}(\hat{H}, H; \hat{\boldsymbol{J}}^*)$ are also isometric. Finally, we remark that, by eqn [23],

$$W^{\pm}(H, \hat{H}; \hat{\boldsymbol{J}}) = W^{\pm}(H, \hat{H}, \hat{J})$$

This implies the asymptotic completeness.

Let us discuss properties of the scattering matrix in the one-channel case where the pair operators $H^\alpha$ do not have negative eigenvalues. The scattering matrix $S(\lambda): L_2(\mathbb{S}^{2d-1}) \to L_2(\mathbb{S}^{2d-1})$, $\lambda > 0$, is of course a unitary operator, but in contrast to the two-particle case the operator $S(\lambda) - I$ is not compact because its kernel contains the Dirac functions $\delta(\xi_\alpha - \xi'_\alpha)$. Nevertheless, the structure of its singularities can be explicitly described. Actually, let $S_\alpha(\lambda)$ be the "two-particle" scattering matrix for the pair $H_0, H_\alpha$. Then

$$S(\lambda) = S_{12}(\lambda) S_{23}(\lambda) S_{13}(\lambda) \tilde{S}(\lambda)$$

where the operator $\tilde{S}(\lambda) - I$ is compact.

The approach described briefly in this section relies on a kind of an advanced perturbation theory where the free problem is determined by the set of all sub-Hamiltonians. Its generalization to the case of an arbitrary number of particles meets with numerous difficulties. A different, nonperturbative, approach which works well for any number of particles will be discussed in the next section.

A purely time-dependent method in three-particle scattering is exposed in Enss (1983).

## Nonperturbative Approach

Now $N$ and $d$ are arbitrary. In the nonperturbative approach (see Graf (1990), Sigal and Soffer (1989), and Yafaev (1993)) the operators $H$ and $H_0$ as well as the Hamiltonians of all subsystems are treated on an equal basis. It is supposed that all pair potentials satisfy condition [11]. No assumptions on subsystems are required.

The starting point of this approach is the limiting-absorption principle, which claims that the operator $\langle x \rangle^{-l}$, $x \in X^{\text{cm}}$, for $l > 1/2$ is $H$-smooth on any compact interval $\Lambda$ not containing the thresholds and eigenvalues of $H$. Its proof relies on the Mourre commutator method (see Cycon *et al.* (1987)). To be more precise, it is deduced from the following estimate:

$$\mathrm{i}([H, A]f, f) \geq c\|f\|^2, \quad c = c(\lambda) > 0$$
$$f \in E(\Lambda_\lambda)\mathcal{H} \qquad [24]$$

for the commutator of $H$ with the generator of translations

$$A = -\mathrm{i} \sum_j (x_j \partial_j + \partial_j x_j)$$

Here $x_j$ are coordinates of $x \in X^{\text{cm}}$ in some orthonormal (with respect to scalar product [6]) basis in $X^{\text{cm}}$, $\lambda$ is neither a threshold nor an eigenvalue of the operator $H$ and $\Lambda_\lambda$ is a sufficiently small interval. Very roughly speaking, the Mourre estimate [24] means that, similarly to the two-particle case, the observable

$$(A e^{-\mathrm{i}Ht} f, e^{-\mathrm{i}Ht} f)$$

is a strictly increasing function of $t$ for all $f \in \mathcal{H}^{(\text{ac})}$.

The limiting-absorption principle implies that the singular continuous spectrum of the operator $H$ is empty, but it is not sufficient for scattering theory. If the limiting-absorption principle were true for the critical value $l = 1/2$, then it would imply asymptotic completeness. Unfortunately, the operator $\langle x \rangle^{-1/2}$ is definitely not smooth even with respect to the free operator $H_0$. However, by introducing an auxiliary differential operator we can fix this problem. This leads to the radiation estimates. These estimates look differently in different regions of the configuration space. Choose any cluster decomposition $a = (\mathcal{C}_1, \ldots, \mathcal{C}_n)$. The radiation estimate morally implies that the motion of a system is asymptotically free in the variable $x_a$ (describing the relative motion of clusters) in the region where particles from each cluster $\mathcal{C}_l$, $l = 1, \ldots, n$, are close to each other compared to distances between different clusters. On the contrary, this motion is very complicated in the variable $x^a$ pertaining to bound states of different clusters. In particular, the radiation estimate is the same as for the two-particle case in the "free" region where all particles are far from each other.

To be more precise, let $\nabla_a = \nabla_{x_a}$ be the gradient in the variable $x_a$ and let $\nabla_a^\perp$,

$$(\nabla_a^\perp u)(x) = (\nabla_a u)(x) - |x_a|^{-2} \langle (\nabla_a u)(x), x_a \rangle x_a$$

be its orthogonal projection in $X_a$ on the subspace orthogonal to the vector $x_a$. Let $\chi_a$ be the

characteristic function of a closed cone $Y_a \subset X^{\rm cm}$ satisfying the condition $Y_a \cap X_b = \emptyset$ for all $b$ such that $X_a \not\subset X_b$. Then the operator

$$G_a = \chi_a \langle x \rangle^{-1/2} \nabla_a^{\perp}$$

is $H$-smooth on $\Lambda$.

A proof of the radiation estimates is based on the consideration of the commutator of $H$ with some differential operator $M = -{\rm i}\sum (m^{(j)}\partial_j + \partial_j m^{(j)})$, where $m^{(j)} = \partial m/\partial x_j$. Here $m$ (it depends on $a$) is a specially constructed function satisfying the following properties:

1. $m(x)$ is homogeneous (for $|x| \geq 1$) of order 1;
2. for any $b$ it does not depend on $x^b$ in some conical neighborhood of the subspace $X_b$;
3. $m(x)$ is convex; and
4. $m(x) = \mu_a |x_a|, \mu_a \geq 1$, on support of the function $\chi_a$.

Note that we can set $m(x) = |x|$ in the case of the operator $H_0$.

Due to properties (1) and (2) the commutator $[V, M]$ is a short-range function (estimated by $\langle x \rangle^{-1-\varepsilon}$ for $\varepsilon > 0$). Due to properties (3) and (4) the commutator $[H_0, M] \geq c G_a^* G_a, c > 0,$ up to short-range terms. The estimate

$$[H, M] \geq c G_a^* G_a - c_1 \langle x \rangle^{-1-\varepsilon}$$

implies that the operator $G_a$ is $H$-smooth on $\Lambda$.

The main difficulty in the $N$-particle problem is that pair potentials $V^{\alpha}(x^{\alpha})$ do not tend to zero as $|x| \to \infty$. The idea of the proof of asymptotic completeness is to introduce auxiliary wave operators such that "effective" perturbations are decaying functions. This requires a suitable smooth partition of unity. Moreover, it is convenient to choose auxiliary identifications as first-order differential operators rather than operators of multiplication. Unfortunately, although such identifications allow one to "kill" directions where the potentials $V^{\alpha}(x^{\alpha})$ do not tend to zero, their commutators with the operator $H_0$ have coefficients decaying at infinity only as $|x|^{-1}$.

Thus, we introduce differential operators

$$M_a = -{\rm i}\sum \left( m_a^{(j)} \partial_j + \partial_j m_a^{(j)} \right)$$

with coefficients $m_a^{(j)} = \partial m_a / \partial x_j$. The functions $m_a$ satisfy properties (1), (2) formulated above and

5. $m_a(x) = 0$ in some conical neighborhoods of the subspaces $X_b$ such that $X_a \not\subset X_b$. To put it differently, $m_a(x) = 0$ in some conical neighborhood of the subspace where $x_i = x_j$ for some $i, j$ belonging to different clusters $\mathcal{C}_1, \ldots, \mathcal{C}_n$.

Let the operator $H_a$ be defined by eqn [9]. Given the limiting-absorption principle and the radiation estimates, we first check the existence of auxiliary wave operators

$$W^{\pm}(H, H_a; M_a E_a(\Lambda))$$

and

$$W^{\pm}(H_a, H; M_a E(\Lambda)) \qquad [25]$$

Here we use that according to (5) coefficients of the differential operator $(V - V^a)M_a$ are, under assumption [11], short-range (in the configuration space $X^{\rm cm}$). By property (2), the function $[V^a, M_a]$ is also short-range. Thus, the operator $VM_a - M_a V^a$ can be taken into account by the limiting-absorption principle. The commutator $[H_0, M_a]$ factorizes into a product of $H_a$- and $H$-smooth operators according to the radiation estimates.

Similar arguments show that, for $\sum_a m_a = m$ and $M = \sum_a M_a$ (the sums here are taken over all possible breakups of the $N$-particle system), the wave operator (observable)

$$W^{\pm}(H, H; \pm M E(\Lambda)) \qquad [26]$$

also exists. Moreover, it can be easily achieved that $m(x) \geq 1$. Then it follows from the Mourre estimate that operator [26] is positive definite on the subspace $E(\Lambda)\mathcal{H}$ and hence its range coincides with this subspace. It means that for all $f \in E(\Lambda)\mathcal{H}$

$$\lim_{t \to \pm\infty} \| \exp(-{\rm i}Ht)f - M \exp(-{\rm i}Ht) g^{\pm} \| = 0 \qquad [27]$$

if $f = W^{\pm}(H, H; ME(\Lambda)) g^{\pm}$.

The existence of wave operators [25] implies that for any $g^{\pm} = E(\Lambda) g^{\pm}$ and $g_a^{\pm} = W^{\pm}(H_a, H; M_a E(\Lambda)) g^{\pm}$

$$\lim_{t \to \pm\infty} \| M \exp(-{\rm i}Ht) g^{\pm} - \sum_a \exp(-{\rm i}H_a t) g_a^{\pm} \| = 0 \qquad [28]$$

Combining eqns [27] and [28], we see that $\exp(-{\rm i}Ht)f$ decomposes asymptotically into simpler evolutions $\exp(-{\rm i}H_a t) g_a^{\pm}$. This is one of the equivalent formulations of asymptotic completeness and leads to eqn [15].

Finally, we note that eqn [15] can be rewritten as

$$\exp(-{\rm i}Ht)f = \sum_a \exp({\rm i}\Phi_a(x_a, t))(2{\rm i}t)^{-d_a/2} \times \hat{f}_a^{\pm}(x_a/(2t)) \psi^a(x^a) + o(1) \qquad [29]$$

where $t \to \pm\infty$, $d_a = \dim X_a$, $\hat{f}_a^{\pm}$ is the Fourier transform of $f_a^{\pm}$ and

$$\Phi_a(x_a, t) = x_a^2(4t)^{-1} - \lambda^a t \qquad [30]$$

## Long-Range Interactions: New Channels

The multiparticle problem acquires a long-range character if pair potentials decay as Coulomb potentials or slower. Similarly to the two-particle problem, for long-range potentials the definition of wave operators should be naturally modified. As in the short-range case, only the asymptotic completeness is a really difficult mathematical problem. Assume that pair potentials satisfy condition

$$|(\partial^\kappa V^\alpha)(x^\alpha)| \le C(1 + |x^\alpha|)^{-\rho-|\kappa|}, \quad \rho > \sqrt{3} - 1$$

for all $|\kappa| \le \kappa_0$ and sufficiently large $\kappa_0$. Then only phase factors in eqn [29] should be modified. Actually, instead of eqn [30] we should set

$$\Phi_a(x_a, t) = x_a^2(4t)^{-1} - \lambda^a t - t\int_0^1 V_a(sx_a, 0)\, ds$$

where $V_a(x) = V(x) - V^a(x)$ and as usual $x = (x_a, x^a)$. As shown in Dereziński (1993), with this definition of wave operators, the asymptotic completeness holds.

On the contrary, if pair potentials decay slower than $|x|^{-1/2}$, then the traditional picture of scattering breaks down (see Yafaev (1996)). Actually, a three-particle system might have additional scattering channels intermediary between the channel where three particles are asymptotically free and the channels where a couple of particles form a bound state. In these additional channels, the bound state of a couple of particles depends on a position of the third particle, and it is destroyed asymptotically.

# Nuclear Magnetic Resonance

**P T Callaghan**, Victoria University of Wellington, Wellington, New Zealand

## Introduction

The existence of nuclear spin and its associated magnetism was first suggested by Wolfgang Pauli in 1924, a conjecture based on the fine details of atomic spectra, the so-called hyperfine structure. The interaction of this nuclear magnetism with an external magnetic field was predicted to result in a finite number of discrete energy levels known as the Zeeman structure. However, the first direct excitation of transitions between nuclear Zeeman levels was by Isador Rabi in 1933, using radiofrequency (RF) waves in an atomic beam apparatus. In 1945, Felix Bloch and co-workers at Stanford, and Edward Purcell and co-workers at MIT, performed the first nuclear magnetic resonance (NMR) experiments in condensed matter, with the RF response of the hydrogen nucleus (proton) being directly detected.

The early prospects for this new technique were limited to precise measurements of magnetic fields and nuclear magnetic moments. However, three transformational discoveries intervened to set NMR on a course that would result in initially unimaginable contributions to physics, chemistry,

engineering, medicine, geology, food science, and biochemistry. In 1950, it was found that atomic nuclei at different sites of a molecular orbital had slightly different resonant frequencies, a phenomenon known as "chemical shift." In the a same year, Erwin Hahn discovered the spin echo, thus opening the possibility that multiple RF pulse trains could be used to remove unwanted nuclear spin interactions while being used to manipulate spin coherences with exquisite resolution. In addition, in 1951, using this spin echo, Herbert Gutowsky and Charles Slichter revealed a hitherto unobserved scalar spin–spin interaction between nuclei, mediated by the molecular orbital electrons.

The discovery of the chemical shift and the scalar coupling would immediately revolutionize chemistry. Further discoveries of nuclear quadrupole interactions and through-space dipolar interactions would add to the capacity of NMR to provide insight regarding structure and order in the solid and liquid crystalline state. But the spin echo would provide a platform for new advances in science in every one of the six decades following the discovery of NMR in 1945. These were successively diffusion and flow NMR, multidimensional NMR, magnetic resonance imaging, protein structure NMR, *ex situ* NMR, and quantum computing NMR.

## Resonant Excitation and Detection

In quantum-mechanical language, the Zeeman Hamiltonian $H$ for a nuclear spin experiencing a magnetic field $\boldsymbol{B}_0$ along the laboratory $z$-axis may be written as

$$H = -\gamma B_0 I_z \qquad [1]$$

$\gamma$ being the (nuclear) gyromagnetic ratio while $I_z$ is the operator for the $z$-component of angular momentum, with eigenvalues $m\hbar$, $m$ lying in the range $-I, -I+1, \ldots, I$. $I$ is the angular momentum quantum number, being either integer or half-integer. From the Schrödinger equation, it can be seen that the eigenkets of $H$ precess about the $z$-axis at a rate $\gamma B_0$, the frequency corresponding to the energy difference between the $2I+1$ Zeeman levels. For convenience, we shall take the eigenvalues of $I_z$ to be simply $m$, dropping the factor $\hbar$, and leading to a Hamiltonian expressed in frequency rather than in energy units.

Resonant excitation between the Zeeman levels is achieved by the application of an RF ($\omega$) magnetic field of amplitude $2B_1$ linearly polarized normal to $\boldsymbol{B}_0$ such that the total Hamiltonian becomes

$$H = -\gamma B_0 I_z - 2\gamma B_1 \cos \omega t I_x \qquad [2]$$

This excitation is easily applied by means of a transversely oriented antenna coil, the same coil generally being used to detect the nuclear spin response. In the frame of reference rotating about $\boldsymbol{B}_0$ at $\omega$, the Hamiltonian transforms to

$$H = -\gamma\left(B_0 - \frac{\omega}{\gamma}\right) I_z - \gamma B_1 I_x - \gamma B_1 \exp(\mathrm{i}2\omega t I_z) I_x \exp(-\mathrm{i}2\omega t I_z) \qquad [3]$$

At resonance, $\omega = \omega_0 = \gamma B_0$. The last term in eqn [3] averages to zero and may be neglected (the Heisenberg condition) provided $\omega \gg \gamma B_1$, that is, $B_0 \gg B_1$. Given $B_0$ of the order of tesla and $B_1$ of the order of millitesla, this condition is easily satisfied. Hence, from the perspective of the rotating frame, the spins at resonance see only the static magnetic interaction $\gamma B_1 I_x$, so that application of this resonant RF field causes spins to nutate about the rotating frame $x$-axis at a rate $\gamma B_1$. Thus, by application of RF pulses of different duration, and phases, one may produce arbitrary reorientation of the spins about various axes in the rotating frame.

With the spin system disturbed from equilibrium, the NMR "signal" is detected via the subsequent free precession, and usually via the same antenna coil used for resonant excitation, Semiclassically, the phenomenon may be pictured as follows. RF excitation nutates an initial $z$-magnetization into the transverse plane of the rotating frame. Such transverse magnetization corresponds the laboratory frame to a magnetization precessing at the Larmor frequency, thus inducing an oscillating emf in the receiver coil. In the next section, we see how to describe this phenomenon in the language of quantum mechanics.

Typically, NMR is performed using the nuclei of common atoms in organic molecules, ($^1$H, $^2$H, $^{13}$C, $^{15}$N, $^{19}$F, $^{31}$P) although for inorganic matter a wider class of nuclei are available. Of all these, the proton is most abundant and most sensitive, having the highest gyromagnetic ratio, $\gamma$, of all stable nuclei.

## The Quantum Statistics of the Spin Ensemble

The nuclear Zeeman energy in typically available laboratory magnetic fields, $\gamma B_0 \hbar$, is many orders of magnitude smaller than the Boltzmann energy, $k_B T$, except at millikelvin temperatures. At room temperature in thermal equilibrium, the fractional difference in populations between the Zeeman levels

is normally very small, for example, for protons, about $10^{-5}$. Of course, the total number of spins available may be very large, for example, on the order of $10^{20}$.

The signal in magnetic resonance is detected as a collective effect of the large ensemble of nuclear spins. The natural language of quantum statistics is that of the density matrix, $\rho$; the time-dependent expectation value for any observable represented by an operator $O$ is then, $\mathrm{tr}(O\rho(t))$, the diagonal sum of the product of $O$ and $\rho$. The time evolution of the density matrix is given by the Liouville equation

$$\mathrm{i}\frac{\partial \rho}{\partial t} = [H, \rho] \qquad [4]$$

where $[\,,]$ is a commutator. For a constant Hamiltonian, this equation gives

$$\rho(t) = \exp(\mathrm{i}Ht)\rho(0)\exp(-\mathrm{i}Ht) \qquad [5]$$

Physical solutions to the density matrix (Liouville space) are $(2I+1)^2$ (square) matrices formed in the $(2I+1)$-dimensional angular momentum eigenbasis. Generally, we may write the density matrix in a representation of irreducible tensor operators. One very convenient representation is the set formed by taking products of spin operators. For example, in the case of spin-1/2 where Liouville space is $2^2$-dimensional, we may write

$$\rho(t) = \tfrac{1}{2}I + a_x I_x + a_y I_y + a_z I_z \qquad [6]$$

where $I$ is the identity operator. The operators $I_x$ and $I_y$ provide the off-diagonal elements of $\rho$ and define the degree of phase coherence in the ensemble, while the operator $I_z$ defines the degree to which the diagonal elements differ, thus defining the polarization. $a_x$ and $a_y$ give the amount of "one-quantum coherence" in the ensemble while $a_z$ gives the polarization. In thermal equilibrium $a_x = a_y = 0$, and the spin ensemble exists in a state of pure longitudinal polarization given, in the high-temperature approximation, $\gamma B_0 \hbar << k_B T$, by

$$\rho_{\mathrm{eqbm}}(0) \approx \frac{1}{(2I+1)}I + \frac{\gamma\hbar B_0}{(2I+1)k_B T}I_z \qquad [7]$$

This is the starting point for all NMR experiments (Figure 1).

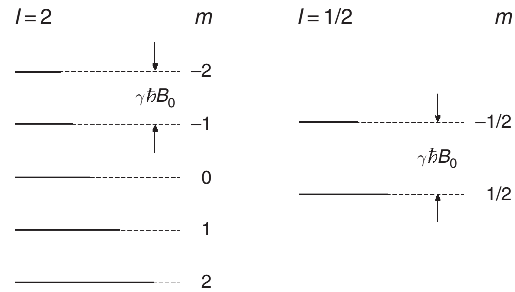

**Figure 1** Schematic Zeeman levels for the case $I = 2$ *and* $I = 1/2$. The bold lines indicate the relative population in each state in thermal equilibrium.

Consider then the detection of precession via the Faraday induction. The size of the signal observed will be proportional to the size of the transverse magnetization $M = \mathrm{tr}[(I_x + \mathrm{i}I_y)\rho(t)]$ present in the rotating frame, this magnetization producing an induced emf with real and imaginary components because of the capacity of heterodyne receivers to detect quadrature phase. In the laboratory frame, the detected signal has a prefactor of $\gamma B_0$ reflecting the Faraday induction, which, taken together with the dependence of the initial equilibrium magnetization on $\gamma B_0$, gives an overall NMR sensitivity $(\gamma B_0)^2$, helping to explain in part why high magnetic fields are advantageous. Take the simple example for $I = 1/2$, where a single 90° resonant RF pulse is applied to the spin system, subsequent free precession occurring under the Zeeman Hamiltonian. The density matrix at detection is

$$\begin{aligned}\rho(t) &= \exp(\mathrm{i}\omega_0 t I_z)\exp\left(\mathrm{i}\frac{\pi}{2}I_x\right)\rho_{\mathrm{eqbm}}(0)\\ &\quad\times\exp\left(-\mathrm{i}\frac{\pi}{2}I_x\right)\exp(-\mathrm{i}\omega_0 t I_z)\\ &= \exp(\mathrm{i}\omega_0 t I_z)\exp\left(\mathrm{i}\frac{\pi}{2}I_x\right)a_{\mathrm{eqbm}}I_z\\ &\quad\times\exp\left(-\mathrm{i}\frac{\pi}{2}I_x\right)\exp(-\mathrm{i}\omega_0 t I_z)\\ &= \exp(\mathrm{i}\omega_0 t I_z)a_{\mathrm{eqbm}}I_y\exp(-\mathrm{i}\omega_0 t I_z)\\ &= a_{\mathrm{eqbm}}I_y\cos(\omega_0 t) + a_{\mathrm{eqbm}}I_x\sin(\omega_0 t)\end{aligned} \qquad [8]$$

Noting $\mathrm{tr}(I_x^2) = \mathrm{tr}(I_y^2) = \mathrm{tr}(I_z^2) = (1/3)(2I+1)I(I+1)$ and $\mathrm{tr}(I_\alpha I_\beta) = 0$, the signal may easily be calculated as $S(t) : a_{\mathrm{eqbm}}\exp(\mathrm{i}\omega_0 t)$, corresponding, upon Fourier transformation, to a unique frequency at $\omega_0$. Note that a basis consisting of products of angular momentum operators are easy to handle since all evolution properties follow from the usual angular momentum commutation algebra.

The spin echo pulse scheme of Figure 2 is one of the most important in NMR. It allows one to refocus dephasing effects caused by inhomogeneous broadening, for example, due to the heterogeneity of the magnetic field across the sample. Rewriting the density matrix equation in the rotating frame, replacing the Zeeman precession

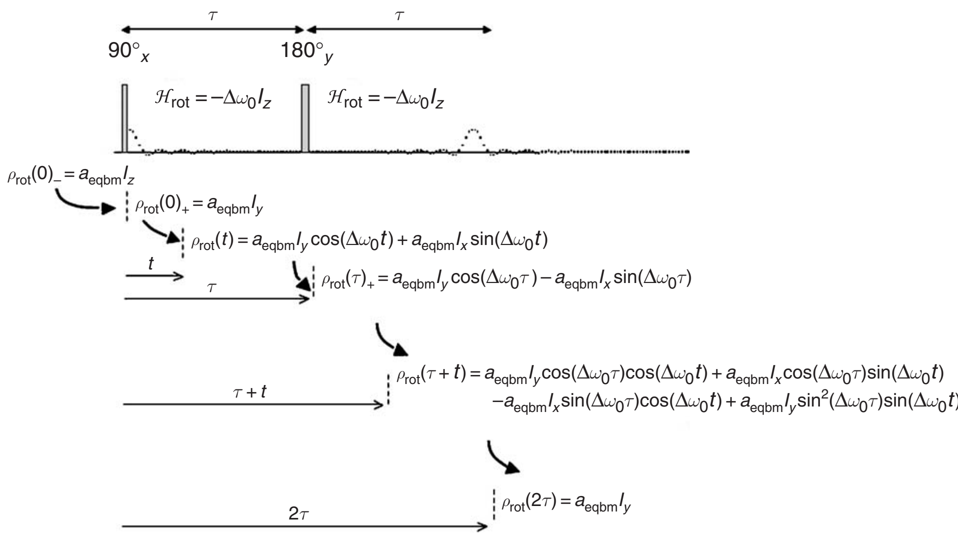

**Figure 2** Spin echo pulse scheme showing the evolution of the density matrix.

by its residual offset, and accounting for both RF pulses,

$$\begin{aligned}\rho_{\rm rot}(2\tau) &= \exp(\mathrm{i}\Delta\omega_0\tau I_z)\exp(\mathrm{i}\pi I_y)\exp(\mathrm{i}\Delta\omega_0\tau I_z)\\ &\quad\times \exp\left(\mathrm{i}\frac{\pi}{2}I_x\right)\rho_{\rm eqbm}(0)\exp\left(-\mathrm{i}\frac{\pi}{2}I_x\right)\\ &\quad\times \exp(-\mathrm{i}\Delta\omega_0\tau I_z)\exp(-\mathrm{i}\pi I_y)\\ &\quad\times \exp(-\mathrm{i}\Delta\omega_0\tau I_z)\\ &= a_{\rm eqbm} I_y \end{aligned} \quad [9]$$

Details of the density matrix evolution are given in Figure 2. The inversion pulse has the effect of completely reversing all the phase shifts that occur during the first interval, resulting in an echo signal when the two time periods are equal. Note the use of nested operators representing the successive influences of RF pulses (assumed to be ideal rotations) and Hamiltonian evolutions. The overall influence of the RF pulses is to render the effective Hamiltonian zero in this case.

This echo sequence (and its equivalent multiple RF train, the Carr–Purcell–Meiboom–Gill sequence) allows one to remove the effect of magnetic field inhomogeneities so as to investigate the underlying homogeneous broadening and associated signal damping.

## Spin Relaxation

The free precession of nuclear spins does not continue indefinitely. Ultimately the off-diagonal elements of the density matrix lose phase coherence while the diagonal elements gradually return to their thermal equilibrium state, two processes known, respectively, as $T_2$ (spin–spin) and $T_1$ (spin–lattice) relaxation. The rate of relaxation depends on interactions between the spins themselves and between the spins and their thermal environment. The process of $T_1$ relaxation requires fluctuations that induce transitions between the Zeeman levels. Clearly the relevant quantum-mechanical operators must possess a nonzero matrix element coupling the Zeeman levels, and the frequency of those fluctuations must match the energy gap spacing. Predominant in causing such relaxation in diamagnetic environments are the internuclear dipolar interactions, while in paramagnetic environments, dipolar interactions between nuclear and electronic spins are effective. One simple way of representing these processes is by the spectral density function, the Fourier power transform of their fluctuations, dipolar interactions causing spin–lattice relaxation due to fluctuations at $\omega_0$ and $2\omega_0$. For a fluctuating interaction with correlation time, $\tau_c$, that spectral density may approximate a Lorentzian of the form

$$J(\omega) = \frac{\tau_c}{1 + \omega^2\tau_c^2} \quad [10]$$

Thus, as the rate of molecular motions varies, due to the influence of temperature on $\tau_c$, the $T_1$ relaxation rate will be a maximum when $\omega_0\tau_c = 1$. Both solids ($\omega_0\tau_c \gg 1$) and liquids ($\omega_0\tau_c \ll 1$) have long $T_1$ relaxation times while soft solids or complex liquids may have faster relaxation. $T_1$ relaxation manifests as an exponential return to equilibrium values of longitudinal magnetization. Typical vales range from hundreds of milliseconds to hours, and the need to re-establish equilibrium between repetitions of the experiment can severely limit signal averaging

and hence available signal-to-noise ratios. Note that $T_1$ relaxation occurs by stimulated emission. Spontaneous emission is effectively absent from nuclear spin systems owing to the long-radiation wavelength.

The case of $T_2$ (spin–spin) relaxation is inherently more complex. First, the definition of "loss of phase coherence" depends on the particular RF pulse sequence employed. Second, the simple perturbation theory description applied to $T_1$ relaxation only works in the fast motion limit, where the $T_2$ relaxation rate may be shown to depend on spectral density terms not only at $\omega_0$ and $2\omega_0$ but also $\omega = 0$. In consequence, $T_2 \ll T_1$. $T_2$ relaxation is sensitive to static components. These static components may dominate in soft solids and solids. Indeed, any term in the Hamiltonian which spreads spin phases, and which cannot be recovered by means of a judicious RF pulse train, will contribute to $T_2$ relaxation. Suppose the effective frequency distribution causing dephasing is described by an ensemble second moment $<\Delta\omega^2>$, and exhibits fluctuations about a mean of zero with correlation time, $\tau_c$. Then we may identify two limiting cases: in the slow motion limit $<\Delta\omega^2>^{1/2}\ \tau_c \gg 1$, the decay of the detected magnetization is Gaussian, and given by a factor $\exp(-1/2 <\Delta\omega^2> t^2)$. In solids, the proton $T_2$ relaxation may take place in a few tens of microseconds. In the fast motion limit $<\Delta\omega^2>^{1/2}\ \tau_c \ll 1$, the decay of the detected magnetization is exponential, and given by a factor $\exp(-<\Delta\omega^2>\tau_c t)$. Liquid state $T_2$ values approach $T_1$ under extreme narrowing conditions.

## The Details of the Nuclear Spin Hamiltonian

Atomic nuclei interact with their environment, with surrounding electrons, and with other nuclear spins. It is precisely this feature that provides such a sensitive probe of material structure and dynamics. For a material immersed in a steady magnetic field $\boldsymbol{B}_0$ along the laboratory $z$-axis, the Hamiltonian for the $i$th nuclear spin can be written

$$H = -\gamma B_0 I_{iz} - \boldsymbol{I}_i.\underline{\underline{S}}.\boldsymbol{B}_0 + \sum_j J\,\boldsymbol{I}_i.\boldsymbol{I}_j + \sum_j \boldsymbol{I}_i.\underline{\underline{D}}.\boldsymbol{I}_j + \boldsymbol{I}_i.\underline{\underline{Q}}.\boldsymbol{I}_i \qquad [11]$$

It is the variety of the terms in the nuclear spin Hamiltonian that imparts power to NMR. The first is the nuclear Zeeman interaction with the applied magnetic field. In modern laboratory superconducting magnets, this interaction can be as large as 1000 MHz, although in earth field applications it can be as small as 2.5 kHz. Given that the sensitivity and resolution of NMR generally improve with increasing magnetic field, the range of 100–1000 MHz is typically the operating regime of choice. All other terms in the nuclear spin Hamiltonian are smaller and thus act as first-order perturbations only, projecting their quantum operators into the zeroth-order Zeeman eigenbasis, the quantum frame of the operator $I_z$. Because several of the terms in $H$ depend on the orientation of the local nuclear environment (e.g., the molecular orbital) with respect to the magnetic field, these terms will fluctuate in the presence of reorientational motions. By the Heisenberg uncertainty principle, fluctuations faster in frequency than the size of the Hamiltonian contribution, expressed in frequency units, will result in an averaging to the mean, a phenomenon known as "motional averaging."

The term $-\boldsymbol{I}_i.\underline{\underline{S}}.\boldsymbol{B}_0$ is the chemical shift that occurs for nuclei in molecular atoms, or the knight shift for nuclei in metals. It is typically a few ppm to several 100 ppm (i.e., 100's Hz to 10 kHz), depending on the nucleus. $\underline{\underline{S}} = \gamma\underline{\underline{\sigma}}$ is a tensor whose principal axes (1, 2, 3) are associated with the local symmetry axis of the molecular orbital (bond) in the vicinity of the nucleus. For a liquid state molecule tumbling rapidly and isotropically, only the averaged trace of $\underline{\underline{\sigma}}, \sigma_i = (1/3)(\sigma_{11} + \sigma_{22} + \sigma_{33})$ survives under motional averaging, giving a fixed frequency shift $-\sigma_i \gamma B_0 I_{iz}$. However, in a solid-state environment, the remaining terms also contribute to the anisotropic chemical shift

$$H_{CS} = -\sigma_i \gamma B_0 I_{iz} - \tfrac{1}{2}(3\cos^2\beta - 1) \times (\sigma_{33} - \sigma_i)\gamma B_0 I_{iz} \qquad [12]$$

where $\beta$ is the polar angle between the magnetic field and the principal axis (the axis "3").

The scalar coupling term, $\sum_j J\boldsymbol{I}_i.\boldsymbol{I}_j$ causes each ($i$th spin) energy level to be sensitive to the quantum states of the neighboring $j$-spins, the coupling constant $J$ being typically tens to hundreds of hertz for nearby spins, but reducing rapidly with greater distance in the molecular orbital. Note that the operator $\sum_j J\boldsymbol{I}_i.\boldsymbol{I}_j$ is nondiagonal in the zeroth-order representation, but provided that the chemical shift between the $I$ and $j$ spins is larger than the coupling frequency (known in chemistry as an AX spin system), the operator reduces to $\sum_j JI_{iz}I_{jz}$ the effect being to split the $i$-spin resonance in to a multiplet, depending on the state of the nearby $j$-spin. For $m$ identical nearby $j$-spins, the multiplet bears a simple

binomial relationship to $m$, allowing one to "read" this number directly. The combination of chemical shift and scalar coupling information is of profound importance in identifying molecular structure in chemistry.

The terms $\sum_j \boldsymbol{I}_i.\underline{\underline{D}}.\boldsymbol{I}_j$ and $\boldsymbol{I}_i.\underline{\underline{Q}}.\boldsymbol{I}_i$ are, respectively, the through-space dipolar interaction, $H_\mathrm{D}$, and the nuclear quadrupole interaction, $H_\mathrm{Q}$, the latter being nonzero only for nuclear spin quantum numbers $I \geq 1/2$, for example, $^2$H. These interactions, projected into the zeroth-order Zeeman frame, for the dipole–dipole interaction, are

$$H_\mathrm{D} = \frac{\mu_0\hbar}{4\pi}\sum_{j>i}\frac{\gamma_i\gamma_j}{r_{ij}^3}\frac{1}{2}\left(1-3\cos^2\theta_{ij}\right) \times \left(3I_{iz}I_{jz} - \boldsymbol{I}_i.\boldsymbol{I}_j\right) \qquad [13]$$

where $r_{ij}$ is the internuclear distance and $\theta_{ij}$ is the angle made by the internuclear vector with the magnetic field direction; while, for the quadrupole interaction

$$H_\mathrm{Q} = \frac{3eV_{ZZ}Q}{4I(2I-1)\hbar}\frac{1}{2}(1-3\cos\theta_{ZZ}) \times \left(3I_z^2 - I(I+1)\right) \qquad [14]$$

where $Q$ is the nuclear quadrupole moment, $V_{ZZ}$ is the electric field gradient (assuming axial symmetry) and $\theta_{ZZ}$ is the angle made by the principal axis of that gradient with the magnetic field direction. For protons in organic matter, the internuclear dipole interaction strength is on the order of 100 kHz, a similar strength being found for the quadrupole interaction of deuterons. However, in the liquid state, these orientation-dependent interactions fluctuate so rapidly that they are typically motionally averaged to zero. Nonetheless, their fluctuations do contribute to the relaxation process.

Liquid-state NMR can result in exceptionally high-resolution (sub-Hz) spectra, if care is taken to adjust the magnetic field harmonics (shims) to produce a highly uniform Zeeman field across the sample. The last contribution of residual inhomogeneities to line broadening can often be removed by gently spinning the sample about its axis at a rate of a few tens of hertz.

## The Evolution Domain, Multiple RF Pulses, and Multidimensional NMR

Having seen the complexity of the spin Hamiltonian, one may envisage experiments where the spin coherences evolve in a much more complicated manner. To this end, consider the case of a molecular liquid two-spin (AX) system coupled via the scalar spin–spin interaction. In first-order perturbation theory, we may represent the simple two-spin Hamiltonian (in the rotating frame of the averaged Larmor frequency) as

$$\begin{aligned} H_\mathrm{rot} &= -\sigma_1\gamma B_0 I_{1z} - \sigma_2\gamma B_0 I_{2z} + J I_{1z}I_{2z} \\ &= -\omega_1 I_{1z} - \omega_2 I_{2z} + J I_{1z}I_{2z} \end{aligned} \qquad [15]$$

We now write down the density matrix in the rotating frame following a single $90^\circ_x$ RF pulse ($I_x$),

$$\begin{aligned} \rho(t) &= \exp(\mathrm{i}\omega_1 t I_{1z} + \mathrm{i}\omega_2 t I_{2z} + \mathrm{i}J I_{1z}I_{2z}t) \\ &\quad \times \exp\left(\mathrm{i}\frac{\pi}{2}I_x\right) a_\mathrm{eqbm}(I_{1z}+I_{2z}) \exp\left(-\mathrm{i}\frac{\pi}{2}I_x\right) \\ &\quad \times \exp(-\mathrm{i}\omega_1 t I_{1z} - \mathrm{i}\omega_2 t I_{2z} - \mathrm{i}J I_{1z}I_{2z}t) \\ &= \exp(\mathrm{i}\omega_1 t I_{1z} + \mathrm{i}\omega_2 t I_{2z} + \mathrm{i}J I_{1z}I_{2z}t) a_\mathrm{eqbm}(I_{1y}+I_{2y}) \\ &\quad \times \exp(-\mathrm{i}\omega_1 t I_{1z} - \mathrm{i}\omega_2 t I_{2z} - \mathrm{i}J I_{1z}I_{2z}t) \\ &= \exp(\mathrm{i}\omega_1 t I_{1z} + \mathrm{i}\omega_2 t I_{2z}) a_\mathrm{eqbm} \\ &\quad \times \left(\left(I_{1y}+I_{2y}\right)\cos\left(\tfrac{1}{2}Jt\right) + 2(I_{1z}I_{2x} + I_{1x}I_{2z}) \right. \\ &\quad \left. \times \sin\left(\tfrac{1}{2}Jt\right)\right) \exp(-\mathrm{i}\omega_1 t I_{1z} - \mathrm{i}\omega_2 t I_{2z}) \\ &= a_\mathrm{eqbm}\left(\begin{aligned} &(I_{1y}\cos\omega_1 t + I_{2y}\cos\omega_2 t \\ &\quad + I_{1x}\sin\omega_1 t + I_{2x}\sin\omega_2 t)\cos\left(\tfrac{1}{2}Jt\right) \\ &\quad + 2\left(I_{1z}I_{2x}\cos\omega_2 t - I_{1z}I_{2y}\sin\omega_2 t\right. \\ &\quad \left. + I_{1x}I_{2z}\cos\omega_1 t - I_{1y}I_{2z}\sin\omega_1 t\right) \\ &\quad \times \sin\left(\tfrac{1}{2}Jt\right) \end{aligned}\right) \end{aligned} \qquad [16]$$

Detection in the rotating frame with $I_x + \mathrm{i}I_y$ gives a signal

$$S(t) \sim a_\mathrm{eqbm}(\exp(\mathrm{i}\omega_1 t) + \exp(\mathrm{i}\omega_2 t))\cos\left(\tfrac{1}{2}Jt\right) \qquad [17]$$

Fourier transformation with respect to $t$ yields a spectrum corresponding to two spectral lines at $\omega_1$ and $\omega_2$, each split into a doublet of two sidebands separated by $J$.

Notice that it is easier to follow the evolution of the density matrix by simply writing down a time sequence of behaviors under the influence of the successive Hamiltonians. Where simultaneous terms in the Hamiltonians commute, the order of their operation may be set at will. Thus, the above example becomes

$$\begin{aligned} I_{1z} + I_{2z} &\xrightarrow{\frac{\pi}{2}I_x} I_{1y} + I_{2y} \xrightarrow{JI_{1z}I_{2z}t} \left(I_{1y}+I_{2y}\right)\cos\left(\tfrac{1}{2}Jt\right) \\ &\quad + 2(I_{1z}I_{2x} + I_{1x}I_{2z})\sin\left(\tfrac{1}{2}Jt\right) \\ &\xrightarrow{\omega_1 t I_{1z} + \omega_2 t I_{2z}} (I_{1y}\cos\omega_1 t + I_{2y}\cos\omega_2 t \\ &\quad + \mathrm{i}I_{1x}\sin\omega_1 t + \mathrm{i}I_{2x}\sin\omega_2 t)\cos\left(\tfrac{1}{2}Jt\right) \\ &\quad + 2\left(I_{1z}I_{2x}\cos\omega_2 t - \mathrm{i}I_{1z}I_{2y}\sin\omega_2 t\right. \\ &\quad \left. + I_{1x}I_{2z}\cos\omega_1 t - \mathrm{i}I_{1y}I_{2z}\sin\omega_1 t\right)\sin\left(\tfrac{1}{2}Jt\right) \end{aligned} \qquad [18]$$

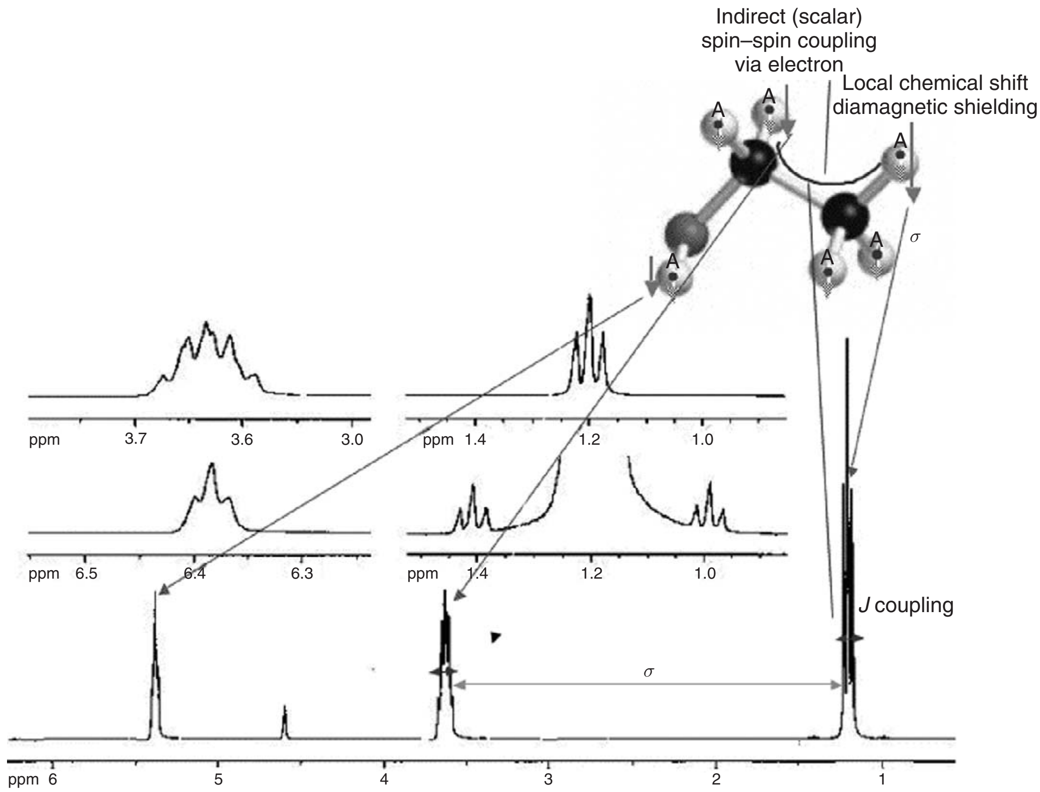

**Figure 3** The proton NMR spectrum of ethanol showing three major peaks, separated by chemical shift, each split into multiplets arising from nearby protons via the scalar coupling.

Now consider a two RF pulse scheme as shown in Figure 4, each RF pulse being $90°_x$. The evolution is

$$\begin{aligned}
&I_{1z}+I_{2z}\xrightarrow{\frac{\pi}{2}I_x} I_{1y}+I_{2y}\xrightarrow{\omega_1 t_1 I_{1z}+\omega_2 t_1 I_{2z}-JI_{1z}I_{2z}t_1}\\
&\quad\big(I_{1y}\cos\omega_1 t_1+I_{2y}\cos\omega_2 t_1+I_{1x}\sin\omega_1 t_1\\
&\qquad +I_{2x}\sin\omega_2 t_1\big)\cos\left(\tfrac{1}{2}Jt_1\right)+2\big(I_{1z}I_{2x}\cos\omega_2 t_1\\
&\qquad -I_{1z}I_{2y}\sin\omega_2 t_1+I_{1x}I_{2z}\cos\omega_1 t_1\\
&\qquad -I_{1y}I_{2z}\sin\omega_1 t_1\big)\sin\left(\tfrac{1}{2}Jt_1\right)\\
&\quad\xrightarrow{\frac{\pi}{2}I_x}\big(-I_{1z}\cos\omega_1 t_1-I_{2z}\cos\omega_2 t_1+I_{1x}\sin\omega_1 t_1\\
&\qquad +I_{2x}\sin\omega_2 t_1\big)\cos\left(\tfrac{1}{2}Jt_1\right)\\
&\qquad +2\big(I_{1y}I_{2x}\cos\omega_2 t_1+I_{1y}I_{2z}\sin\omega_2 t_1\\
&\qquad\qquad +I_{1x}I_{2y}\cos\omega_1 t_1+I_{1z}I_{2y}\sin\omega_1 t_1\big)\sin\left(\tfrac{1}{2}Jt_1\right)\\
&\quad\xrightarrow[\text{Keeping only observable magnetization}]{\omega_1 t_2 I_{1z}+\omega_2 t_2 I_{2z}+JI_{1z}I_{2z}t_2}\\
&\qquad\big(I_{1x}\sin\omega_1 t_1\cos\omega_1 t_2+I_{2x}\sin\omega_2 t_1\cos\omega_2 t_2\big)\\
&\qquad\times\cos\left(\tfrac{1}{2}Jt_1\right)\cos\left(\tfrac{1}{2}Jt_2\right)+\big(I_{1x}\sin\omega_2 t_1\sin\omega_1 t_2\\
&\qquad +I_{2x}\sin\omega_1 t_1\sin\omega_2 t_2\big)\times\sin\left(\tfrac{1}{2}Jt_1\right)\sin\left(\tfrac{1}{2}Jt_2\right)
\end{aligned}\quad [19]$$

If the idealized experiment is performed with two independent time dimensions $t_1$ and $t_2$, then detection in the rotating frame over the $t_2$ period with $I_x + iI_y$ gives a signal (restricting our attention to the quadrant of positive frequencies)

$$\begin{aligned}
S(t_1,t_2)\sim\, &a_{\mathrm{eqbm}}\big(\exp(i\omega_1 t_1)\exp(i\omega_1 t_2)+\exp(i\omega_2 t_1)\\
&\times\exp(i\omega_2 t_2)\big)\cos\left(\tfrac{1}{2}Jt_1\right)\cos\left(\tfrac{1}{2}Jt_2\right)\\
&+a_{\mathrm{eqbm}}\big(\exp(i\omega_2 t_1)\exp(i\omega_1 t_2)\\
&+\exp(i\omega_1 t_1)\exp(i\omega_2 t_2)\big)\\
&\times\sin\left(\tfrac{1}{2}Jt_1\right)\sin\left(\tfrac{1}{2}Jt_2\right)
\end{aligned}\quad [20]$$

When Fourier transformed in two dimensions with respect to $t_1$ and $t_2$, the pattern shown in Figure 5 results. Remarkably, while the diagonal spectrum is the same pair of doublets seen in the figure, this two-dimensional spectrum contains off-diagonal antiphase peaks for scalar-coupled sites where magnetization transfer has occurred.

The idea of performing NMR in two or more dimensions was first proposed by Jean Jeener in 1971. The example outlined above, correlation spectroscopy (COSY), is just one of an array of coherence transfer experiments using multiple RF pulse trains and time domain evolution of the spin ensemble. Notice that in the COSY experiment, $t_1$ is an evolution dimension during which no detection of NMR signal occurs, while $t_2$ is the detection domain.

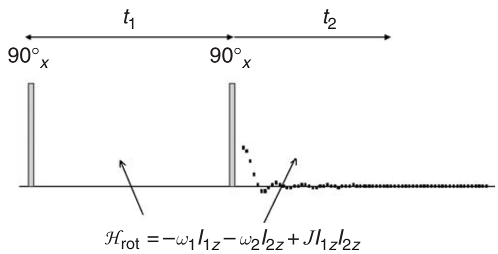

**Figure 4** RF pulse scheme used for COSY experiment.

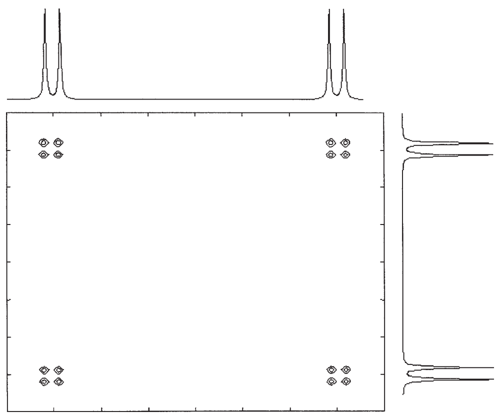

**Figure 5** Schematic COSY (modulus) spectrum for an AX spin system. Not that the (antiphase) off-diagonal peaks indicate $J$-couplings between chemical-shift-separated spins.

The effect of the evolution is indelibly imprinted in the spin system density matrix allowing later recall of vital information concerning the interactions present in the spin Hamiltonian. The COSY experiment allows one to determine which spins are coupled via their molecular orbital electrons. Other multidimensional methods that rely on dipole–dipole relaxation effects, such as NOESY, determine which spin sites have "through-space" proximity.

The use of two- and higher-dimensional methods has allowed the NMR spectra of biological macromolecules to be unraveled, with COSY methods used for spectral assignment of amino acid units, and NOESY methods used to determine any close proximities of amino acids otherwise well separated in the sequence. Such distance information has allowed the reconstruction of protein conformations by NMR.

The second RF pulse of Figure 4 also generates a state of the density matrix, $I_{1y}I_{2x}$ known as a double quantum coherence, and, in the simple COSY experiment, lost to observable magnetization. Other RF pulse schemes can take advantage of this state, converting it via suitable "coherence pathways" into an observable. For a detailed summary of these various NMR phenomena, readers are referred to the book by Ernst *et al.* (1987).

## Solid-State NMR

As with $J$ couplings, dipolar interactions and quadrupole interactions ($I > 1/2$) are bilinear in the spin operators and can be used to generate various higher-order coherence pathways in NMR experiments. Unlike the simple spin–spin coupling, they have an angular dependence. In solids, these interactions may broaden the NMR resonance line by tens to hundreds of kilohertz. In the case where a probe nucleus is located at a known site in the material (often achieved by deuteron labeling), these Hamiltonian terms may contribute important information about structure, and especially orientational anisotropy. For example, the quadrupole interaction for the spin-1 deuteron (see eqns [11] and [14]) depends as $P_2(\cos\theta_{ZZ}) = (1/2)(3\cos\theta_{ZZ} - 1)$ on the angle between the external magnetic field and the electric field gradient (generally associated with the local molecular orbital or bond direction, and taken here to be axially symmetric). Note that the first-order contribution of the quadrupole interaction leads to an unequal separation of the $m = 1, 0, -1$ Zeeman energy levels, resulting in a doublet NMR spectrum, for any particular orientation, $\theta_{ZZ}$. Such a unique orientation might be found in a single crystal, or in a nematic liquid crystalline state. For a polycrystalline material, however, the NMR spectrum has a contribution from all orientations, leading to a characteristic powder pattern. The details of $^2H$ spectral distributions may be used to characterize the degree of orientational order in solids and soft, anisotropic matter.

For $^1H$, $^{13}C$, and other spin-1/2 nuclei, dipolar interactions (with a wide distribution of spin spacings and internuclear vector orientation) may severely broaden the NMR spectrum in the solid state (see eqns [11] and [13]). Such interactions, along with quadrupole interactions for nuclei with $I > 1/2$, may be significantly reduced by modulating the effective dipolar Hamiltonian at a rate faster than its strength in frequency units. Two methods are available, one (magic angle spinning or MAS) relying on the angular terms in eqns [13] and [14], and the other (multiple pulse line narrowing) on the spin terms. The MAS technique relies on spinning the sample rapidly about at angle oriented at 54.4° to the magnetic field, such that the average value of $P_2(\cos\theta_{ij})$ becomes its projection along this spinning axis, while the projection of the spinning axis residual is $P_2(\cos 54.4°) \approx 0$. Multiple pulse methods rely on a successive reorientation of the spin system such that the effective dipolar Hamiltonian that results from the application of the nested evolution operators is rendered close to zero.

In practice, MAS techniques work best with $^{13}C$ NMR where the moderate $^{1}H$–$^{13}C$ dipolar interactions may be removed with achievable spinning speeds (a few tens of kilohertz). Furthermore, the larger proton magnetization ($\gamma_{^1H}/\gamma_{^{13}C} \approx 4$) can be transferred to the $^{13}C$ nuclei via Hartman–Hahn cross-polarization thus significantly enhancing sensitivity. Such methodology is referred to as CPMAS NMR.

The real art of solid-state NMR is in removing the unwanted dipolar or quadrupolar interactions, but leaving specific interactions of interest. This may be achieved by including in the MAS experiment, specific combinations of pulses which recouple selected spins. Some of the most sophisticated experiments in modern NMR are to be found in this domain of application.

## Conclusion

NMR provides exceptional structural information concerning molecules, biomolecules as well as molecular assemblies, liquid crystals, soft solids, and solids. In addition, the method provides unique information concerning molecular dynamics, through both relaxation methods and the direct measurement of diffusion or flow. One spectacular application of NMR concerns its use in imaging, achieved by giving the Larmor frequency a spatial tag through the use of deliberately inhomogeneous magnetic fields. This topic is covered in the article on Magnetic Resonance Imaging.

# Number Theory in Physics

**M Marcolli**, Max-Planck-Institut für Mathematik, Bonn, Germany

Several fields of mathematics have closely been associated to physics: this has always been the case for the theory of differential equations. In the early twentieth century, with the advent of general relativity and quantum mechanics, topics such as differential and Riemannian geometry, operator algebras, and functional analysis, or group theory also developed a close relation to physics. In the 1990s, mostly through the influence of string theory, algebraic geometry also began to play a major role in this interaction. Recent years have seen an increasing number of results suggesting that number theory also is beginning to play an essential part on the scene of contemporary theoretical and mathematical physics. Conversely, ideas from physics, mostly from quantum field theory and string theory, have started to influence work in number theory.

In describing significant occurrences of number theory in physics, we will, on the one hand, restrict our attention to quantum physics, while, on the other, we will assume a somewhat extensive definition of number theory that will allow us to include arithmetic algebraic geometry. The territory is vast and an extensive treatment would go beyond the size limits imposed by the encyclopedia. The choice of topics represented here inevitably reflects the limited knowledge, particular interests, and bias of the author. Very useful references, collecting a lot of material on number theory and physics, are the proceedings of the Les Houches conference in 2003 (Beilinson and Manin 1986), as well as the two volumes of a previous Les Houches conference on number theory and physics, which took place in 1989, published by Springer in 1990 and 1992. A number theory and physics database is presently maintained online by M R Watkins.

In the following, we have organized the material by topics in number theory that have so far made an appearance in physics, and for each we briefly describe the relevant context and results. This singles out many themes. We first discuss a class of functions that occur in physics and their special values that are of great number-theoretic importance. This includes the dilogarithm, the polylogarithms and multiple polylogarithms, and the multiple zeta values. We also discuss the most important symmetry groups of number theory, the Galois groups, and occurrences in physics of some forms of Galois theory. We then discuss how techniques from the arithmetic geometry of algebraic varieties, especially Arakelov geometry, play a role in string theory. Finally, we discuss briefly the theory of motives and outline its possible relation to quantum physics. From the physics point of view, it seems that the most promising directions in which number-theoretic tools have come to play a crucial role are to be found mostly in the realm of rational conformal field theories and of noncommutative geometry, as well as in certain aspects of string theory.

Among the topics that are very relevant to this theme, but that will not be touched upon in this article, there are important subjects such as the theory of "arithmetic quantum chaos," the use of methods of random matrix theory applied to the study of zeros of zeta functions, or mirror symmetry and its connection to modular forms. The interested reader can find such topics treated in other articles of this encyclopedia and in the references mentioned above (*see* Quantum Ergodicity and Mixing of Eigenfunctions; Random Matrix Theory in Physics; Mirror Symmetry: a Geometric Survey).

## Dilogarithm, Multiple Polylogarithms, Multiple Zeta Values

The dilogarithm is defined as

$$Li_2(z) = \int_z^0 \frac{\log(1-t)}{t}\,dt = \sum_{n=1}^{\infty} \frac{z^n}{n^2}$$

It satisfies the functional equation $Li_2(z) + Li_2(1-z) = Li_2(1) - \log(z)\log(1-z)$, where $Li_2(1) = \zeta(2)$, for $\zeta(s)$ the Riemann zeta function. A variant is given by the Rogers dilogarithm $L(x) = Li_2(x) + (1/2)\log(x)\log(1-x)$. For more details, see Zagier's paper (Julia *et al.* 2005, vol. II).

The polylogarithms are similarly defined by the series $Li_k(z) = \sum_{n\geq 1} z^n/n^k$. In quantum electrodynamics, there are corrections to the value of the gyromagnetic ratio, in powers of the fine structure constant. The correction terms that are known exactly involve special values of the zeta function such as $\zeta(3), \zeta(5)$ and values of polylogarithms such as $Li_4(1/2)$. The series defining the polylogarithm function $Li_s(z) = \sum_{n\geq 1} z^n/n^s$ converges absolutely for all $s \in \mathbb{C}$ and $|z| < 1$ and has analytic continuation to $z \in \mathbb{C} \setminus [1,\infty)$. The Fermi–Dirac and Bose–Einstein distributions are expressed in terms of the polylogarithm function as

$$\int_0^\infty \frac{x^s}{e^{x-\mu} \pm 1}\,dx = -\Gamma(s+1) Li_{1+s}(\pm e^\mu)$$

The multiple polylogarithms are functions defined by the expressions

$$Li_{s_1,\ldots,s_r}(z_1, z_2, \ldots, z_r) = \sum_{n_1>n_2>\cdots>n_r>0} \frac{z_1^{n_1} z_2^{n_2} \cdots z_r^{n_r}}{n_1^{s_1} n_2^{s_2} \cdots n_r^{s_r}} \qquad [1]$$

By analytic continuation, the functions $Li_{s_1,\ldots,s_r}(z_1, z_2, \ldots, z_r)$ are defined for all complex $s_i$ and for $z_i$ in the complement of the cut $[1,\infty)$ in the complex plane. Multiple zeta values of weight $k$ and depth $r$ are given by the expressions

$$\zeta(k_1, \ldots, k_r) = \sum_{n_1>n_2>\cdots>n_r>0} \frac{1}{n_1^{k_1} \cdots n_r^{k_r}} \qquad [2]$$

with $k_i \in \mathbb{N}$ and $k_1 \geq 2$. These satisfy many combinatorial identities and nontrivial relations over $\mathbb{Q}$. For an informative overview on the subject, see Cartier (2002). Notice that, for the sums in [1] and [2], a different summation convention can also be found in the literature.

### Conformal Field Theories and the Dilogarithm

There is a relation between the torsion elements in the algebraic $K$-theory group $K_3(\mathbb{C})$ and rational conformally invariant quantum field theories in two dimensions (see Nahm (2005)). There is, in fact, a map, given by the dilogarithm, from torsion elements in the Bloch group (closely related to the algebraic $K$-theory) to the central charges and scaling dimensions of the conformal field theories.

This correspondence arises by considering sums of the form

$$\sum_{m\in\mathbb{N}^r} \frac{q^{Q(m)}}{(q)_m} \qquad [3]$$

where $(q)_m = (q)_{m_1} \cdots (q)_{m_r}, (q)_{m_i} = (1-q)(1-q^2)\cdots(1-q^{m_i})$ and $Q(m) = m^t Am/2 + bm + h$ has rational coefficients. Such sums are naturally obtained from considerations involving the partition function of a bosonic rational conformal field theory (CFT). In

particular, [3] can define a modular function only if all the solutions of the equation

$$\sum_j A_{ij} \log(x_j) = \log(1 - x_i) \qquad [4]$$

determine elements of finite order in an extension $\hat{B}(\mathbb{C})$ of the Bloch group, which accounts for the fact that the logarithm is multivalued. The Rogers dilogarithm gives a natural group homomorphism $(2\pi i)^2 L : \hat{B}(\mathbb{C}) \to \mathbb{C}/\mathbb{Z}$, which takes values in $\mathbb{Q}/\mathbb{Z}$ on the torsion elements. These values give the conformal dimensions of the fields in the theory.

### Feynman Graphs

Multiple zeta values appear in perturbative quantum field theory. D Kreimer (2000) developed a connection between knot theory and a class of transcendental numbers, such as multiple zeta values, obtained by quantum field-theoretic calculations as counterterms generated by corresponding Feynman graphs. Broadhurst and Kreimer (1997) identified Feynman diagrams with up to nine loops whose corresponding counterterms give multiple zeta values up to weight 15. Recently, Kreimer showed some deep analogies between residues of quantum fields and variations of mixed Hodge–Tate structures associated to polylogarithms.

Testing predictions about the standard model of elementary particles, in the hope of detecting new physics, requires developing effective computational methods handling the huge number of terms involved in any such calculation, that is, efficient algorithms for the expansion of higher transcendental functions to a very high order. The interesting fact is that abstract number-theoretic objects, such as multiple zeta values and multiple polylogarithms, appear naturally in this context (cf., e.g., Moch *et al.* (2002)). The explicit recursive algorithms are based on Hopf algebras and produce expansions of nested finite or infinite sums involving ratios of gamma functions and $Z$-sums (Euler–Zagier sums), which naturally generalize multiple polylogarithms and multiple zeta values. Such sums typically arise in the calculation of multiscale multiloop integrals. The algorithms are designed to recursively reduce the $Z$-sums involved to simpler ones with lower weight or depth.

## Galois Theory

Given a number field $\mathbb{K}$, which is an algebraic extension of $\mathbb{Q}$ of some degree $[\mathbb{K}:\mathbb{Q}] = n$, there is an associated fundamental symmetry group, given by the absolute Galois group $\mathrm{Gal}(\bar{\mathbb{K}}/\mathbb{K})$, where $\bar{\mathbb{K}}$ is an algebraic closure of $\mathbb{K}$. Even in the case of $\mathbb{Q}$, the absolute Galois group $\mathrm{Gal}(\bar{\mathbb{Q}}/\mathbb{Q})$ is a very complicated object, far from being fully understood.

One can consider an easier symmetry group, which is the abelianization of the absolute Galois group. This corresponds to considering the field $\mathbb{K}^{ab}$, the "maximal abelian extension" of $\mathbb{K}$, which has the property that

$$\mathrm{Gal}(\mathbb{K}^{ab}/\mathbb{K}) = \mathrm{Gal}(\bar{\mathbb{K}}/\mathbb{K})^{ab}$$

The Kronecker–Weber theorem shows that for $\mathbb{K} = \mathbb{Q}$ the maximal abelian extension can be identified with the cyclotomic field (generated by all roots of unity), $\mathbb{Q}^{ab} = \mathbb{Q}^{\mathrm{cycl}}$, and the Galois group is identified with $\mathrm{Gal}(\mathbb{Q}^{ab}/\mathbb{Q}) \cong \hat{\mathbb{Z}}^*$, where $\hat{\mathbb{Z}}^* = \mathbb{A}_f^*/\mathbb{Q}_+^*$. In general, for other number fields, one has the "class field theory isomorphism"

$$\theta : \mathrm{Gal}(\mathbb{K}^{ab}/\mathbb{K}) \xrightarrow{\simeq} C_{\mathbb{K}}/D_{\mathbb{K}}$$

where $C_{\mathbb{K}} = \mathbb{A}_{\mathbb{K}}^*/\mathbb{K}^*$ is the group of idele classes and $D_{\mathbb{K}}$ the connected component of the identity in $C_{\mathbb{K}}$. In general, however, one does not have an explicit description of the generators of the maximal abelian extension $\mathbb{K}^{ab}$ and the action of the Galois group. This is the content of the explicit class field theory problem, Hilbert's 12th problem. In addition to the Kronecker–Weber case, a complete answer is known in the case of imaginary quadratic fields $\mathbb{K} = \mathbb{Q}(\sqrt{-d})$, with $d > 1$ a positive integer. In this case generators are obtained by evaluating modular functions at a point $\tau$ in the upper-half plane such that $\mathbb{K} = \mathbb{Q}(\tau)$ and the Galois action is described explicitly through the group of automorphisms of the modular field, through Shimura reciprocity. For a survey of the explicit class field theory problem and the case of imaginary quadratic fields, see Stevenhagen (2001).

As we mentioned above, understanding the structure of the absolute Galois group $\mathrm{Gal}(\bar{\mathbb{Q}}/\mathbb{Q})$ is a fundamental question in number theory. Grothendieck described, in his famous proposal "Esquisse d'un programme," how to obtain an action of $\mathrm{Gal}(\bar{\mathbb{Q}}/\mathbb{Q})$ on an essentially combinatorial object, the set of "dessins d'enfants." These are connected graphs (on a surface) such that the complement of the graph is a union of open cells and the vertices have two different markings, with the properties that adjacent vertices have opposite markings. Such objects arise by considering the projective line $\mathbb{P}^1$ minus three points. Any finite cover of $\mathbb{P}^1$ branched only over $\{0, 1, \infty\}$ gives an algebraic curve defined over $\bar{\mathbb{Q}}$. The dessin is the inverse image under the covering map of the segment $[0, 1]$ in $\mathbb{P}^1$. The absolute Galois group $\mathrm{Gal}(\bar{\mathbb{Q}}/\mathbb{Q})$ acts on the data of the curve and the covering map, hence on the set of

dessins. A theorem of Bielyi shows that, in fact, all algebraic curves defined over $\bar{\mathbb{Q}}$ are obtained as coverings of the projective line ramified only over the points $\{0, 1, \infty\}$. This has the effect of realizing the absolute Galois group as a subgroup of outer automorphisms of the profinite fundamental group of the projective line minus three points. For a general reference on the subject, see Schneps (1994).

A different type of Galois symmetry of great arithmetic significance is "motivic" Galois theory. This will be discussed later in the section dedicated to motives, where we discuss a surprising occurrence in the context of perturbative quantum field theory and renormalization.

## Quantum Statistical Mechanics and Class Field Theory

In quantum statistical mechanics, one considers an algebra of observables, which is a unital $C^*$-algebra $\mathcal{A}$ with a time evolution $\sigma_t$. States are given by linear functionals $\varphi : \mathcal{A} \to \mathbb{C}$ satisfying $\varphi(1) = 1$ and positivity $\varphi(x^* x) \geq 0$. Equilibrium states $\varphi$ at inverse temperature $\beta$ satisfy the Kubo–Martin–Schwinger (KMS) condition, namely, for all $x, y \in \mathcal{A}$ there exists a bounded holomorphic function $F_{x,y}(z)$ on the strip $0 < \Im(z) < \beta$, which extends continuously to the boundary, such that for all $t \in \mathbb{R}$

$$F_{x,y}(t) = \varphi(x\sigma_t(y))$$

and

$$F_{x,y}(t + \mathrm{i}\beta) = \varphi(\sigma_t(y)x) \qquad [5]$$

Cases of number-theoretic interest arise when one considers the noncommutative space of commensurability classes of $\mathbb{Q}$-lattices up to scaling as algebra of observables, with a natural time evolution determined by the covolume, as shown in the paper *Quantum Statistical Mechanics of* $\mathbb{Q}$*-Lattices* of Connes–Marcolli (Julia *et al.* 2005, vol. I). A $\mathbb{Q}$-lattice in $\mathbb{R}^n$ consists of a pair $(\Lambda, \phi)$ of a lattice $\Lambda \subset \mathbb{R}^n$ together with a homomorphism of abelian groups $\phi : \mathbb{Q}^n/\mathbb{Z}^n \longrightarrow \mathbb{Q}\Lambda/\Lambda$. Two $\mathbb{Q}$-lattices are commensurable, $(\Lambda_1, \phi_1) \sim (\Lambda_2, \phi_2)$, iff $\mathbb{Q}\Lambda_1 = \mathbb{Q}\Lambda_2$ and $\phi_1 = \phi_2 \bmod \Lambda_1 + \Lambda_2$.

**The Bost–Connes system** The quantum statistical mechanical system considered by Bost and Connes (1995) corresponds to the case of one-dimensional $\mathbb{Q}$-lattices. The partition function of the system is the Riemann zeta function $\zeta(\beta)$. The system has spontaneous symmetry breaking at $\beta = 1$, with a single KMS state for all $0 < \beta \leq 1$. For $\beta > 1$, the extremal equilibrium states are parametrized by the embeddings of $\mathbb{Q}^{\mathrm{cycl}}$ in $\mathbb{C}$ with a free transitive action of the idele class group $C_{\mathbb{Q}}/D_{\mathbb{Q}} = \hat{\mathbb{Z}}^*$. At zero temperature, the evaluation of $\mathrm{KMS}_\infty$ states on elements of a rational subalgebra intertwines the action of $\hat{\mathbb{Z}}^*$ by automorphisms of $(\mathcal{A}, \sigma_t)$ with the action of $\mathrm{Gal}(\mathbb{Q}^{ab}/\mathbb{Q})$ on the values of the states. This recovers the explicit class field theory of $\mathbb{Q}$ from a physical perspective.

**Noncommutative space of adele classes** The algebra $\mathcal{A}$ of the Bost–Connes system is the noncommutative algebra of functions $f(r, \rho)$, for $\rho \in \hat{\mathbb{Z}}$ and $r \in \mathbb{Q}^*$ such that $r\rho \in \hat{\mathbb{Z}}$, with the convolution product

$$f_1 * f_2(r, \rho) = \sum_{s \in \mathbb{Q}^* : s\rho \in \hat{\mathbb{Z}}} f_1(rs^{-1}, s\rho) f_2(s, \rho) \qquad [6]$$

and the adjoint $f^*(r, \rho) = \overline{f(r^{-1}, r\rho)}$. According to the general philosophy of Connes style noncommutative geometry, it is the algebra of coordinates of the noncommutative space defined by the "bad quotient" $\mathrm{GL}_1(\mathbb{Q}) \setminus (\mathbb{A}_f \times \{\pm 1\})$ – a noncommutative version of the zero-dimensional Shimura variety $\mathrm{Sh}(\mathrm{GL}_1, \{\pm 1\}) = \mathrm{GL}_1(\mathbb{Q}) \setminus (\mathrm{GL}_1(\mathbb{A}_f) \times \{\pm 1\})$. Its "dual system" (in the sense of Connes's duality of type III and type II factors) is obtained by taking the crossed product by the time evolution. It gives the algebra of coordinates of the noncommutative space defined by the quotient $\mathbb{A}/\mathbb{Q}^*$. This is the noncommutative space of "adele classes" used by Connes in his spectral realization of the zeros of the Riemann zeta function.

**The $\mathrm{GL}_2$-system** A generalization of the Bost–Connes system was introduced by Connes and Marcolli in the paper *Quantum Statistical Mechanics of* $\mathbb{Q}$*-Lattices* (Julia *et al.* 2005). This corresponds to the case of two-dimensional $\mathbb{Q}$-lattices. The partition function is the product $\zeta(\beta)\zeta(\beta - 1)$. The system in this case has two phase transitions, with no KMS states for $\beta \leq 1$. For $\beta > 2$, the extremal KMS states are parametrized by the invertible $\mathbb{Q}$-lattices, namely, those for which $\phi$ is an isomorphism. The algebra $\mathcal{A}$ has an arithmetic structure given by a rational algebra of unbounded multipliers. This rational algebra contains modular functions and Hecke operators. At zero temperature, extremal KMS states can be evaluated on these multipliers. Symmetries of $(\mathcal{A}, \sigma_t)$ are realized in part by endomorphisms (as in the theory of superselection sectors) and the symmetry group acting on low-temperature KMS states is the group of automorphisms of the modular field $\mathrm{GL}_2(\mathbb{A}_f)/\mathbb{Q}^*$. For a generic set of extremal $\mathrm{KMS}_\infty$ states, evaluation at the rational algebra intertwines this action with the action on the values of an embedding of the modular field as a subfield of $\mathbb{C}$.

**The complex multiplication system** In the case of an imaginary quadratic field $\mathbb{K} = \mathbb{Q}(\tau)$, an analogous construction is possible. A one-dimensional $\mathbb{K}$-lattice is a pair $(\Lambda, \phi)$ of a finitely generated $\mathcal{O}$-submodule $\Lambda$ of $\mathbb{C}$, with $\Lambda\mathbb{K} = \mathbb{K}$, and a homomorphism of $\mathcal{O}$-modules $\phi : \mathbb{K}/\mathcal{O} \to \mathbb{K}\Lambda/\Lambda$. Two $\mathbb{K}$-lattices are commensurable iff $\mathbb{K}\Lambda_1 = \mathbb{K}\Lambda_2$ and $\phi_1 = \phi_2 \bmod \Lambda_1 + \Lambda_2$. Connes *et al.* (Preprint 2005) constructed a quantum statistical mechanical system describing the noncommutative space of commensurability classes of one-dimensional $\mathbb{K}$-lattices up to scale. The partition function is the Dedekind zeta function $\zeta_{\mathbb{K}}(\beta)$. The system has a phase transition at $\beta = 1$ with a unique KMS state for higher temperatures and extremal KMS states parametrized by the invertible $\mathbb{K}$-lattices at lower temperatures. There is a rational subalgebra induced by the rational structure of the $GL_2$-system (one-dimensional $\mathbb{K}$-lattices are also two-dimensional $\mathbb{Q}$-lattices with compatible notions of commensurability). The symmetries of the system are given by the idele class group $\mathbb{A}^*_{\mathbb{K},f}/\mathbb{K}^*$. The action is partly realized by endomorphisms corresponding to the possible presence of a nontrivial class group (for class number $>1$). The values of extremal $KMS_\infty$ states on the rational subalgebra intertwine the action of the idele class group with the Galois action on the values. This fully recovers the explicit class field theory for imaginary quadratic fields.

#### Conformal Field Theory and the Absolute Galois Group

Moore and Seiberg considered data associated to any rational conformal field theory, consisting of matrices, obtained as monodromies of some holomorphic multi-valued functions on the relevant moduli spaces, satisfying polynomial equations. Under reasonable hypotheses, the coefficients of the Moore–Seiberg matrices are algebraic numbers. This allows for the presence of interesting arithmetic phenomena. Through the Chern–Simons/Wess–Zumino–Witten correspondence, it is possible to construct three-dimensional topological field theories from solutions to the Moore–Seiberg equations.

On the arithmetic side, Grothendieck proposed in his "Esquisse d'un programme" the existence of a Teichmüller tower given by the moduli spaces $M_{g,n}$ of Riemann surfaces of arbitrary genus $g$ and number of marked points $n$, with maps defined by operations such as cutting and pasting of surfaces and forgetting marked points, all encoded in a family of fundamental groupoids. He conjectured that the whole tower can be reconstructed from the first two levels, providing, respectively, generators and relations. He called this a "game of Lego–Teichmüller." He also conjectured that the absolute Galois group acts by outer automorphisms on the profinite completion of the tower. The basic building blocks of the tower are provided by "pairs of pants," that is, by projective lines minus three points.

This leads to a conjectural relation between the Moore–Seiberg equations and this Grothendieck–Teichmüller setting (cf. Degiovanni 1994) according to which solutions of the Moore–Seiberg equations provide projective representations of the Teichmüller tower, and the action of the absolute Galois group $\mathrm{Gal}(\bar{\mathbb{Q}}/\mathbb{Q})$ corresponds to the action on the coefficients of the Moore–Seiberg matrices.

Rational conformal field theories are, in general, one of the most promising sources of interactions between number theory and physics, involving interesting Galois actions, modular forms, Brauer groups, and complex multiplication. Some fundamental work in this direction was done by, for example, Borcherds and Gannon.

## Arithmetic Algebraic Geometry

In this section we describe occurrences in physics of various aspects of the arithmetic geometry of algebraic varieties.

#### Arithmetic Calabi–Yau

In the context of type II string theory, compactified on Calabi–Yau 3-folds, Greg Moore considered certain black hole solutions and a resulting dynamical system given by a differential equation in the corresponding moduli. The fixed points of these equations determine certain "black hole attractor varieties." In the case of varieties obtained from a product of elliptic curves or of a K3 surface and an elliptic curve, the attractor equation singles out an arithmetic property: the elliptic curves have complex multiplication. The class number of the corresponding imaginary quadratic field counts U-duality classes of black holes with the same area. Other results point to a relation between the arithmetic properties of Calabi–Yau 3-folds and conformal field theory. For instance, it was shown by Schimmrigk that, in certain cases, the algebraic number field defined via the fusion rules of a conformal field theory as the field defined by the eigenvalues of the integer-valued fusion matrices

$$\phi_i * \phi_j = (N_i)_j^k \phi_k$$

can be recovered from the Hasse–Weil $L$-function of the Calabi–Yau. An interesting case is provided by the Gepner model associated with the Fermat quintic Calabi–Yau 3-fold.

### Arakelov Geometry

For $\mathbb{K}$ a number field and $O_{\mathbb{K}}$ its ring of integers, a smooth proper algebraic curve $X$ over $\mathbb{K}$ determines a smooth minimal model $X_{O_{\mathbb{K}}}$, which defines an arithmetic surface $\mathcal{X}_{O_{\mathbb{K}}}$ over Spec($O_{\mathbb{K}}$). The closed fiber $X_{\wp}$ of $\mathcal{X}_{O_{\mathbb{K}}}$ over a prime $\wp \in O_{\mathbb{K}}$ is given by the reduction mod $\wp$.

When Spec($O_{\mathbb{K}}$) is "compactified" by adding the Archimedean primes, one can correspondingly enlarge the group of divisors on the arithmetic surface by adding formal real linear combinations of irreducible "closed vertical fibers at infinity." Such fibers are only treated as formal objects. The main idea of Arakelov geometry is that it is sufficient to work with "infinitesimal neighborhood" $X_{\alpha}(\mathbb{C})$ of these fibers, given by the Riemann surfaces obtained from the equation defining $X$ over $\mathbb{K}$ under the embeddings $\alpha : \mathbb{K} \hookrightarrow \mathbb{C}$ that constitute the Archimedean primes. Arakelov developed a consistent intersection theory on arithmetic surfaces, by computing the contribution of the Archimedean primes to the intersection indices using Hermitian metrics on these Riemann surfaces and the Green function of the Laplacian.

A general introduction to the subject of Arakelov geometry can be found in Lang (1988). Manin (1991) showed that these Green functions can be computed in terms of geodesics in a hyperbolic 3-manifold that has the Riemann surface $X_{\alpha}(\mathbb{C})$ as its conformal boundary at infinity.

**The Polyakov measure** A first application to physics of methods of Arakelov geometry was an explicit formula obtained by Beilinson and Manin (1986) for the Polyakov bosonic string measure in terms of Faltings's height function at algebraic points of the moduli space of curves.

The partition function for the closed bosonic string has a perturbative expansion $Z = \sum_{g \geq 0} Z_g$, with

$$Z_g = e^{\beta(2-2g)} \int_{\Sigma} e^{-S(x,\gamma)} Dx D\gamma \qquad [7]$$

written in terms of a compact Riemann surface $\Sigma$ of genus $g$, maps $x : \Sigma \to \mathbb{R}^d$, and metrics $\gamma$ on $\Sigma$. The classical action is of the form

$$S(x, \gamma) = \int_{\Sigma} d^2 z \sqrt{|\gamma|} \gamma^{ab} \partial_a x^{\mu} \partial_b x^{\mu} \qquad [8]$$

Using the invariance of the classical action with respect to the semidirect product of diffeomorphisms of $\Sigma$ and the conformal group, the integral is reduced (in the critical dimension $d = 26$ where the conformal anomaly cancels) to a zeta regularized determinant of the Laplacian for the metric on $\Sigma$ and an integration over the moduli space $M_g$ of genus $g$ algebraic curves. Beilinson and Manin gave an explicit formula for the resulting Polyakov measure on $M_g$ using results of Faltings on Arakelov geometry of arithmetic surfaces. In particular, their argument uses essentially the properties of the Faltings metrics on the invertible sheaves $d(L)$ given by the "multiplicative Euler characteristics" of sheaves $L$ of relative 1-forms. For a suitable choice of bases $\{\phi_j\}$ and $\{w_j\}$ of differentials and quadratic differentials, the formula for the Polyakov measure is then of the form (up to a multiplicative constant)

$$d\pi_g = |\det B|^{-18} (\det \Im \tau)^{-13} W_1 \wedge \bar{W}_1 \wedge \cdots \wedge W_{3g-3} \wedge \bar{W}_{3g-3} \qquad [9]$$

with $\tau$ in the Siegel upper-half space, $B_{ij} = \int_{a_i} \phi_j$, and the $W_j$ given by the images of the basis $w_j$ under the Kodaira–Spencer isomorphism.

**Holography** In the case of the elliptic curve $X_q(\mathbb{C}) = \mathbb{C}^*/q^{\mathbb{Z}}$, a formula of Alvarez-Gaume, Moore, and Vafa gives the operator product expansion of the path integral for bosonic field theory as

$$g(z,1) = \log \left( |q|^{B_2(\log|z|/\log|q|)/2} |1-z| \times \prod_{n=1}^{\infty} |1-q^n z| \, |1-q^n z^{-1}| \right) \qquad [10]$$

where $B_2$ is the second Bernoulli polynomial. Expression [8] is in fact the Arakelov Green function on $X_q(\mathbb{C})$ (cf. Lang (1988)).

Using this and analogous results for higher genus Riemann surfaces, Manin and Marcolli (2001) showed that the result of Manin (1991) on Arakelov and hyperbolic geometry can be rephrased in terms of the AdS/CFT correspondence, or holography principle. Expression [8] can then be written as a combination of terms involving geodesic lengths in the Euclidean BTZ black hole.

In the case of higher genus curves, the Arakelov Green function on a compact Riemann surface, which is related to the two-point correlation function for bosonic field theory, can be expressed in terms of the semiclassical limit of gravity (the geodesic propagator) on the bulk space of Euclidean versions of asymptotically $AdS_{2+1}$ black holes introduced by K Krasnov.

## Motives

There are several cohomology theories for algebraic varieties: de Rham, Betti, étale cohomology. de Rham

and Betti are related by the period isomorphism, and comparison isomorphisms relate Étale and Betti cohomology. In the smooth projective case, they have the expected properties of Poincaré duality, Künneth isomorphisms, etc. Moreover, Étale cohomology provides interesting $\ell$-adic representations of $\mathrm{Gal}(\bar{k}/k)$. In order to understand what type of information, such as maps or operations can be transferred from one to another cohomology, Grothendieck introduced the idea of the existence of a "universal cohomology theory" with realization functors to all the known cohomology theories for algebraic varieties. He called this the theory of "motives." Properties that can be transferred between different cohomology theories are those that exist at the motivic level. A short introduction to motives can be found in Serre (1992).

The first constructions of a category of motives proposed by Grothendieck covers the case of smooth projective varieties. The corresponding motives form a $\mathbb{Q}$-linear abelian category of "pure motives." Roughly, objects are varieties and morphisms are "correspondences" given by algebraic cycles in the product, modulo a suitable equivalence relation. The category also contains Tate objects generated by $\mathbb{Q}(1)$, which is the inverse of the pure motive $H^2(\mathbb{P}^1)$. Grothendieck's standard conjectures imply that the category of pure motives is equivalent to the category of representations $\mathrm{Rep}_G$ of a "motivic Galois group," which in the case of pure motives is proreductive. The subcategory of pure Tate motives has as motivic Galois group the multiplicative group $\mathbb{G}_m$. The situation is more complicated for "mixed motives," for which constructions were only very recently proposed (e.g., in the work of Voevodsky). These provide a universal cohomology theory for more general classes of algebraic varieties. Mixed Tate motives are the subcategory generated by the Tate objects. There is again a motivic Galois group. For mixed motives it is an extension of a proreductive group by a prounipotent group, with the proreductive part coming from pure motives and the prounipotent part from the presence of a weight filtration on mixed motives. The multiple zeta values appear as periods of mixed Tate motives.

### Renormalization and Motivic Galois Theory

A manifestation of motivic Galois groups in physics arises in the context of the Connes–Kreimer theory of perturbative renormalization (for an introduction to this topic, *see* Hopf Algebra Structure of Renormalizable Quantum Field Theory). In fact, according to the Connes–Kreimer theory, the Bogoliubov–Parasiuk–Hepp–Zimmerman (BPHZ) renormalization scheme with dimensional regularization and minimal subtraction can be formulated mathematically in terms of the Birkhoff factorization

$$\gamma(z) = \gamma_-(z)^{-1}\gamma_+(z) \qquad [11]$$

of loops in a prounipotent Lie group $G$, which is the group of characters of the Hopf algebra of Feynman graphs. Here, the loop $\gamma$ is defined on a small punctured disk around the critical dimension $D$, $\gamma_+$ is holomorphic in a neighborhood of $D$, and $\gamma_-$ is holomorphic in the complement of $D$ in $\mathbb{P}^1(\mathbb{C})$. The renormalized value is given by $\gamma_+(D)$ and the counterterms by $\gamma_-(z)$.

The paper of Connes and Marcolli *Renormalization, the Riemann–Hilbert Correspondence*, and *Motivic Galois Theory* in volume II of Julia *et al.* (2005) shows that the data of the Birkhoff factorization are equivalently described in terms of solutions to a certain class of differential systems with irregular singularities. This is obtained by writing the terms in the Birkhoff factorization as time-ordered exponentials, and then using the fact that

$$\mathrm{T}e^{\int_a^b \alpha(t)\,\mathrm{d}t} := 1 + \sum_{n=1}^{\infty} \int_{a\le s_1\le\cdots\le s_n\le b} \alpha(s_1)\cdots\alpha(s_n)\,\mathrm{d}s_1\cdots\mathrm{d}s_n$$

is the value $g(b)$ at $b$ of the unique solution $g(t)\in G$ with value $g(a)=1$ of the differential equation $\mathrm{d}g(t) = g(t)\alpha(t)\,\mathrm{d}t$.

The singularity types are specified by physical conditions, such as the independence of the counterterms on the mass scale. These conditions are expressed geometrically through the notion of $G$-valued "equisingular connections" on a principal $\mathbb{C}^*$-bundle $B$ over a disk $\Delta$, where $G$ is the prounipotent Lie group of characters of the Connes–Kreimer Hopf algebra of Feynman graphs. The "equisingularity" condition is the property that such a connection $\omega$ is $\mathbb{C}^*$-invariant and that its restrictions to sections of the principal bundle that agree at $0\in\Delta$ are mutually equivalent, in the sense that they are related by a gauge transformation by a $G$-valued $\mathbb{C}^*$-invariant map regular in $B$; hence, they have the same type of (irregular) singularity at the origin.

The classification of equivalence classes of these differential systems via the Riemann–Hilbert correspondence and differential Galois theory yields a Galois group $U^* = U \rtimes \mathbb{G}_m$, where $U$ is prounipotent, with Lie algebra the free graded Lie algebra with one generator $e_{-n}$ in each degree $n\in\mathbb{N}$. The group $U^*$ is identified with the motivic Galois group of mixed Tate motives over the cyclotomic ring $\mathbb{Z}[e^{2\pi i/N}]$, for $N=3$ or $N=4$, localized at $N$.

### Speculations on Arithmetical Physics

In a lecture written for the 25th Arbeitstagung in Bonn, Y Manin presented intriguing connections between arithmetic geometry (especially Arakelov geometry) and physics. The theme is also discussed in Manin (1989). These considerations are based on a philosophical viewpoint according to which fundamental physics might, like adeles, have Archimedean (real or complex) as well as non-Archimedean ($p$-adic) manifestations. Since adelic objects are more fundamental and often simpler than their Archimedean components, one can hope to use this point of view in order to carry over some computation of physical relevance to the non-Archimedean side where one can employ number-theoretic methods.

**Adelic physics?** Some of the results mentioned in the previous sections seem to lend themselves well to this adelic interpretation. The quantum statistical mechanics of $\mathbb{Q}$-lattices relies fundamentally on adeles and it admits generalizations to systems associated to other algebraic varieties (Shimura varieties) that have an adelic description and adelic groups of symmetries. The result on the Polyakov measure also has an adelic flavor, as it uses essentially the Archimedean component of the Faltings height function. The latter is in fact a product of contributions from all the Archimedean and non-Archimedean places of the field of definition of algebraic points in the moduli space, so that one can expect that there would be an adelic Polyakov measure, of which one normally sees the Archimedean side only. The Freund–Witten adelic product formula for the Veneziano string amplitude fits in the same context, with $p$-adic amplitudes

$$B_p(\alpha, \beta) = \int_{\mathbb{Q}_p} |x|_p^{\alpha-1} |1-x|_p^{\beta-1}\, dx$$

and $B_\infty(\alpha,\beta)^{-1} = \prod_p B_p(\alpha,\beta)$ (cf. Varadarajan (2004)).

**Adelic physics and motives** A similar adelic philosophy was taken up by other authors, who proposed ways of introducing non-Archimedean and adelic geometries in quantum physics. A recent survey is given in Varadarajan (2004). For instance, Volovich (1995) proposed spacetime models based on cohomological realizations of motives, with étale topology "interpolating" between a proposed non-Archimedean geometry at the Planck scale and Euclidean geometry at the macroscopic scale. In this viewpoint, motivic $L$-functions appear as partition functions and actions of motivic Galois groups govern the dynamics.

## Operads

**J Stasheff**, Lansdale, PA, USA

### Introduction

An operad is an abstraction of a family of composable functions of $n$ variables for various $n$, useful for the "bookkeeping" and applications of such families. Operads are particularly important and useful in categories with a good notion of "homotopy," where they play a key role in organizing hierarchies of higher homotopies, reflecting their original use as a tool in homotopy theory, especially for studying (iterated) loop spaces. For several years now, operads have become increasingly important in mathematical physics, especially in string field theory, where they organize the terms of higher order in perturbed actions, and in deformation quantization.

The major focus of this article will be on operads as they are relevant to mathematical physics, but will also include some background material from homotopy theory, where they originated. A borderland where homotopy theory and cohomological physics overlap is the world of differential graded vector spaces, including those of differential forms, ghosts, anti-ghosts, etc., sometimes lumped together as BRST theory. Here, as elsewhere in contemporary mathematical physics, the flow has been in both directions – sometimes physicists have discovered or reinvented known mathematics but finding new applications, at other times physics has suggested new concepts for mathematicians to develop further. In the case of operads, they have provided general structure for varieties of algebras, some of which are novel types contributed by physicists.

For a reasonably up-to-date introduction and survey, consider Markl *et al.* (2002), although there have been many developments since then. Two particularly important original works are Boardman and Vogt (1973) and May (1972).

### Definitions and Examples

The term "operad" is due to May, building on work of Stasheff and of Boardman–Vogt. The most fundamental example of an operad is the endomorphism operad $\mathcal{E}nd_X := \{\mathrm{Map}(X^n, X)\}_{n\geq 1}$ where, for a set or topological space $X$, $\{\mathrm{Map}(X^n, X)\}$ means the set or space of functions or continuous functions from the $n$-fold product of $X$ with itself to $X$, together with the operations

$$\circ_i : Map(X^n, X) \times Map(X^m, X) \longrightarrow Map(X^{n+m-1}, X)$$

given, for $1 \leq i \leq n$, by

$$(f \circ_i g)(x_1, \ldots, x_{m+n-1}) \\ = f(x_1, \ldots, x_{i-1}, g(x_i, \ldots, x_{i+m-1}), x_{i+m}, \ldots)$$

In the endomorphism operad $\mathcal{E}nd_X$, there are easily discovered relations involving iterated $\circ_i$-operations and the symmetric group $\Sigma_n$ actions on the $X^n$s. For example,

$$(f \circ_i g) \circ_j h = f \circ_i (g \circ_{j-i+1} h) \\ \text{for } i \leq j \leq i + m - 1$$

if $g$ is a function of $m$ variables, since only the name of the position for the insertion is changed.

An operad $(\mathcal{O}, \circ_i)$ consists of a collection $\{\mathcal{O}(n)\}_{n\geq 1}$ of objects and maps $\circ_i : \mathcal{O}(n) \times \mathcal{O}(m) \to \mathcal{O}(n + m - 1)$ for $m, n \geq 1$ and $i \leq n$ satisfying the relations manifest in the example $\mathcal{E}nd_X$.

May's original definition corresponds to simultaneous insertions into all possible positions of inputs into $f \in Map(X^n, X)$. In most examples, the structures are "manifest" without appeal to the technical definitions.

It helps to see graphic examples of operads, particularly ones relevant for physics. Two kinds that are particularly important are the tree operads and the little disks (or cubes) operads.

Let $\mathcal{T}(n)$ be the set of planar trees with one root and $n$ leaves labeled (arbitrarily) 1 through $n$. The collection $\mathcal{T} = \{\mathcal{T}(n)\}_{n\geq 1}$ of sets of trees forms an operad by grafting the root of $g$ to the leaf of $f$ labeled $i$, as in **Figure 1**, where the leaves are assumed labeled in order from left to right. **Figure 1** can be interpreted as portraying the $\circ_4$ result of inserting a 3-linear operation into a 5-linear one.

The little $n$-disks operad $\mathcal{D}_n = \{\mathcal{D}_n(j)\}_{j\geq 1}$ where $\mathcal{D}_n(j)$ consists of an ordered collection of $j$ $n$-disks

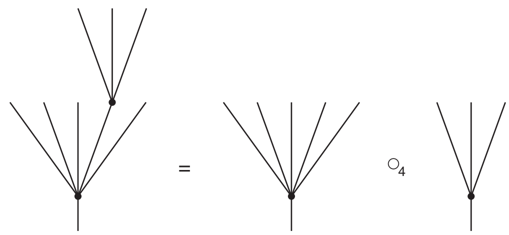

**Figure 1** Grafting with the leaves numbered from left to right.

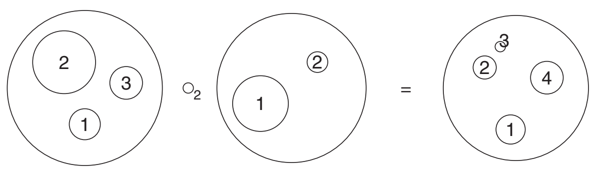

**Figure 2** The little 2-disks operad.

embedded in the standard $n$-dimensional unit disk $D^n$ with disjoint interiors, the embedding being of the form $az + b$ with $0 < a \in \mathbb{R}$. The operations are given as indicated in Figure 2.

Just as group theory without representations is rather sterile, so are operads best appreciated by their representations known as (varieties of) algebras, especially algebras with higher homotopies.

An algebra $A$ over an operad $\mathfrak{P}$ "is" a map of operad $\mathfrak{P} \to \mathcal{E}nd_A$. This is just a compact way of saying that an algebra $A$ has a coherent system of maps $\mathfrak{P}(n) \times A^n \to A$. Much of this article will speak in terms of such algebras with the corresponding operad being understood.

## Operads in Homotopy Theory

A major motivation for the development of operads was the desire to have a homotopy-invariant characterization of based loop spaces and iterated loop spaces. Precisely such coherent systems of higher homotopies provided the answers. For based loop spaces, the operad in question $\mathcal{K} = \{K_n\}_{n\geq 1}$ consists of the polytopes known as "associahedra." The usual product of based loops is only homotopy associative.

If we fix a specific associating homotopy and consider the five ways of parenthesizing the product of four loops, there results a pentagon whose edges correspond to a path of loops (Figure 3).

From the leftmost vertex to the rightmost, consider the two paths of loops across the top or around the bottom. By further adjustment of parameters, the pentagon can be filled in by a family of such paths.

The associahedron $K_n$ can be described as a convex polytope with one vertex for each way of associating $n$ ordered variables, that is, ways of inserting parentheses in a meaningful way in a word

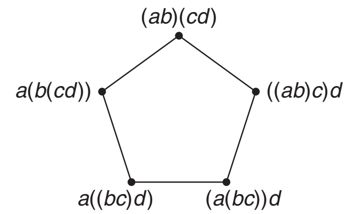

**Figure 3** The associahedron $K_4$.

of $n$ letters. The edges correspond to a single application of an associating homotopy. More generally, the cellular structure of the associahedra is well described by planar rooted trees, the vertices corresponding to binary trees and so forth (see Figure 4).

For $K_5$, see Figure 5 or a rotatable image available at http://igd.univ-lyon1.fr/~ chapoton/stasheff.html. The facets are all products of two associahedra of lower dimension and specific imbeddings can be given to play the role of the $\circ_i$ operations as in an operad.

An $A_\infty$-space is a space $Y$ which admits a coherent family of maps

$$m_n : K_n \times Y^n \to Y$$

so that they make $Y$ an algebra over the operad (without $\Sigma_n$-actions) $\mathcal{K} = \{K_n\}_{n\geq 1}$.

The main result by Stasheff is: A connected space Y (of the homotopy type of a CW-complex) has the homotopy type of a based loop space $\Omega X$ for some X if and only if Y is an $A_\infty$-space.

Homotopy characterization of iterated loop spaces $\Omega^n X_n$ for some space $X_n$ required the full power of the theory of operads with the symmetries.

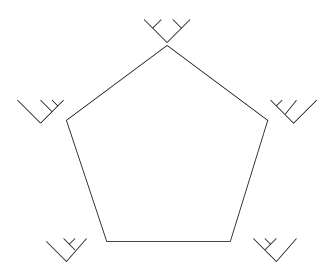

**Figure 4** $K_4$ with vertices labeled by trees.

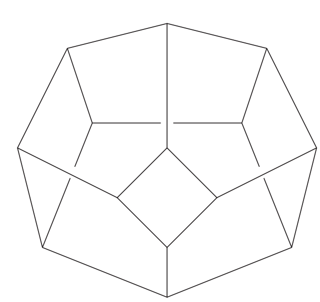

**Figure 5** The associahedron $K_5$.

An early motivation for the invention of a theory of operads was the consideration of infinite loop spaces, that is, a sequence of spaces $X_n$ such that each $X_n$ is homotopy equivalent to $\Omega X_{n+1}$.

Although introduced originally in the category of topological spaces, operads were available almost immediately for differential graded (dg) vector spaces, also known as chain complexes. In physics, the differential is often called a BRST operator, a term that should be reserved for a special kind of dg algebra, see below.

## Operads in Algebra

The $\circ_i$ notation first appeared in Gerstenhaber's study of the algebraic structure of the Hochschild cohomology of an associative algebra, about the same time as the construction of the associahedra where the operations were given in a less convenient notation. Recall the Hochschild cohomology of an associative algebra $A$ is the homology of the complex $\mathrm{Hom}(A^{\otimes n}, A)$ with the coboundary given as follows (all signs below are indicated as $\pm$, any of the standard references will specify conventions and signs): for $f \in \mathrm{Hom}(A^{\otimes n}, A)$ and $g \in \mathrm{Hom}(A^{\otimes m}, A)$ let

$$f \circ g = \Sigma_1^n \pm f \circ_i g \qquad [1]$$

Gerstenhaber then defines his bracket as $[f, g] = f \circ g \pm g \circ f$. With hindsight, he realized that the Hochschild coboundary can be written as

$$\delta h = [m, h] \qquad [2]$$

where $m : A \otimes A \to A$ is the multiplication. Moreover, the associativity of $m$ is equivalent to

$$[m, m] = 0 \qquad [3]$$

### $A_\infty$-Algebras

In the setting of graded vector spaces $V = \oplus_{r \in \mathbb{Z}} V^r$, there are two conventions for defining $A_\infty$-algebras, which differ by a shift in grading. We adopt the physics convention so that $A$ here is the suspension of that considered in the original papers. The cellular chains of the associahedra form the $A_\infty$-operad, providing the following definition.

**Definition 1** $A_\infty$-algebra (Strong homotopy associative algebra). Let $A$ be a $\mathbb{Z}$-graded vector space $A = \oplus_{r \in \mathbb{Z}} A^r$ and suppose that there exists a collection of degree 1 multilinear maps

$$\mathfrak{m} := \{m_k : A^{\otimes k} \to A\}_{k \geq 1}$$

$(A, \mathfrak{m})$ is called an $A_\infty$-algebra when the multilinear maps $m_k$ satisfy the following relations:

$$\sum_{p+q=n+1} \sum_{i=1}^{p} \pm m_p \circ_i m_q = 0 \qquad [4]$$

with an appropriate set of signs for $n \geq 1$.

A weak $A_\infty$-algebra consists of a collection of degree 1 multilinear maps

$$\mathfrak{m} := \{m_k : A^{\otimes k} \to A\}_{k \geq 0}$$

satisfying the above relations, but for $n \geq 0$ and in particular with $k, l \geq 0$.

**Remark 1** The "weak" version is fairly new, inspired by physics, where $m_0 : \mathbb{C} \to A$, regarded as an element $m_0(1) \in A$, is related to what physicists refer to as a "background." The augmented relation then implies that $m_0(1)$ is a cycle, but $m_1 m_1$ need no longer be 0, rather

$$m_1 m_1 = \pm\, m_2(m_0 \otimes 1) \pm\, m_2(1 \otimes m_0) \qquad [5]$$

Just as associativity was captured by the equation $[m, m] = 0$, so the defining relations of the definition of an $A_\infty$-algebra are captured by

$$[\mathfrak{m}, \mathfrak{m}] = 0 \qquad [6]$$

Decades later it was realized that considering $T^c A = \Sigma A^{\otimes n}$ as a coalgebra with

$$\Delta(a_1 \otimes \cdots \otimes a_n) = \Sigma_{p+q} \pm (a_1 \otimes \cdots \otimes a_p) \otimes (a_{p+1} \otimes \cdots \otimes a_n)$$

we then have an isomorphism

$$\Sigma \mathrm{Hom}(A^{\otimes n}, A) \simeq \mathrm{Coder}(T^c A)$$

Here Coder is the space of all coderivations of $T^c A$. The Gerstenhaber bracket is indeed the "intrinsic" commutator bracket of coderivations via the above isomorphism. As such, it satisfies a graded version of the Jacobi identity; after a shift in grading from the original one of Hochschild, the Hochschild cochain complex forms a dg Lie algebra.

### $L_\infty$-Algebras

Since an ordinary Lie algebra $\mathfrak{g}$ is regarded as ungraded, the defining bracket is regarded as skew-symmetric. For dg Lie algebras and $L_\infty$-algebras, we need graded symmetry, which refers to symmetry with signs determined by the grading. The basic operation is

$$\tau : x \otimes y \mapsto (-1)^{|x||y|} y \otimes x \qquad [7]$$

Also we adopt the convention that tensor products of graded functions or operators have the signs built

in; for example, $(f \otimes g)(x \otimes y) = (-1)^{|g||x|} f(x) \otimes g(y)$. By decomposing each permutation as a product of transpositions, there is then defined the sign of a permutation of $n$ graded elements, for example, for any $c_i \in V, 1 \le i \le n$, and any $\sigma \in \mathfrak{S}_n$, the permutation of $n$ graded elements is defined by

$$\sigma(c_1, \ldots, c_n) = (-1)^{\epsilon(\sigma)}(c_{\sigma(1)}, \ldots, c_{\sigma(n)}) \qquad [8]$$

The sign $(-1)^{\epsilon(\sigma)}$ is often referred to as the Koszul sign of the permutation.

**Definition 2** (Graded symmetry). A graded symmetric multilinear map of a graded vector space $V$ to itself is a linear map $f: V^{\otimes n} \to V$ such that for any $c_i \in V, 1 \le i \le n$, and any $\sigma \in \mathfrak{S}_n$ (the permutation group of $n$ elements), the relation

$$f(c_1, \ldots, c_n) = (-1)^{\epsilon(\sigma)} f(c_{\sigma(1)}, \ldots, c_{\sigma(n)}) \qquad [9]$$

holds.

**Definition 3** By a $(k, l)$-unshuffle of $c_1, \ldots, c_n$ with $n = k + l$ is meant a permutation $\sigma$ such that for $i < j \le k$, we have $\sigma(i) < \sigma(j)$ and similarly for $k < i < j \le k + l$. We denote the subset of $(k, l)$-unshuffles in $\mathfrak{S}_{k+l}$ by $\mathfrak{S}_{k,l}$ and by $\mathfrak{S}_{k+l=n}$, the union of the subsets $\mathfrak{S}_{k,l}$ with $k + l = n$. Similarly, a $(k_1, \ldots, k_i)$-unshuffle means a permutation $\sigma \in \mathfrak{S}_n$ with $n = k_1 + \cdots + k_i$ such that the order is preserved within each block of length $k_1, \ldots, k_i$. The subset of $\mathfrak{S}_n$ consisting of all such unshuffles we denote by $\mathfrak{S}_{k_1,\ldots,k_i}$.

**Definition 4** $L_\infty$-algebra (Strong homotopy Lie algebra). Let $L$ be a graded vector space and suppose that a collection of degree 1 graded symmetric linear maps $\mathfrak{l} := \{l_k : L^{\otimes k} \to L\}_{k \ge 1}$ is given. $(L, \mathfrak{l})$ is called an $L_\infty$-algebra iff the maps satisfy the following relations:

$$\sum_{\sigma \in \mathfrak{S}_{k+l=n}} (-1)^{\epsilon(\sigma)} l_{1+l}(l_k(c_{\sigma(1)}, \ldots, c_{\sigma(k)}), \\ [c_{\sigma(k+1)}, \ldots, c_{\sigma(n)}) = 0 \qquad [10]$$

for $n \ge 1$.

A weak $L_\infty$-algebra consists of a collection of degree 1 graded symmetric linear maps $\mathfrak{l} := \{l_k : L^{\otimes k} \to L\}_{l \ge 0}$ satisfying the above relations, but for $n \ge 0$ and with $k, l \ge 0$.

**Remark 2** The alternate definition in which the summation is over all permutations, rather than just unshuffles, requires the inclusion of appropriate coefficients involving factorials.

Just as an $A_\infty$-algebra can be described as a coderivation of $T^c A$, similarly an $L_\infty$-algebra $L$ can be described as a coderivation on $S^c L$, the symmetric subcoalgebra of $T^c A$.

The operad of Lie algebras was defined rather late, although it was earlier implicit in the work of Fred Cohen. It is defined as the homology $H_{n-1}(\mathrm{Config}(\mathbb{R}^2, n))$ for $n \ge 1$, where $\mathrm{Config}(\mathbb{R}^2, n)$ denotes the configuration space of ordered $n$-tuples of distinct points in $\mathbb{R}^2$. Equivalently, the configurations can be thought of as the centers of the little 2-disks. The open disks being contractible to their centers, this is a suboperad of the full homology $H_\bullet(\mathcal{D}_2)$.

Just as a Lie algebra is obtained from an associative algebra using the commutator as bracket and, inversely, a Lie algebra gives rise to its universal enveloping associative algebra, an $L_\infty$-algebra can be obtained from an $A_\infty$-algebra by $n$-variable analogs of commutators and there is a universal enveloping $A_\infty$-algebra of a given $L_\infty$-algebra.

### Open–Closed Homotopy Algebras

Open–closed string field theory suggests interaction between an $L_\infty$-algebra $\mathcal{H}_c$ and an $A_\infty$-algebra $\mathcal{H}_o$ including a strong homotopy representation of $\mathcal{H}_c$ on $\mathcal{H}_o$ by strong homotopy derivations. Here is the formal definition:

**Definition 5** Let $\mathcal{H} = \mathcal{H}_o \oplus \mathcal{H}_c$ be a graded vector space and $(\mathcal{H}_c, \mathfrak{l})$ be a weak $L_\infty$-algebra. Consider a collection of multilinear maps

$$\mathfrak{n} := \{n_{k,l} : (\mathcal{H}_o)^{\otimes k} \otimes (\mathcal{H}_c)^{\otimes l} \to \mathcal{H}_o\}_{k,l \ge 0}$$

each of which is graded symmetric on $(\mathcal{H}_c)^{\otimes l}$. We denote the collection also by $\mathfrak{n}$. We call $(\mathcal{H}, \mathfrak{n}, \mathfrak{l})$ a (partial) open-closed homotopy algebra (OCHA) when $\mathfrak{n}$ satisfies the following relations (up to some factorial coefficients):

$$0 = \sum_{k,l \ge 0} \sum_{p=0}^{m-k} \sum_{\sigma \in \mathfrak{S}_n} \pm n_{m+1-k,n-l}(o_1, \ldots, o_p, \\ n_{k,l}(o_{p+1}, \ldots, o_{p+k}; c_{\sigma(1)}, \ldots, c_{\sigma(l)}), \\ o_{p+k+1}, \ldots, o_m; c_{\sigma(l+1)}, \ldots, c_{\sigma(n)}) \\ + \sum_{\sigma \in \mathfrak{S}_n} \sum_{l=1}^{n} \pm n_{m,n+1-l}(o_1, \ldots, o_m; \\ l_l(c_{\sigma(1)}, \ldots, c_{\sigma(l)}), c_{\sigma(l+1)}, \ldots, c_{\sigma(n)}) \qquad [11]$$

### Other Algebras of Interest

The Hochschild complex also has a graded product (without invoking the shift) known as the cup product. Except for the signs and the grading, the bracket and the product satisfy the Leibniz rule of a Poisson algebra on the cohomology; the result is

axiomatized as a "Gerstenhaber algebra." However, on the cochain complex, the Lie bracket and the associative product are compatible only up to homotopy.

This naturally raises the issue of an operad for strong homotopy Gerstenhaber algebras. The operad $\mathcal{G}$ for Gerstenhaber algebras is the homology of the little disks operad, $H_\bullet(\mathcal{D}_2)$. But now we have choices: in addition to relaxing the Leibniz rule up to homotopy, the bracket could be relaxed to be part of an $L_\infty$-algebra and/or the product could be relaxed to be part of an $A_\infty$-algebra. The choice which is now known as the $G_\infty$-operad is defined in terms of a procedure which works for what are known as quadratic operads, indicating they have generators in $\mathcal{O}(2)$ and relations in $\mathcal{O}(3)$: the corresponding $\mathcal{O}_\infty$ has "dual" relations. For example, this gives the classical Koszul duality between Lie and commutative associative algebras. The $\mathcal{G}_\infty$-operad can also be described as the "minimal model" of $\mathcal{G}$ in the sense of Markl.

Another alternative is to consider just the "brace" operations, originally introduced by Kadeishvili and later independently by Getzler, but described in the Hochschild complex setting by Gerstenhaber–Voronov. Together with the cup product, these determine an operad denoted $\mathcal{HG}$ which acts on the Hochschild complex; there is an operad map from $\mathcal{G}_\infty$ to $\mathcal{HG}$, hence $\mathcal{G}_\infty$ also acts on the Hochschild complex. Finally, Tamarkin showed that $\mathcal{G}_\infty$ is quasi-isomorphic to the dg operad of singular chains on the little disks operad, thus providing one of several proofs of what had been a conjecture by Deligne.

Algebras with invariant inner products $<-,->$ are of considerable importance in mathematics and especially in mathematical physics; invariance means $<a, bc> = <ab, c>$ or $<a, [b, c]> = <[a, b], c>$ in, respectively, the associative or the Lie case (with appropriate signs in the graded case). Using the inner product, $n$-ary operations $A^{\otimes n} \to A$ can be converted to operations $A^{\otimes n+1} \to \mathbb{C}$ of which we can require cyclic symmetry. To handle such algebras, there is a notion of "cyclic operad." In terms of trees, the transition is to take a rooted tree and then regard the root edge as just another leaf. This point of view corresponds to an essential symmetry for particle interactions.

## Operads in Mathematical Physics

One reason for the explosive development of operad theory in the 1990s was the introduction of operadic structures in field theories, for example, conformal field theories (CFTs) and string field theories (SFTs). These operadic structures were directly related to the moduli spaces of Riemann surfaces with punctures or boundaries (or other decorations) in these physical theories.

Two special "higher-homotopy algebras" have been emphasized because they are particularly important in mathematical physics: $A_\infty$ for open-string field theory and $L_\infty$ for closed-string field theory and for deformation quantization. Open–closed string field theory combines $A_\infty$-algebra and $L_\infty$-algebra in a particular way known as an OCHA.

The operad for $L_\infty$-algebras is given a very nice and physically relevant geometric interpretation in terms of a real compactification of the moduli space of Riemann spheres with punctures, while for OCHAs, there is a real compactification of the moduli space of Riemann disks with punctures on the boundary or in the interior (bulk). Thus, this operad can be regarded as obtained from a moduli space of configurations of points (punctures) in the disk by compactifying the moduli spaces by adding boundary strata where two (or more) points (punctures) collide. Points on the boundary strata can be visualized as "bubble trees" of disks and/or spheres, see Figure 6. Alternatively, the little disks operad can be regarded as being obtained by "decorating" the points with little disks, while for OCHAs there is also a basic half-disk decorated with little disks in the bulk and little half-disks for the boundary points. The corresponding colored operad is Voronov's "Swiss-cheese operad." "Colored" refers to the fact that disks can be inserted into half-disks but not vice versa. Compare trees with two "colors" of edges with grafts restricted to ones which match colors.

### On-Shell versus Off-Shell

In cohomological physics, the "on-shell" states or observables are usually given by the cohomology with respect to an internal differential, which in physics is called the BRST differential or BRST operator, though originally this meant the Chevalley–Eilenberg differential associated to the action of the Lie algebra of

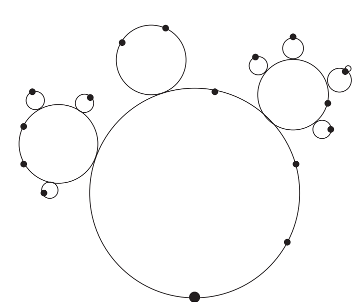

**Figure 6** Bubble tree for circle configurations.

gauge symmetries of a physical theory. The generators of the Chevalley–Eilenberg cochain complex are known as "ghosts". On-shell subspaces of algebras which are not closed under the product of the larger "off-shell" algebra are called "open" algebras by physicists. Quite generally, this situation gives rise to an algebra over an appropriate operad. A special case involves a differential graded algebra $A$ and a linear imbedding $H(A) \subset A$. The (co)homology is in turn a graded algebra (with 0 as differential), but inherits a higher-homotopy structure so that cohomology and original algebra are equivalent.

In the associative case, the inheritance is a result of Kadeishvili:

*Let* $(A,\ d)$ *be a differential graded associative or* $A_\infty$*-algebra, then the homology* $H(A)$ *inherits the structure of an* $A_\infty$*-algebra.*

Even if the original algebra $A$ is strictly associative, the inherited $A_\infty$-structure generally has nontrivial operations $m_i$.

Analogous results hold for $L_\infty$-algebras and others. It is the $L_\infty$-version that is relevant for closed-string field theory (CSFT). Zwiebach showed the quantum theory of covariant closed strings has an action defined in terms of an infinite chain of string field products. The genus-0 (tree level) string field algebra is an $L_\infty$-algebra inherited from the off-shell state space modeled by the Batalin–Vilkovisky (BV) construction. The higher-order brackets provide higher-order correlation or $n$-point functions which play a crucial role in the extended Lagrangian of the theory.

### Batalin–Fradkin–Vilkovisky and Batalin–Vilkovisky Constructions

The constructions of Batalin–Fradkin–Vilkovisky (BFV) for constrained Hamiltonian systems and of Batalin–Vilkovisky (BV) for Lagrangians with symmetries are important examples of $L_\infty$-structures derived from "open" algebra settings, though the $L_\infty$-structures were recognized quite a while after the constructions.

The BFV setting is that of a symplectic manifold $W$ with a family of constraints, that is, a family of functions $\phi^\alpha \in C^\infty(W)$. The constraints are called "first class" if the ideal they generate is closed under the Poisson bracket. The vector space spanned by the constraints will in general be an open algebra; the structure of the bracket is given by structure functions, rather than structure constants. The zero locus of all the constraints forms the constraint surface $V$. In the first-class case, the constraints are in involution and determine a foliation $\mathcal{F}$ of $V$. If the space of leaves $V/\mathcal{F}$ is a manifold, it would be considered the true physical space and the physical observables would be functions in $C^\infty(V/\mathcal{F})$. BFV construct a differential graded Poisson algebra such that the cohomology in degree 0 agrees with $C^\infty(V/\mathcal{F})$ when that makes sense and, in the regular case, the rest of the cohomology is that of the differential forms along the leaves of the foliation. The BFV differential is a deformation of the Chevalley–Eilenberg/BRST differential and can be constructed most efficiently by the same techniques used in proving Kadeishivili's inheritance theorem. Crucially, it is an inner derivation with respect to the Poisson bracket. After the fact, an $L_\infty$-structure can be observed in the extended algebra.

For a Lagrangian with symmetries, BV develop a similar construction, the main difference being that there is no Poisson bracket initially, but one is constructed by adjoining "anti-fields" as conjugate to the fields but of ghost degree –1 and the differential of an anti-field being the Euler–Lagrange expression for the corresponding field. Then, as in the Hamiltonian case, ghosts and anti-ghosts, etc. are adjoined and the construction proceeds in a parallel fashion.

### Deformation Quantization

Once algebras over an operad $\mathfrak{P}$ are considered, it is natural to consider also morphisms of such algebras over a fixed $\mathfrak{P}$.

From a homotopy point of view, the appropriate maps need not respect the operad structure strictly but only up to higher homotopy; indeed, there is a related operad to define such maps. For $L_\infty$-algebras, such $L_\infty$-maps play a key role in deformation quantization. That refers to deformation of the commutative multiplication of a Poisson algebra in the direction of the Poisson bracket; that is, to first order, the deformation is given by the bracket.

More generally, for any associative algebra $A$ with multiplication $m$, one considers formal deformations

$$a \star b = m(a,b) + tm_1(a,b) + t^2 m_2(a,b) + \cdots \quad [12]$$

where each $m_i \in \mathrm{Hom}(A \otimes A, A)$. The associativity of $\star$ provides a sequence of constraints on the $m_i$. In particular, $m_1$ must be a Hochschild cocycle and the obstruction to the existence of $m_2$ is a class in the Hochschild cohomology of degree 3. In fact, the primary obstruction is represented by $[m_1, m_1]$. If it is cohomologous to zero, that fact identifies candidates for $m_2$, that is,

$$[m_1, m_1] = \pm 2[m, m_2] \quad [13]$$

or, using the notation $d = [m,]$,

$$dm_2 - 1/2[m_1, m_1] = 0 \quad [14]$$

once known as the integrability equation but now, more frequently, as a Maurer–Cartan equation. For a Poisson algebra, the Poisson bracket is a Hochschild cocycle but in general a full deformation need not exist. However, for the algebra $A$ of smooth functions on a Poisson (e.g., symplectic) manifold $M$, Kontsevich showed that such a full formal deformation does exist.

The guiding philosophy is that deformations are controlled by a dg Lie or $L_\infty$-algebra $L$, unique up to $L_\infty$-homotopy equivalence. Therefore, the obstructions can be computed in any of the equivalent dg Lie algebras. Moreover, the structure of the obstructions is known sufficiently so that if there is an equivalent dg Lie algebra with $d$ in fact zero, then all the obstructions to deformation quantization vanish. The key to Kontsevich's proof was the construction of an $L_\infty$-map, inducing an isomorphism in cohomology, from the Lie algebra of polyvector fields on $\mathbb{R}^d$ with the Schouten bracket and $d=0$ to the Lie algebra of multidifferential operators on $A=C^\infty(\mathbb{R}^d)$ regarded as a subalgebra of the Hochschild cochain complex for $A$ with the Gerstenhaber bracket.

### BV Algebras

In addition to their construction of a differential graded Gerstenhaber algebra (a differential graded commutative algebra with a compatible Poisson bracket of degree 1), BV introduced a new mathematical structure, adding a second-order differential operator $\Delta$ relating the commutative product and the bracket. The operator $\Delta$ is a derivation of the bracket and of square zero. Moreover,

$$[a,b] = \Delta(ab) - \Delta(a)b \pm a\Delta(b) \qquad [15]$$

so that the failure of $\Delta$ to be a derivation of the product is given by the bracket.

The definition of a BV algebra is then a Gerstenhaber algebra with such an operator, though alternative definitions exist in which $\Delta$ and the product are primary and the bracket is defined by the above equation. From the operadic/higher-homotopy point of view, one can then go on to consider $BV_\infty$ algebras.

Recall that $A_\infty$-algebras and $L_\infty$-algebras (among others) can be characterized by an "inner" coderivation $d=[m,\ ]$ of square zero on an appropriate "standard" construction. In the context of BV algebras, where the bracket is more commonly written as {,}, the classical action is an element $S_0$ such that $\{S_0,S_0\}=0$ or, equivalently, $d=\{S_0,\ \}$ is of square zero. The quantum analog $S$ is a perturbation of $S_0$ and satisfies instead

$$\{S,S\} = \Delta S \qquad [16]$$

This was originally called the "master equation," but now is increasingly referred to as a "Maurer–Cartan" equation.

### Insertion Operads

There is another class of operads illustrated by trees (and more generally graphs) with a very different sort of "composition," namely insertion of one graph into another. The most directly relevant to physics is the kind of insertion used by Connes and Kreimer in their Hopf algebra constructed for renormalization of Feynman diagrams. For example, consider all finite graphs with exactly two external edges and internal numbered edges. Given two graphs $\Gamma_1,\Gamma_2$, define $\Gamma_1\circ_i\Gamma_2$ by cutting edge $i$ of $\Gamma_1$ and identifying the dangling edges with the two external edges of $\Gamma_2$.

For planar trees, yet another insertion operad is obtained by Chapoton, isolating a part of a structure due to Kontsevich, in which a small neighborhood of a vertex of the second planar tree is removed and the dangling edges are attached to a vertex of the first tree by entering through the angles between the edges at that vertex (Figure 7).

Inside the $\mathcal{HG}$-operad is the operad $\mathcal{B}race$ for an abstract brace algebra (forgetting the cup product), first described as such by Chapoton using the insertion operations of Kontsevich and Soibelman.

### $A_\infty$-Categories

Also of importance for applications to mathematical physics is the notion of an $A_\infty$-category, first made explicit by Fukaya and now playing a major role in string D-brane theory and homological mirror symmetry. The D-branes are the objects of the $A_\infty$-category and the open strings with boundaries on two (possibly equal) D-branes $B_1,B_2$ are the morphisms from $B_1$ to $B_2$. The operations $m_i$ are defined only on tuples $(a_1,\ldots,a_i)$ of "composable" morphisms (e.g., strings).

### PROPs

While an operad is an abstraction of a family of composable functions of $n$ variables for various $n$, a PROP is an abstraction of a family of functions in

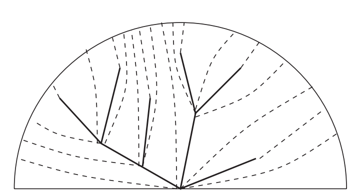

**Figure 7** Angles determined by edges with leaves extended to the semicircle.

Hom($A^{\otimes p}, A^{\otimes q}$) for all $p$ and $q$. Now the relevant images are graphs with $p$ input legs and $q$ output legs with composition being defined by grafting output legs of one graph to inputs of another. Feynman diagrams are the obvious example in physics or, in conformal field theory, tubular neighborhoods of such graphs, which is to say, Riemann surfaces with boundary circles: $p$ as inputs and $q$ as outputs.

# Operator Product Expansion in Quantum Field Theory

**H Osborn**, University of Cambridge, Cambridge, UK

## Introduction

The operator product expansion (OPE) provides an algebraic structure in quantum field theory. In a sense it supercedes or rather transcends the equal-time commutation relations, which provide the traditional starting point for the canonical quantization of any quantum field theory. The essential idea is that for any two local operator quantum fields at spacetime points $x_1, x_2$ their product may be expressed in terms of a series of other local quantum fields at a point $x$, which may be identified with $x_1$ or $x_2$, times c-number coefficient functions which depend on $x_1 - x_2$. The set of operators which may appear depends on the particular quantum field theory and must of course be in accord with any requirements of conserved quantum numbers. The coefficient functions depend on $x_1 - x_2$ in a fashion which depends on the dimensions of the various operators involved, at least up to renormalization group corrections. The most singular contributions are those for the operators appearing in the OPE with lowest scale dimension. From a phenomenological point of view, only the first few terms in the OPE are of relevance. However, theoretically, especially for conformal field theories, it is desirable to know the full expansion to all orders in powers of $x_1 - x_2$ in such a way that the operator product may

be replaced by the full expansion in appropriate correlation functions. We first discuss the OPE for free theories and then the interacting case.

## Free Field Theory

The OPE is most straightforward in free field theory when it almost reduces to a Taylor series expansion. For a simple free massless scalar field $\phi(x)$ then in four dimensions we may write

$$\phi(x)\phi(0) = \frac{C}{x^2} + :\phi(x)\phi(0): \qquad [1]$$

where :: denotes normal ordering (moving all annihilation operators to the right of creation operators) and $C$ is just a normalization numerical constant (for canonical normalization $C = 1/4\pi^2$). The $1/x^2$ term proportional to the identity operator reflects the leading singular behavior at short distances of $\phi(x)\phi(0)$, the power being determined by $\phi$ having dimension 1. For the normal-ordered term we may expand in terms of an infinite set of local operators by using the Taylor expansion

$$:\phi(x)\phi(0): = \sum_{n=0}^{\infty} \frac{1}{n!} x^{\mu_1} \cdots x^{\mu_n} :\partial_{\mu_1} \cdots \partial_{\mu_n}\phi(0)\phi(0): \qquad [2]$$

where the operator appearing in the $n$th term has dimension $n+2$. Manifestly at short distances only the leading terms are relevant. Equation [1] also provides a point splitting definition of the local composite operator $:\phi^2(0):$ in terms of limit of $\phi(x)\phi(0)$ as $x \to 0$ after subtraction of the singular $C/x^2$ term.

The OPE can be easily generalized to composite operators defined by normal ordering. For $:\phi^2:$ we have, by applying Wick's theorem,

$$:\phi^2(x)::\phi^2(0): = \frac{2C^2}{x^4} + \frac{4C}{x^2} :\phi(x)\phi(0): + :\phi^2(x)\phi^2(0): \qquad [3]$$

where Taylor series expansion may be applied to both $:\phi(x)\phi(0):$ and also $:\phi^2(x)\phi^2(0):$ to give an infinite sequence of local operators of increasing dimensions.

The expansion in terms of local operators may be reordered. For instance, from [1] we may write, using $\partial^2\phi = 0$,

$$\phi(x)\phi(0) = \frac{C}{x^2} + \left(1 + \tfrac{1}{2}x^\mu\partial_\mu + \tfrac{1}{4}x^\mu x^\nu \partial_\mu\partial_\nu + \tfrac{1}{16}x^2\partial^2\right) :\phi^2(0): - \tfrac{1}{2}x^\mu x^\nu T_{\mu\nu} + \mathrm{O}(x^3) \qquad [4]$$

where

$$T_{\mu\nu} = :\partial_\mu\phi\partial_\nu\phi: -\tfrac{1}{4}\eta_{\mu\nu} :\partial\phi\cdot\partial\phi: \qquad [5]$$

is the energy–momentum tensor. In [4], and also in a similar context subsequently, we define $\partial :\phi^2(0): = \partial_y :\phi^2(y):|_{y=0}$. The expansion [4] provides a point splitting definition of $T_{\mu\nu}$ and also demonstrates that many operators appearing in the OPE are expressible in terms of overall derivatives of lower-dimension operators. We may also note that without further input there is an ambiguity in the definition of $T_{\mu\nu}$ of the form

$$T_{\mu\nu} \sim T_{\mu\nu} + a(\partial_\mu\partial_\nu - \tfrac{1}{4}\eta_{\mu\nu}\partial^2) :\phi^2: \qquad [6]$$

In a conformal theory, however, we require $a = -1/6$.

## Interacting Theories

The OPE becomes an essential tool in the context of interacting quantum field theories. For renormalizable quantum field theories various results can be proved to all orders in the standard perturbative expansion and are naturally assumed to be properties of the complete theory. In interacting theories we may no longer use normal ordering to define composite operators which, in general, have anomalous dimensions. The coefficient functions appearing in the OPE also gain perturbative corrections but these are constrained by renormalization group (RG) Callan–Symanzik equations.

Again if we consider the simplest case of a massless scalar theory as above but now with a renormalized coupling constant $g$ the leading terms in the expansion of $\phi(x)\phi(0)$ are of the form (here we assume a $Z_2$ symmetry under $\phi \to -\phi$, otherwise the operator $\phi$ would be expected to appear in the OPE)

$$\phi(x)\phi(0) = \frac{C(g,\mu^2x^2)}{x^2} + D(g,\mu^2x^2)\phi^2(0) + \cdots \qquad [7]$$

where $\mu$ is an arbitrary renormalization scale. This arbitrariness is reflected in the RG equation

$$\left(\mu\frac{\partial}{\partial\mu} + \beta(g)\frac{\partial}{\partial g} + 2\gamma_\phi(g)\right) C(g,\mu^2x^2) = 0 \qquad [8]$$

At a fixed point $\beta(g_*) = 0$ this equation may be solved with an arbitrary choice of normalization to give $C(g_*,\mu^2x^2) = (\mu^2x^2)^{-\gamma_\phi(g_*)}$, which corresponds to the fields $\phi$ having a modified scale dimension $1 + \gamma_\phi(g_*)$. In a similar fashion the coefficient $D(g,\mu^2x^2)$ in [7] satisfies

$$\left(\mu\frac{\partial}{\partial\mu} + \beta(g)\frac{\partial}{\partial g} + 2\gamma_\phi(g) - \gamma_{\phi^2}(g)\right) \times D(g,\mu^2x^2) = 0 \qquad [9]$$

where it is necessary to introduce a new anomalous dimension function $\gamma_{\phi^2}(g)$ related to the composite

operator $\phi^2$. Although it is natural to label the operator as $\phi^2$ its definition in terms of the elementary field $\phi$ is essentially only as given in terms of the OPE [9]. At a fixed point again $D(g_*, \mu^2 x^2) = k(\mu^2 x^2)^{-\gamma_\phi(g_*)+(1/2)\gamma_{\phi^2}(g_*)}$, where the coefficient $k$ is determined by the scale of the three-point function $\langle\phi(x)\phi(y)\phi^2(0)\rangle$. In asymptotically free theories the RG equations show that at short distances the coefficient functions tend to those of free field theory but with calculable logarithmic corrections. More generally, for a set of operators $\{O_i\}$ the OPE has the form

$$O_i(x)O_j(0) \sim \frac{1}{(x^2)^p}\sum_k C_{ijk}(g,\mu^2x^2)O_k(0) \qquad [10]$$

where $p$ is determined by the free scale dimensions of the $O_i$ and

$$\begin{aligned}\left(\mu\frac{\partial}{\partial\mu}+\beta(g)\frac{\partial}{\partial g}\right)&C_{ijk}(g,\mu^2x^2)\\ =\sum_n\big(&\gamma_{kn}(g)C_{ijn}(g,\mu^2x^2)-\gamma_{in}(g)C_{njk}(g,\mu^2x^2)\\ &-\gamma_{jn}(g)C_{ink}(g,\mu^2x^2)\big)\end{aligned} \qquad [11]$$

with $\gamma_{in}(g)$ the anomalous dimension matrix arising from the mixing of composite operators.

An important aspect of the OPE is that the coefficient functions may be calculated perturbatively, essentially by applying the OPE in some suitable correlation function. Essentially the OPE provides a factorization between short-distance UV singularities and nonperturbative effects. In a Feynman graph the short distances in an operator product correspond to the large-momentum behavior and power-counting theorems allow a factorization up to calculable logarithmic corrections. A detailed analysis depends on the detailed technicalities of the proofs of renormalization to all orders of perturbation theory.

The coefficient functions in the OPE should be independent of any infrared or nonperturbative long-distance effects (such as confinement in QCD). However, the operators which appear in the OPE, such as $\phi^2$ above, may have nonzero expectation values which are absent to all orders in perturbation theory.

## Perturbative Example

The general considerations can be illustrated by considering a scalar field theory to lowest order in a perturbative expansion. We consider a four dimensional theory with a single scalar field and a potential $V(\phi) = \frac{1}{2}m^2\phi^2 + \frac{1}{24}g\phi^4$. Using dimensional regularization $m^2$, as well as $g$, is treated as a coupling with an associated $\beta$-function $\gamma_{\phi^2}(g)m^2$. With a mass term the operator $\phi^2$ mixes with the identity operator so that

$$\begin{aligned}(\mathcal{D}+\gamma_{\phi^2}(g))\langle\phi^2(0)\rangle &= -\gamma_{\phi^2 I}(g)m^2\\ \mathcal{D} = \mu\frac{\partial}{\partial\mu}+\beta(g)&\frac{\partial}{\partial g}+\gamma_{\phi^2}(g)m^2\frac{\partial}{\partial m^2}\end{aligned} \qquad [12]$$

where $\gamma_{\phi^2 I}$ reflects the mixing. At one loop order we have

$$\beta(g)=\frac{3g^2}{16\pi^2},\quad \gamma_{\phi^2}(g)=\frac{g}{16\pi^2},\quad \gamma_{\phi^2 I}(g)=\frac{1}{8\pi^2} \qquad [13]$$

and we may also set $\gamma_\phi(g)=0$. In this case in the operator product expansion (7) the coefficient $C$ also depends on $m^2x^2$ and the RG equations [8] and [9] are now modified to include the effects of mixing

$$\begin{aligned}&\mathcal{D}C(g,m^2x^2,\mu^2x^2) = m^2x^2\gamma_{\phi^2 I}(g)D(g,\mu^2x^2)\\ &(\mathcal{D}-\gamma_{\phi^2}(g))D(g,\mu^2x^2)=0\end{aligned} \qquad [14]$$

From lowest order perturbation theory with [13], and using [14] to include all orders in $g\ln\mu^2x^2$, we have in this approximation

$$\begin{aligned}C(g,&m^2x^2,\ \mu^2x^2)\\ &=\frac{1}{4\pi^2}-\frac{2m^2x^2}{g}\left(1+\frac{3g}{32\pi^2}\ln\mu^2x^2\right)^{2/3}\\ &\quad\times\left(\left(1+\frac{3g}{32\pi^2}\ln\mu^2x^2\right)^{-1/3}-1\right)\\ D(g,&\mu^2x^2)=\left(1+\frac{3g}{32\pi^2}\ln\mu^2x^2\right)^{1/3}\end{aligned} \qquad [15]$$

The operator product expansion then reproduces the small $x$ behavior of the two point function $\langle\phi(x)\phi(0)\rangle$ at one loop, expanding $C, D$ to first order in $g$, if we take

$$\langle\phi^2(0)\rangle = -\frac{m^2}{8\pi^2}\ln\frac{\mu}{m}+O(g) \qquad [16]$$

which is in accord with [12]. If $m^2<0$ the symmetry $\phi\leftrightarrow-\phi$ is broken and it is necessary to shift the field $\phi=\nu+f$, with $\nu^2=-6m^2/g$ and the field $f$ has a mass $m_f$ with $m_f^2=-2m^2$. The operator product expansion [7] with the same coefficient functions as in [15] remains valid. The two point function $\langle\phi(x)\phi(0)\rangle$, which includes a nonperturbative term $\nu^2$, is again reproduced for small $x$ at one loop now if

$$\langle\phi^2(0)\rangle = -\frac{6m^2}{g}-\frac{m^2}{2\pi^2}\ln\frac{\mu}{m_f}+O(g) \qquad [17]$$

but in this case it is necessary to expand $D(g,\mu^2x^2)$ to $O(g^2)$ as a consequence of the leading $1/g$ term in [17]. Note that both [16] and [17] contain the nonperturbative dependance on $\ln m$ and $\ln m_f$ which is present in the two point function.

## Conformal Field Theories

When the $\beta$-function vanishes and a quantum field theory enjoys conformal invariance the operator product expansion is a potentially convergent expansion. It is natural to restrict to conformal quasiprimary operators which do not mix with lower scale dimensions under conformal transformations. If we consider, for instance, two scalar operators $\phi$ with scale dimension $\Delta_\phi$ then the OPE has the generic form

$$\phi(x)\phi(0) = \frac{1}{x^{2\Delta_\phi}} + \sum_I C_{\phi\phi O^I} \frac{1}{(x^2)^{1/2}(2\Delta_\phi - \Delta^I + \ell)} \times C^{(\ell)}_{\Delta^I}(x,\partial)^{\mu_1,\ldots,\mu_\ell} O^I_{\mu_1,\ldots,\mu_\ell}(0) \qquad [18]$$

where there is a sum over quasiprimary operators $O^I_{\mu_1,\ldots,\mu_\ell}$ with scale dimension $\Delta^I$ and spin $\ell$, so they are symmetric traceless tensors of rank $\ell$. In the first term in [18] the coefficient is chosen to be 1 by a choice of normalization. The coefficients $C_{\phi\phi O^I}$, with a standard normalization for $O^I$, are then determined by the coefficients of the corresponding three-point functions involving $\phi\phi$ and $O^I$. In [18] $C^{(\ell)}_{\Delta^I}$ are differential operators which sum up the contributions of all derivatives or descendants of the quasiprimary operator $O^I$. They can be explicitly given in terms of an integral representation, for any spacetime dimension, where the scale is fixed by requiring for the leading term $C^{(\ell)}_{\Delta^I}(x,0)^{\mu_1,\ldots,\mu_\ell} = x^{\mu_1}\cdots x^{\mu_\ell}$ – traces. The spectrum of operators which appear is obviously a property of the particular conformal field theory.

## Ward Identities

If the theory has a symmetry with corresponding conserved currents then there are Ward identities which constrain the OPE of fields with the conserved current. For a current $J_{\mu a}$ then we have, in $d$ dimensions, the singular contribution in the OPE is given by

$$J_{\mu a}(x)O(0) \sim -\frac{1}{S_d}\frac{x_\mu}{(x^2)^{(1/2)d}} t_a O(0) \qquad [19]$$

where $t_a$ are a set of matrix generators corresponding to the symmetry acting on the fields $O$ and $S_d$ is the volume of the unit $(d-1)$-dimensional sphere, $S_4 = 2\pi^2$. For a conserved current there are no anomalous dimensions and the coefficient in [19], which depends on the normalization for the current $J_{\mu a}$, is chosen so that $[Q_a, O(0)] = -t_a O(0)$ with $Q_a$ the charge formed from $J_{\mu a}$. For the energy–momentum tensor the operator there is an analogous result. We consider the simpler case of a conformal theory when the energy–momentum tensor is both conserved and traceless and

$$T_{\mu\nu}(x)O(0) \sim A_{\mu\nu}(x)O(0) + B_{\mu\nu\lambda}(x)\partial^\lambda O(0) + \cdots \qquad [20]$$

where $A_{\mu\nu}(x) = \mathrm{O}(x^{-d})$ and $B_{\mu\nu\lambda}(x) = \mathrm{O}(x^{-d+1})$. As a distribution $A_{\mu\nu}(x)$ is ambiguous up to terms proportional to $\delta^d(x)$. If $\Delta$ is the scale dimension of $O$ and $s_{\mu\nu}$ are the Lorentz spin generators acting on $O$ the Ward identities then give

$$\begin{aligned}\partial^\mu A_{\mu\nu}(x) &= \left(\frac{\Delta}{d}\eta_{\nu\lambda} + C_{\nu\lambda} + \tfrac{1}{2}s_{\nu\lambda}\right)\partial^\lambda\delta^d(x)\\ A_{\mu\mu}(x) &= C_{\mu\mu}\delta^d(x)\\ \partial^\mu B_{\mu\nu\lambda}(x) &= -\eta_{\nu\lambda}\delta^d(x)\end{aligned} \qquad [21]$$

where $C_{\mu\nu}$ is a constant tensor reflecting the arbitrariness in $A_{\mu\nu}$, it is immaterial as far as Ward identities are concerned. We may choose

$$\frac{\Delta}{d}\eta_{\nu\lambda} + C_{\nu\lambda} = 0 \qquad [22]$$

(If desired, we might also take $A'_{\mu\nu}(x) = A_{\mu\nu}(x) + (1/2)s_{\mu\nu}\delta^d(x)$ in which case $\partial_\mu A'_{\mu\nu}(x) = 0, A'_{[\mu\nu]}(x) = (1/2)s_{\mu\nu}\delta^d(x)$ but such an antisymmetric piece seems unnatural). In general there is no unique form for $A_{\mu\nu}(x)$, as a consequence of the freedom of choice for $C_{\nu\lambda}$ in [21]. However, for a scalar field $O$ we must have, for $x \neq 0$,

$$\begin{aligned}A_{\mu\nu}(x) &= \frac{\Delta}{d-1}\frac{1}{S_d}\left(\eta_{\mu\nu} - d\frac{x_\mu x_\nu}{x^2}\right)\frac{1}{(x^2)^{(1/2)d}}\\ &= -\frac{\Delta}{(d-1)(d-2)}\frac{1}{S_d}\partial_\mu\partial_\nu\frac{1}{(x^2)^{(1/2)d-1}}\end{aligned} \qquad [23]$$

with the overall scale determined by [21].

For the operator product of the current $J_{\mu a}$ with itself there is an additional term proportional to the identity operator of the form

$$J_{\mu a}(x)J_{\nu b}(0) \sim C_J\delta_{ab}\left(\eta_{\mu\nu} - 2\frac{x_\mu x_\nu}{x^2}\right)\frac{1}{x^{2(d-1)}} \qquad [24]$$

where the coefficient $C_J$, which determines the scale of the two-point function for $J_{\mu a}$, is well defined since the normalization of the current is determined through the Ward identity. A similar result also holds for the operator product of the energy–momentum tensor with itself, with an overall coefficient $C_T$. In general, we may also write for the operator product of two scalar fields $O$:

$$O(x)O(0) \sim C_O\frac{1}{x^{2\Delta}} - \frac{C_O}{C_T S_d}\frac{d\Delta}{d-1}\frac{1}{(x^2)^{\Delta-(1/2)d+1}} \times x^\mu x^\nu T_{\mu\nu}(0) \qquad [25]$$

neglecting other contributions. The contribution of the energy–momentum tensor does not therefore introduce any new coefficient.

## Two Dimensions

In two dimensions the OPE plays an essential role in the discussion of conformal field theories. For a Euclidean metric it is natural to use complex variables $z$ and $\bar{z}$. The energy–momentum tensor in this case reduces to a chiral field $T(z)$ and its conjugate $\bar{T}(\bar{z})$. For the operator product with a chiral field $\phi(z)$ with scale dimension $\Delta$,

$$T(z)\phi(0) \sim \frac{\Delta}{z^2}\phi(0) + \frac{1}{z}\phi'(0) \qquad [26]$$

and, for the operator product of $T$ with itself,

$$T(z)T(0) \sim \frac{c}{2z^4} + \frac{2}{z^2}T(0) + \frac{1}{z}T'(0) \qquad [27]$$

Here $c$ is the Virasoro central charge, which plays a critical role in the discussion of two-dimensional conformal field theories, it is given by the two-point function which follows from [27], $\langle T(z)T(0)\rangle = (1/2)cz^{-4}$.

In simple rational conformal field theories the operators are organized into conformal blocks by the infinite-dimensional extended conformal symmetry in two dimensions. This allows the full spectrum of operators and their dimensions to be determined and in consequence complete results for the OPE to be found in many cases.

## Further Remarks

The OPE reflects the locality properties of quantum field theories and can be extended without difficulty to curved space backgrounds. For a product $\phi(x)\phi(0)$, the separation $x^2$ may be replaced by a biscalar at $x$ and 0 but it is necessary to include in the OPE contributions involving the background Riemann tensor as well as the operator fields present in flat space. There is also a generalization of the OPE for superfields on superspace.

At a fundamental level although the OPE can be derived to all orders in perturbation theory the contribution of nonperturbative effects such as instantons to the coefficients is not entirely clear. Issues of associativity have yet to be fully analyzed.

There are also important applications to the phemenonological analysis of QCD when assumptions about the OPE and saturation of sum rules can lead to results for the vacuum expectation value of gauge-invariant operators such as $F^{\mu\nu}F_{\mu\nu}$.

# Optical Caustics

**A Joets**, Université Paris-Sud, Orsay, France

## Introduction

Optical caustics are the bright forms created by the focalization, natural or artificial, of light (Figure 1). Special caustic points, called focuses, are produced by stigmatic optical systems in order to visualize objects. However, there are no special conditions for producing usual caustics. Every congruence of rays always generates a caustic, more or less intricate.

Caustics have been observed and described since a long time, tracing back to antiquity. The name itself was coined after the Greek root "kausticos" meaning burning and expressing that a high energy density is produced by ray focalization at a caustic point. Conceptually, they appeared in the literature as "evolutes," "envelopes," "centers of curvature," "focals," etc. However, these different approaches, often too restricted, were unable to clarify the

**Figure 1** Optical caustics may be produced by reflection (on window glasses) or by refraction (through the wavy surface of a swimming pool). Here the light source, the Sun, has some angular extension and the caustic appears somewhat blurred.

general properties of caustics, for instance, their classification in generic types. This difficult question was solved only recently in the framework of the singularity theory which appeared in the second half of the twentieth century (Whitney 1955, Thom 1956). Caustics are now understood as physical realizations of Lagrangian singularities, and they are often called optical singularities or optical catastrophes.

The aim of this introductory article is to show in which sense caustics can be understood as singularities, and to present their main properties.

## The Physical Phenomenon

Caustics are usually observed by interposing a screen on the ray trajectories and their trace in the screen forms a set of bright curves called "fold" ($A_2$). Across the fold, the number of rays passing through a given point jumps by $\pm 2$. Two fold curves may join at some point forming there a tip called cusp ($A_3$). A simple example is provided by the nephroid that one sees in a cup of coffee when the light is reflected off the cylindrical sides. In the three-dimensional (3D) space, the folds form surfaces and the cusps form curves (Figure 2). For particular positions of the screen, three other types of caustics may be observed: the swallowtail ($A_4$), the meeting point of two cusp lines; the elliptic umbilic ($D_4^-$), the meeting point of three cusp lines; and the hyperbolic umbilic ($D_4^+$) where a cusp line tangentially meets a fold surface (Figure 2). These five caustic types are generic in the sense that any other type of caustic point is unstable and decomposes into these generic caustic points under small perturbations. The perfect focus is an example of a nongeneric caustic point, obtained by imposing a special symmetry. The natural focusing of light, as in gravitational optics, produces only generic caustics. A caustic point is then a generalized focus. The caustic surface is a complex surface in the 3D physical space, generally self-intersecting and possessing singular lines $A_3$ ending at singular points $A_4, D_4^-$, or $D_4^+$.

At the scale of the wavelength of the light, the caustics have a more complex structure. Instead of well-defined surfaces, lines and points, one observes a system of interference fringes concentrated in the vicinity of the geometrical caustic. Each type of caustic point has its own diffraction pattern (also called diffraction catastrophe) (Figure 3). These interference systems are easily produced, for instance, by focusing a coherent laser beam by a

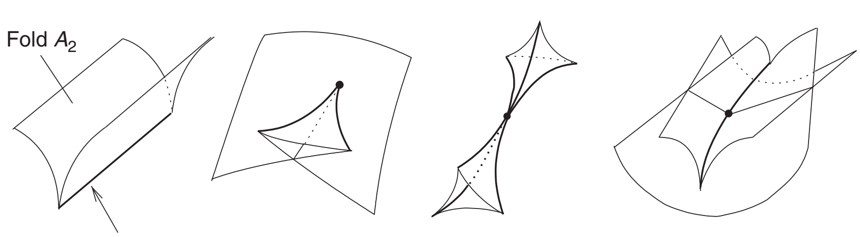

**Figure 2** The five generic types of caustics of the 3D space.

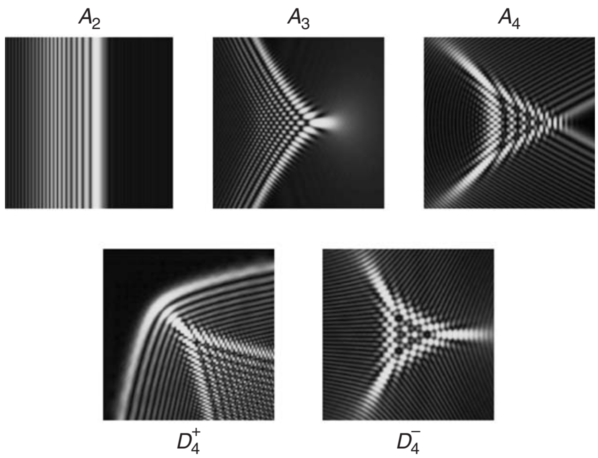

**Figure 3** Interference fringes produced by the five generic caustics of the 3D space (numerical simulation).

corrugated glass or by a water droplet. An important feature is revealed by Gouy's experiment, in which bright and dark fringes are inverted when the rays are forced to pass through a focus (Guillemin and Sternberg 1977). The experiment shows that the wave undergoes a phase shift of $\pi/2$ when the associated ray passes through a caustic point.

So, caustics are fundamental objects of both the geometrical optics and the wave optics.

## Modeling Caustics

Because of the presence of a caustic, a congruence of rays generally presents intersecting rays. At the points of intersection, the coordinates $q_1, q_2, q_3$ of the physical space $R^3$ are unable to distinguish the various intersecting rays and they do not constitute a convenient system of coordinates. It is then interesting to construct an abstract space in which the rays are represented by nonintersecting curves. The initial congruence is recovered by projecting the abstract space into the physical one. All the models use this type of construction in which the properties of the caustics are deduced from those of the projection.

### Caustics as Envelopes of Rays

In this geometrical modeling, each ray is labeled by two parameters $r_1, r_2$, for instance, the coordinates on the initial wave front $W$. A third coordinate $r_3$ specifies the points along the ray, for instance, by assigning their distance to $W$. Taken together, these three coordinates represent the congruence of rays, and define a 3D space, the source space $M = \{r_1, r_2, r_3\}$. By construction, the rays in $M$ do not intersect. The coordinates $(q_1, q_2, q_3)$ of the current point $P \in R^3$ along each ray depend differentiably on the coordinates $(r_1, r_2, r_3)$ and define a "projection" $f:(r_1, r_2, r_3) \mapsto (q_1, q_2, q_3)$ from the source space $M$ into the physical space $R^3$.

The caustic points correspond to the envelope of the rays. At a caustic point $P$, the energy density flowing along the rays becomes infinite, since the small volume delimited by neighboring rays is shrunk into a small surface at $P$. This behavior may be simply expressed with the help of the projection $f$: the rank rk of the derivative $Df$ is equal to 2 at the point representing $P$ in $M$. This motivates the following definition. Given a map $f: M \to N$, a point $x \in M$ is said to be critical (or singular) if the rank of the derivative $Df$ is less than the maximal possible value min(dim $M$, dim $N$). Here, $\dim M = \dim N = 3$, and a critical point is a point where rk $< 3$. The set $\Sigma \subset M$ of the critical points is called the singular set. The caustic $C$ is the image of the singular set: $C = f(\Sigma)$. One also says that the caustic points are the critical values of $f$.

In practice, the derivative $Df$ is expressed by the Jacobian matrix $J = \partial(q_1, q_2, q_3)/\partial(r_1, r_2, r_3)$ and the singular set $\Sigma$ is defined by solving the equation

$$\det(J) = 0 \qquad [1]$$

If this equation permits one to express explicitly one coordinate, say $r_3$, as a function of the other two, the caustic surface $C$ is found in parametric form: $q_1 = q_1(r_1, r_2, r_3(r_1, r_2))$, etc. For a homogeneous medium, equation [1] is of second degree in $r_3$ and the caustic is composed of two sheets which meet at the umbilic points $D_4$.

Equation [1] gives all caustic points independently of their nature, that is, it does not distinguish between $A_2$, $A_3$, $A_4$, $D_4^-$, and $D_4^+$. A refinement allows one to recognize different types of caustic points. One defines the Thom–Boardman class $\Sigma^i$ as the points in $M$ where $Df$ has a kernel of dimension $i$. Then one defines inductively the class $\Sigma^{i,\ldots,j,k}$ as the class $\Sigma^k$ of the restriction of $f$ to $\Sigma^{i,\ldots,j}$. Thus, $\Sigma^0$ represents the regular points (noncaustic points), $\Sigma^{1,0}$ the fold points $A_2$, $\Sigma^{1,1,0}$ the cusp points $A_3$, $\Sigma^{1,1,1,0}$ the swallow-tail points $A_4$, and $\Sigma^{2,0}$ the umbilics $D_4$ (hyperbolic or elliptic). Altogether, the classes $\Sigma^I$, $I \neq 0$, form the singular set $\Sigma$.

The Thom–Boardman classes constitute a simple and powerful tool for computing the structure of a caustic. Each class is obtained by canceling some functional determinants associated with the map $f$ or with its restriction to some class. However, the method presents the weakness of ignoring the special nature of a set of rays: its Lagrangian character. As a consequence, it is unable, for instance, to distinguish between $D_4^-$ and $D_4^+$.

### Caustics as Lagrangian Singularities

As for mechanics, the natural framework for geometrical optics is a phase space: the cotangent space $T^*R^3 = \{p_i, q_i\}$ of the configuration space $R^3 = \{q_i\}$. The phase space is characterized by its symplectic structure, that is, the differential 2-form $\omega = \sum_i \mathrm{d}p_i \wedge \mathrm{d}q_i$, which is nondegenerate and closed ($\mathrm{d}\omega = 0$).

A set of rays in the phase space is defined by specifying the wave vector (or momentum) $\boldsymbol{p}$ at each point $\boldsymbol{q}$ of the congruence. In the simple case where only one ray passes through each point, one has $\boldsymbol{p} = \nabla S$, where $S$ is the optical length $\int n\,\mathrm{d}s$ and $n$ the refractive index. In other words, $\boldsymbol{p}$ is the differential of the optical length. The wave vector $\boldsymbol{p}$ is tangent to the ray and orthogonal to the (geometrical) wave front $S = \text{const}$. The eikonal equation shows that its modulus is $n$. As a direct consequence of the relation $\boldsymbol{p} = \nabla S$, the symplectic form annihilates identically for these $\boldsymbol{p}$. However, in general, because of the presence of the caustics, one must not expect to have $\boldsymbol{p} = \nabla S$ for some function $S$. Nevertheless, it is possible to keep the more general property to annihilate $\omega$. This motivates the definition of a Lagrangian submanifold: a submanifold $L \subset T^*R^3$ of dimension 3 (that is, half of the dimension of the phase space) on which the symplectic form vanishes: $\omega|_L = 0$. Every congruence of rays is described by a Lagrangian submanifold. The Lagrangian submanifold plays the same role as the source space in the preceding section. The role of the projection $f$ is played by the natural projection $\pi$ from the phase space into the configuration space $\pi(\boldsymbol{p}, \boldsymbol{q}) = \boldsymbol{q}$, or more precisely to its restriction to $L$: $f = \pi|_L$. It is called a Lagrangian map (or Lagrangian projection) and it is again a map between two spaces of the same dimension (here 3). When $L$ is given by an embedding $\iota : L \to T^*R^3$, one has $f = \pi \circ \iota$. A caustic is then defined as the set of critical values of a Lagrangian map.

There exist two remarkable results showing that a Lagrangian submanifold may be described in terms of functions or of families of functions. As a consequence, caustics are not directly related to the singularities of maps but, more particularly, to the singularities of functions.

**",1,5,3,0,0pc,0pc,0pc,0pc>Generating function of a Lagrangian submanifold** The 3D Lagrangian submanifold $L \subset \{p_i, q_i\}$ is locally defined by three coordinates $p_\alpha (\alpha \in A)$ and $q_\beta (\beta \in B)$ depending on the three other ones $p_\beta$ and $q_\alpha$: $p_\alpha = p_\alpha(q_\alpha, p_\beta)$, $q_\beta = q_\beta(q_\alpha, p_\beta)$. One can show that this may be done in such a way that each conjugate pair $(q_i, p_i)$ gives exactly one independent variable and one dependent variable. Formally: $A \cup B = \{1, 2, 3\}$, $A \cap B = \emptyset$.

In fact, introducing the function $S(q_\alpha, p_\beta) = \int \langle p, \mathrm{d}q \rangle - \langle q_\beta, p_\beta \rangle (\langle , \rangle$ denotes the scalar product), the local equation for $L$ takes a more simple form:

$$q_\beta = -\frac{\partial S}{\partial p_\beta}, \qquad p_\alpha = \frac{\partial S}{\partial q_\alpha} \qquad [2]$$

The function $S$ is well defined, since, by the definition of a Lagrangian submanifold $\int \langle p, \mathrm{d}q \rangle$ is locally path independent: it depends only on its end points. $S$ is called a (local) generating function.

Formula [2] generalizes $\boldsymbol{p} = \nabla S$, to which it reduces when $B = \emptyset$, that is, for nonintersecting rays.

**",1,5,3,0,0pc,0pc,0pc,0pc>Generating family and optical catastrophes** Formula [2] may be rewritten in an interesting way. Taking the $|B|$ variables $p_\beta$ as internal parameters $x$ and $q = (q_\alpha, q_\beta)$ as external parameters, we construct a function $F$ of $x$ parametrized by $q$: $F(x, q) = S(q_\alpha, x) + \langle q_\beta, x \rangle$. Now the Lagrangian submanifold $L$ is defined by

$$L = \left\{ (q, p) : \exists x : \frac{\partial F}{\partial x} = 0,\ p = \frac{\partial F}{\partial q} \right\}$$

$F$ is called the generating family. The first equation $\partial F / \partial x = 0$ determines the rays passing through the fixed external parameter $\boldsymbol{q} \in R^3$. The second one distinguishes these rays according to their wave vector $\boldsymbol{p}$. Each ray corresponds to a critical point (i.e., an extremum) of $F$ considered as a function of $x$. At a caustic point, two infinitely close rays are converging and $F$ then presents a degenerate critical point. So the generating-family technique links the caustics to the theory of singularities of functions depending on some parameters, that is, to the catastrophe theory (Thom 1969). Caustics are also called optical catastrophes.

The generating families are not uniquely defined, even locally. In optics, one may always take for $F$ the equivalent family "optical length" $d$, considered as a function defined on the initial wave front $W$ (this is discussed in the following).

### Caustics as the Locus of Wave Front Singularities

There exists a remarkable duality linking rays and wave fronts. As a consequence, the caustic points (i.e., Lagrangian singularities) are related to singularities of wave fronts (i.e., Legendrian singularities). A typical wave front $W$ may possess only two types of singularities: cuspidal curves and swallow-tail points. During the motion of $W$, governed by the eikonal equation, the cuspidal curves generate surfaces, and

swallow tails generate curves. These surfaces are exactly the fold surfaces of the caustic $C$ and the curves are the cusp lines of $C$. The point singularities of the caustic, that is, the swallow tails and the umbilics, correspond to bifurcations of the instantaneous wave front, at certain moments of its motion.

### Caustics as Short Wave Asymptotic

The fine observation of the optical caustics shows that they never appear as the well-defined surfaces given by the geometrical optics, but rather as diffraction patterns concentrated around these surfaces. So wave optics is the natural framework to account for this fundamental feature. One exploits the fact that the wave number $k = 2\pi/\lambda$ ($\lambda$: wavelength of the light) is a large parameter. This short-wave approximation permits the use of powerful expansion techniques and clarifies the relation with the geometrical optics viewpoint, formally obtained for $k$ tending to infinity.

**The stationary phase** In the most simple model, the Huygens–Fresnel principle, the amplitude $U(P)$ of the optical field may be evaluated by adding the secondary disturbances emitted from the points $Q$ of some initial wave front $W$:

$$U(P) = c \iint_W \frac{\mathrm{e}^{ikd}}{d} G \, \mathrm{d}s \qquad [3]$$

where $d$ is the distance $QP$. $G$ is the inclination factor, a smooth function defined on $W$ and $c$ some prefactor. For simplicity, $G$ and $n$ (the refractive index) are assumed to be constant. Defining $a = cG/d$, formula [3] appears as an integral of the form $\int a(y)\mathrm{e}^{ik\phi(y)}\mathrm{d}y$. This type of integral may be evaluated for large $k$ by the method of stationary phase. The principal contributions are due to points where the phase $\phi$ is stationary: $\nabla\phi = 0$. For wave optics, $\phi$ is the length $PQ$, considered as a function of $Q$ and parametrized by $P$. The stationary condition means that $PQ$ is normal to $W$, that is, it represents a ray of geometrical optics. The function $PQ$ is a generating family in the sense of the discussion earlier.

If no stationary points exist, that is, if $P$ is in the shadow, the integral is $O(k^{-N})$ for any $N$. Otherwise, and if the critical points are not degenerate, the phase stationary method gives (Guillemin and Sternberg 1977):

$$U(P) = \frac{2\pi}{k} \sum_{\text{rays } PQ} \mathrm{e}^{(1-\sharp)\pi\mathrm{i}/2} \times \frac{a(Q)\mathrm{e}^{\mathrm{i}kd}}{|(1-\mu_1 d)(1-\mu_2 d)|^{1/2}} + O(k^{-2}) \qquad [4]$$

where $\mu_1^{-1}$ and $\mu_2^{-1}$ are the two principal radii of curvature at $Q \in W$, and $\sharp$ the number of caustic points (also called focal points) along the ray $PQ$.

In the stationary-phase approach, the caustic $C$, locus of centers of curvature of $W$, appears as an obstacle in constructing asymptotics, since formula [4] diverges when $d\mu_i \to 1$, that is, when $P$ tends to $C$. It is, nevertheless, remarkable that $C$ also appears explicitly when [4] is valid, via the $\mu_i$'s and $\sharp$. In particular, the term $\mathrm{e}^{-\sharp\mathrm{i}\pi/2}$, applied in the case of a focus ($\sharp = 2$), accounts for the phase shift of $\pi$ observed in Gouy's experiment.

**Asymptotics on caustics** Uniform asymptotic formulas, valid also on the caustic, need a more complex theoretical framework, for instance, Maslov's theory, presented here in a necessarily simplified version (see Maslov and Fedoriuk (1981) for more detail).

The starting point is the equation of wave optics, that is, the Helmholtz equation

$$(\Delta + k^2 n^2)U = 0 \qquad [5]$$

where the refractive index $n$ generally varies from point to point. For $k \to \infty$, one looks for an asymptotic solution in the (tentatively) form:

$$U(P) = \mathrm{e}^{\mathrm{i}kS(q_1,q_2,q_3)} \sum_{j=0}^{\infty} (\mathrm{i}k)^{-j} \varphi_j(q_1,q_2,q_3) \qquad [6]$$

Inserting this form in eqn [5] one obtains the eikonal equation (or characteristic equation) for the phase $S$:

$$(\nabla S)^2 = n^2$$

and an infinite series of equations for the amplitudes $\varphi_j$, called the transport equations. One knows that the Cauchy problem for the eikonal equation may be reduced to the integration of the corresponding Cauchy problem for the Hamilton system (or bicharacteristic system):

$$\frac{\mathrm{d}q}{\mathrm{d}t} = \frac{\partial H}{\partial p} = 2p, \qquad \frac{\mathrm{d}p}{\mathrm{d}t} = -\frac{\partial H}{\partial q} = \nabla n^2$$

where $H = \langle p, p \rangle - n^2$. Its solutions, the bicharacteristics $q(t,\xi)$, $p(t,\xi)$ are parametrized by the "time" $t$ and the 2D parameter $\xi$ parametrizing the points on the initial wave front $W$. The bicharacteristics form a 3D Lagrangian submanifold $L$ in the phase space $\{p_i, q_i\}$ and one recovers the preceding situation. Assuming $L$ to be simply connected, one defines a global phase function $S$ on $L$ by formula $S(t,\xi) = \int \langle p, \mathrm{d}q \rangle$.

In a domain $\Omega_j \subset L$ not containing the singular set and in which the coordinates $t, \xi$ are in a one-to-one correspondence with the physical coordinates, $S$

becomes a function of $q_i$. Using the transport equation, one finds the leading term of the asymptotic solution (with accuracy to $k^{-1}$) in the following form:

$$U(P) = (K(\Omega_j)\varphi)(q) = \sqrt{\left|\frac{d\sigma}{dq_i}\right|}e^{ikS(q_1,q_2,q_3)}\varphi(q_1,q_2,q_3) \qquad [7]$$

where $d\sigma$ and $dq_i$, respectively, represent the measures on the Lagrangian submanifold and on the physical space. The amplitude $\varphi$ depends on the initial conditions. Formula [7] defines a precanonical operator $K(\Omega_j)$. It has the same form as [4], with the same drawback to diverge near the singular set $\Sigma$, where $dq_i = 0$.

In a domain $\Omega_j$ containing the singular set, $L$ is locally parametrized by mixed coordinates $q_\alpha, p_\beta$. The basic idea is then, roughly speaking, to carry out a Fourier transform $F_k$ with respect to these $p_\beta$ (in fact, a variant of the usual Fourier transform, in which the parameter $k$ appears in the prefactor and in the phase term). This leads one to consider, instead of $\mathcal{L} = \Delta + k^2n^2$, the operator $\hat{\mathcal{L}} = F_k\mathcal{L}F_k^{-1}$, and instead of $U$, the unknown function $V = F_kU$. In this Fourier space, $V$ may be found in the same way as $U$ was found in the preceding case, with $S$ replaced here by the local generating function $S_j(q_\alpha, p_\beta) = S - \langle q_\beta, p_\beta\rangle$. Coming back to the real space by $F_k^{-1}$, one obtains (with the same accuracy):

$$U(P) = (K(\Omega_j)\varphi)(q) = F_k^{-1}\left[\sqrt{\left|\frac{d\sigma}{dp_\beta dq_\alpha}\right|}e^{ikS_j(q_\alpha,p_\beta)}\varphi(q_\alpha,p_\beta)\right] \qquad [8]$$

There is no divergence in this local solution. So local short-wave asymptotics may be found everywhere, even on the caustic where they have a more complex form than the form [6] or [7].

**Global asymptotics and Maslov's index** The global asymptotic solution is obtained by formally gluing the local solutions by a partition of unity $\Sigma e_j = 1$ subordinate to a covering $\{\Omega_j\}$ of $L$. However there is a difficulty. The representations of the same precanonical operator in different local coordinates $q_\alpha$, $p_\beta$, even not containing the singular set, agree only up to a constant multiplier $e^{i\pi m/2}$, where the integer $m$ is the number of negative eigenvalues of some matrix. One is led to multiply every precanonical operator by a convenient phase factor $e^{-i\pi\gamma/2}$, where $\gamma \in Z_4$ is called Maslov's index. The coherency of the phase factor in different domains is realized by using the important property of $\Sigma$ to be co-oriented. Thus, $\gamma$ counts the number of passages of an oriented path on $L$ from the negative side of $\Sigma$ to its positive side, minus the number of passages in the opposite sense. Maslov's index is locally constant and jumps by $\pm 1$ only across the singular set $\Sigma$. The global canonical operator is now formally defined as $K = \Sigma_j e^{-i\pi\gamma_j/2}K(\Omega_j)e_j$.

Finally, the canonical operator $K$ is well defined only if it is independent of the $\{\Omega_j\}$ and $e_j$ used for its definition. This possibility is expressed (in the case of a simply connected $L$) by the following property, intrinsically attached to $L$: the Maslov index cancels on every closed loop. So the only obstruction for global asymptotics is the nontriviality of the characteristic class defined by Maslov's index and not the caustic.

The central object of the caustic modeling is then the projection of the submanifold representing the rays ($M$ or $L$) into the physical space. The possibility to reduce this projection to some normal form is the key result for the local classification of caustics.

## Local Classification of Caustics

### Equivalence, Stability, and Genericity

In order to distinguish different types of singularities, one has to define an equivalence relation. Two Lagrangian maps $f_i : T^*M_i \supset L_i \to M_i$ $(i = 1, 2)$, are said to be Lagrange equivalent if there is a diffeomorphism $h : T^*M_1 \to T^*M_2$ preserving both the symplectic and the fiber structures, and sending $L_1$ to $L_2$. In fact, only the local problem of classification makes sense, and one considers, instead of Lagrangian maps, germs of Lagrangian maps. A map germ is a map locally defined, that is, defined in an infinitely small neighborhood around a point (depending on the germ). The notion of Lagrange equivalence is extended to the germs. A Lagrangian singularity is then the Lagrange equivalence class of a germ at a critical point. Each equivalence class represents a type of Lagrangian singularity, that is, a type of caustic point.

The example of the perfect focus point shows that there exist singularities which are totally unstable. In this sense, they correspond to idealized situations not physically realizable, and they have to be disregarded. Conversely, stable singularities resist under the action of small perturbations. They correspond to Lagrangian germs for which all neighboring germs are Lagrange equivalent (not necessarily at the same point, but near the point considered).

Now the important question is: do the stable germs represent the generality? In the best case, stable germs form a dense open set. This means that every germ may be approximated by stable germs. In this case, one says that the stable germs are generic.

Stability and genericity are disctinct notions. It turns out that they coincide for low values of the dimension $n$ of the “physical space” ($n < 6$), but they may disagree at higher dimensions.

### Classification of Stable Caustics

The fundamental result of the theory is the local classification of Lagrangian singularities (Arnol’d 1972). With the help of the generating families, the study of Lagrangian singularities is reduced to the study of singularities of families of functions. More precisely, at a singular point, every stable Lagragian map is equivalent to one of the following maps, given by their generating function $S$ and by their generating family $F$:

$$
\begin{aligned}
A_2: \quad & S = p_1^3 \\
& F = x^3 + q_1 x \\
A_3: \quad & S = \pm p_1^4 + q_2 p_1^2 \\
& F = \pm x^4 + q_1 x^2 + q_2 x \\
A_4: \quad & S = p_1^5 + q_2 p_1^3 + q_3 p_1^2 \\
& F = x^5 + q_1 x^3 + q_2 x^2 + q_3 x \\
D_4^{\pm}: \quad & S = p_1^3 \pm p_1 p_2^2 + q_3 p_1^2 \\
& F = x_1^2 x_2 \pm x_2^3 + q_1 x_2^2 + q_2 x_2 + q_3 x_1
\end{aligned}
$$

These polynomial functions are called normal forms. The stable singularities are generic. In other words, every other type of singularity is destroyed by infinitely small perturbations and gives a set of singularities belonging to the list. The five generic caustics have been observed and experimentally studied in detail (Berry and Upstill 1980, Nye 1999).

By inserting the normal forms $S$ in a short-wave asymptotic, one obtains the diffraction patterns associated with the five caustic types (**Figure 3**). They generalize the Airy function which corresponds to the fold singularity.

The normal forms describe at once the geometry of the caustics and the interference systems around them.

### Codimension, Corank, Multiplicity, and Index

Lagrangian singularities are also characterized by some numbers. They have a codimension $c$ equal to the difference between the dimension of the physical space and their dimension: $c(A_2) = 1$, $c(A_3) = 2$, $c(A_4) = c(D_4^{\pm}) = 3$. They have a corank ck, equal to the difference between the dimension of the space and the rank of the Lagrangian map: $\mathrm{ck}(A_2) = \mathrm{ck}(A_3) = \mathrm{ck}(A_4) = 1$, $\mathrm{ck}(D_4^{\pm}) = 2$. The corank is the number of internal parameters of the generating family $F$. They also have a multiplicity $\mu$, which is the number of nondegenerate critical points of $F$, that is, the number of rays coinciding at the singularity. In the 3D space, one has $\mu = c + 1$: $\mu(A_2) = 2$, $\mu(A_3) = 3$, $\mu(A_4) = \mu(D_4^{\pm}) = 4$.

Short-wave asymptotics near the caustic present remarkable scaling properties (Berry and Upstill 1980). In particular, the amplitude $|U(P)|$ increases like $k^{\delta}$ as $k \to \infty$. The number $\delta$ depends only on the type of the singularity and it is called the singularity index. The more “degenerate” the singularities, the larger the index, and then the brighter the caustic point: $\delta(A_2) = 1/6 < \delta(A_3) = 1/4 < \delta(A_4) = 3/10 < \delta(D_4^{\pm}) = 1/3$.

## Global Organization of Caustics

The global properties of caustics are less understood than the local ones. There is, nevertheless, an interesting result concerning specifically the caustics in the 3D space (Chekanov 1986). Given a Lagrangian map $f: L \to R^3$, the Euler characteristic $\chi(\Sigma)$ of the singular set $\Sigma \subset L$ and the number $\sharp D_4(-1/2)$ of umbilics of index –1/2 are related by the formula

$$\chi(\Sigma) + 2\sharp D_4(-1/2) = 0 \qquad [9]$$

At an umbilic point $T$, $\Sigma$ is locally a cone with vertex at $T$. The index is defined according to the relative positions of the following elements: the 2D plane $\Pi = \ker f$, the cusp lines $A_3 \subset \Sigma$ passing through $T$, and the characteristic line $l$ which represents the ray at $T$. If $l$ and $A_3$ are separated by $\Pi$, the index is equal to $+1/2$, and to $-1/2$ in the other case. The index of an elliptic umbilic is always equal to $-1/2$.

The validity of Chekanov’s formula [9] requires that $L$ lies on a hypersurface $E$ of the phase space, convex with respect to the wave vectors. The characteristics are the orthocomplements of $E$. In this framework, the singularities are called optical singularities, because such an $E$ is always defined in geometrical optics by the eikonal equation. All Lagrangian singularities can be realized as optical singularities. Chekanov’s formula has been experimentally checked (Joets and Ribotta 1996).

The Chekanov relation has an important consequence on the caustic bifurcations (also called metamorphoses or perestroikas), that is, the generic transformations modifying the topology of a caustic depending on one parameter. Among the 11 possible caustic bifurcations, considered as bifurcations of general Lagrangian singularities, four of them cannot be realized as bifurcations of optical Lagrangian singularities. So Chekanov’s relation reduces the number of optical metamorphoses to seven.

## Extensions

### Caustics in Spaces of Higher Dimension

The local classification of Lagrangian singularities has been extended in spaces of higher dimension. For $n=4$, in addition to the preceding ones, two new singularities appear: the butterfly $A_5$ and the parabolic umbilic $D_5$. For $n=5$, in addition to $A_6$ and $D_6^{\pm}$, one has a new type of umbilic: $E_6$. However, in higher dimensions, the classification becomes more complex. In addition to stable singularities, like those of the series $A_i$, $D_i$, $E_i$, one encounters unstable generic singularities which depend on arbitrary parameters (moduli). Despite this difficulty, there exists a classification of generic Lagrangian singularities up to the dimension $n=10$.

The Maslov index has been extended in spaces of higher dimension and has led to the discovery of invariants associated with particular types of singularities (Vassilyev 1988). These invariants control the number of some types of singularities. For instance, in dimension $n=4$, the number of $A_5$ (taking account of sign) is equal to zero.

### Symmetrical Caustics

Another extension consists in imposing some constraint, for instance, a symmetry (Janeczko and Roberts 1993). Symmetrical caustics are not merely the symmetrized usual caustics. Many of them result from the stabilization of unstable singularities of higher codimension by the symmetry. For example, in the 3D space, the butterfly $A_5$ is unstable, but the symmetrical butterfly is a generic singularity in the class of Lagrangian singularities having the mirror symmetry.

### Nonoptical Caustics

Caustics, as locus of focalization, are not restricted to the usual optics. They are also observed in electronic optics or in gravitational optics and the preceding results apply to these waves. They also appear in nonelectromagnetic waves, for instance, acoustic waves, seismic waves, etc. Propagation always generates caustics.

Optical caustics are now understood as Lagrangian singularities and, as singularities, their interest is not restricted to optics. They became indispensable for understanding other domains of mathematical physics, for instance, the variational calculus, the classical mechanics, the Hamilton–Jacobi equations, the control theory, the field theory, etc.

# Optimal Cloning of Quantum States

**M Keyl**, Università di Pavia, Pavia, Italy

## Introduction

According to the well-known "no-cloning theorem" (Wootters and Zurek 1982) perfect copying of quantum information is impossible, that is, there is no machine which takes a quantum system in an unknown state as input and produces two systems of the same kind, such that none of them is distinguishable from the input by a statistical experiment. In this qualitative form, however, the theorem is not very useful, because in the presence of noise classical information cannot be copied perfectly as well. Therefore, the crucial point is that even under ideal conditions the errors produced in the clones cannot be made arbitrarily small. The best we can hope for is to find an optimal cloning device which makes these errors as small as possible.

More generally, we can consider cloning devices, which take as input a certain number, $N$, of identically prepared systems, and produce a larger number, $M$, of systems as output. Again, the cloning task is to make the output state resemble as much as possible a state of $M$ systems all prepared in the same state as the inputs. This variant of the problem is of interest as a "quantum amplifier." It also has a better chance of reasonable success than a cloning device operating on single-input systems: in the limit of many-input systems, the device can make a good statistical estimate of the input density matrix and hence produce arbitrarily good clones.

### Figures of Merit

To get a precise mathematical description of the problem, let us consider a one-particle Hilbert space $\mathcal{H}$ (which is assumed to be finite dimensional, $\mathcal{H} = \mathbb{C}^d$, if nothing else is explicitly stated) and the algebras $\mathcal{B}(\mathcal{H}^{\otimes N}), \mathcal{B}(\mathcal{H}^{\otimes M})$ of (bounded) operators on the $N$-fold, respectively $M$-fold, tensor product of $\mathcal{H}$. A quantum operation which takes $N$ particles as input and produces $M$ output particles is then described, in the Heisenberg picture, by a completely positive, unital map (a completely positive, unital and normal map if $\mathcal{H}$ is infinite dimensional):

$$T : \mathcal{B}(\mathcal{H}^{\otimes M}) \to \mathcal{B}(\mathcal{H}^{\otimes N}) \quad [1]$$

while the Schrödinger picture representation is given in terms of the (pre-)dual of $T$, that is,

$$T_* : \mathcal{B}_*(\mathcal{H}^{\otimes N}) \to \mathcal{B}_*(\mathcal{H}^{\otimes M}) \quad [2]$$

where $\mathcal{B}_*(\,\cdot\,)$ denotes the space of trace-class operators. Hence, if $T$ operates on input systems in the (joint) state $\rho^{\otimes N}$, the output systems (i.e., the "clones") are in the state $T_*(\rho^{\otimes N})$. We will call each such $T$ a cloning map.

Now our aim is to find an operation $T$ such that the output state $T_*(\rho^{\otimes N})$ approximates the product state $\rho^{\otimes M}$ as well as possible. The quality of the approximation is measured by a distance function $\delta$ on the convex set $\mathcal{S}(\mathcal{H}^{\otimes M}) \subset \mathcal{B}_*(\mathcal{H}^{\otimes M})$ of density operators on $\mathcal{H}^{\otimes M}$ and, since it is impossible to minimize $\delta(T_*(\rho^{\otimes N}), \rho^{\otimes M})$ for all $\rho$ simultaneously, we are looking only for the worst case. Hence, the quality of a cloning map $T$ is measured by a figure of merit of the form

$$\Delta_{X,\delta}(T) = \sup_{\rho \in X} \delta\big(T_*(\rho^{\otimes N}), \rho^{\otimes M}\big) \quad [3]$$

Here $X \subset \mathcal{S}(\mathcal{H})$ is a set of "preferred" density operators whose role will be explained in the next section. An optimal cloning device is described by a cloning map $\hat{T}$ which minimizes $\Delta_{X,\delta}$, that is,

$$\Delta_{X,\delta}(\hat{T}) \le \Delta_{X,\delta}(T) \quad [4]$$

should hold for each cloning map $T$.

### The Preferred Set of States

The set $X \subset \mathcal{S}(\mathcal{H})$ of density operators introduced in the last equation describe *a priori* knowledge about the one-particle input state $\rho$; for example, if we want to clone only signal states $\rho_1, \ldots, \rho_k$ used to transmit classical information through a quantum channel, the choice for $X$ is $\{\rho_1, \ldots, \rho_k\}$. Other possibilities include: $X = S(\mathcal{H})$ if nothing is known about $\rho$, the set of pure states, the states in the "equatorial plane" of the Bloch sphere, or Gaussian states if $\mathcal{H}$ is infinite dimensional. Each different choice for $X$ leads to a different variant of the cloning problem, and we will summarize the most relevant cases treated in the literature in the section "Examples."

A different kind of *a priori* knowledge is *a priori* measures, that is, instead of knowing that all possible input states lie in a special set $X$, we know for each measurable set $X \subset \mathcal{S}(\mathcal{H})$ the probability $\mu(X)$ for $\rho \in X$. Such a situation typically arises when we are trying to clone states of systems which

originate from a source with known characteristics. In this case, we can use mean errors,

$$\bar{\Delta}_{\mu,\delta}(T) = \int_{\mathcal{S}(\mathcal{H})} \delta\big(T^*(\rho^{\otimes N}),\ \rho^{\otimes M}\big)\mu(\mathrm{d}\rho) \qquad [5]$$

as a figure of merit. Sometimes these are easier to compute than maximal errors as in eqn [3]. Often, however, $\Delta$ leads to stronger results than $\bar{\Delta}$, therefore we will concentrate our discussion on maximal rather than mean errors.

### The Distance Measure

The remaining freedom in eqn [3] is the distance measure $\delta$ and there are mainly two physically different choices: we can either check the quality of each clone separately or we can test, in addition, the correlations between output systems. The most common choice for a figure of merit for the first type is given by (where $\hat{\mathrm{tr}}_j$ denotes partial trace over all but the $j$th tensor factor)

$$\Delta_1(T) = \sup_{\rho\in X,j} \big|1 - \mathcal{F}\big(\hat{\mathrm{tr}}_j T_*(\rho^{\otimes N}),\ \rho\big)\big| \qquad [6]$$

Here $\mathcal{F}(\rho,\sigma)$ denotes the (quadratic) fidelity of $\rho$ and $\sigma$, that is,

$$\mathcal{F}(\rho,\sigma) = \mathrm{tr}\left(\left(\rho^{1/2}\sigma\rho^{1/2}\right)^{1/2}\right)^2 \qquad [7]$$

and the supremum is taken over all $\rho\in X$ and $j=1,\ldots,N$. $\Delta_1$ measures the worst one-particle error of the output state $T^*(\sigma^{\otimes N})$, and we will refer to it in the following as the local error. If we are interested in correlations too, we have to choose

$$\Delta_{\mathrm{all}}(T) = \sup_{\rho\in X} \big|1 - \mathcal{F}\big(T_*(\rho^{\otimes N}), \rho^{\otimes M}\big)\big| \qquad [8]$$

$\Delta_{\mathrm{all}}$ measures again a "worst-case" error, but now of the full output with respect to $M$ uncorrelated copies of the input $\rho$. We will call it the global error. Alternative figures of merit arise if we replace the fidelity in eqns [6] and [8] by other distance measures like the trace norm, the Hilbert–Schmidt norm, or the relative entropy. If $X$ consists only of pure states, the operations $T$ which minimize $\Delta_1$ or $\Delta_{\mathrm{all}}$ are usually not altered by such different choices. If $X$ is a set of mixed states, however, the correct choice is unclear and might depend on the precise physical context (there is, in particular, no reason to prefer fidelities).

## General Properties

Before we consider more special examples in the next section, let us discuss some general properties of the figure of merit $\Delta_{X,\delta}$ from eqn [3] and the corresponding optimization problem.

### Existence of Solutions

If the distance measure $\delta$ is continuous in the first argument, the optimization problem [4] has a solution, that is, optimal cloning machines exist: the set $\mathcal{T}$ of cloning maps [1] is compact and the quantity $\Delta_{X,\delta}$ is – as a supremum over continuous functions – lower-semicontinuous. Hence, the statement follows from the fact that a lower-semicontinuous function on a compact set always admits a minimizer.

This argument can be generalized to the infinite-dimensional case, if we choose the set $\mathcal{T}$ of allowed cloning maps more carefully (the restriction to normal channels proposed above is most probably not sufficient for this purpose) and if we equip it with an appropriate topology. The latter should be weak enough for $\mathcal{T}$ to be compact, and strong enough for $\Delta_{X,\delta}$ to be lower-semicontinuous. A typical choice is the weak*-topology arising from an embedding of $\mathcal{T}$ into the dual of a Banach space (such that we can apply the Banach–Alaoglu Theorem). Detailed studies in this direction are, however, not yet available.

### Covariant Cloning Maps

To solve the optimization problem [4] is a difficult and, in many cases, impossible task. However, it can be simplified significantly if $X$ and $\delta$ admit a nontrivial symmetry group. Hence, consider again a distance $\delta$ which is continuous and convex in its first argument and a closed subgroup $G$ of the group $U(d)$ of unitary operators on $\mathcal{H}=\mathbb{C}^d$, such that

$$UXU^* \subset X, \quad \delta\big(U^{\otimes M}\rho U^{\otimes M*}, U^{\otimes M}\sigma U^{\otimes M*}\big) = \delta(\rho,\sigma) \qquad [9]$$

hold for all $U\in G$ and $\rho,\sigma\in\mathcal{S}(\mathcal{H}^{\otimes M})$. Then $\Delta_{X,\delta}$ is invariant under the induced $G$ action on the set $\mathcal{T}$ of cloning maps, that is,

$$\Delta_{X,\delta}(\tau_U T) = \Delta_{X,\delta}(T) \quad \text{with } (\tau_U T)(A) = U^{\otimes N} T(U^{\otimes M*} A U^{\otimes M}) U^{\otimes N*} \qquad [10]$$

holds for all $U\in G$ and all $T\in\mathcal{T}$. Convexity of $\Delta_{X,\delta}$ in $T$ implies (with the Haar measure $\mu_{\mathrm{H}}$ on $G$)

$$\Delta_{X,\delta}(\bar{T}) \le \Delta_{X,\delta}(T), \quad \text{with } \bar{T} = \int_G \tau_U(T)\mu_{\mathrm{H}}(\mathrm{d}U) \qquad [11]$$

for all $T$. Hence, we can replace each cloning map by its group average $\bar{T}$ without sacrificing the

quality of the clones. This implies that $\bar{T}$ is optimal if $T$ is, and, since $\bar{T}$ is $G$-covariant,

$$\tau_U(\bar{T}) = \bar{T} \quad \forall U \in G \qquad [12]$$

we can conclude, together with the arguments from the last section, that the optimization problem [4] always admits covariant solutions. Similarly, we can show that permutation invariant (sometimes called "symmetric") solutions exist, that is, cloners which do not prefer a particular clone or a particular input system.

This is a very useful result, because the set of covariant and permutation-invariant $T$ is much smaller than the set of all cloning maps, and it can be parametrized in terms of irreducible representations of $G$ and the permutation group. In particular, the case $G = U(d)$ (such a $T$ is often called "universal" because it does not prefer any direction in the Hilbert space $\mathcal{H}$) leads to quite general solutions.

### Relationships with Quantum State Estimation

If a procedure to estimate the input state $\rho$ from a measurement on the $N$-fold system in the joint state $\rho^{\otimes N}$ is given, there is a simple way to produce a cloning machine: we just have to take the estimate $\hat{\rho}$ for the density matrix $\rho$ and prepare $M > N$ systems in the state $\hat{\rho}^{\otimes M}$. If $X$ is finite and estimation (which in this case is called hypothesis testing) is done in terms of a positive operator valued measure $(E_\sigma)_{\sigma \in X}$, $E_\sigma \in \mathcal{B}(\mathcal{H}^{\otimes N})$, the probability to get the estimate $\sigma \in X$ when the input is in the state $\rho^{\otimes N}$ is given by $\mathrm{tr}(E_\sigma \rho^{\otimes N})$. Hence, the cloning map derived from this estimation scheme is given by

$$\tilde{E}_*(\rho^{\otimes N}) = \sum_{\sigma \in X} \mathrm{tr}\left(E_\sigma \rho^{\otimes N}\right)\sigma^{\otimes M} \qquad [13]$$

A generalization to arbitrary $X$ is straightforward, but requires the use of measure theory. It is easy to see that the cloning map $\tilde{E}$ from eqn [13] is in general not optimal, in particular if $M$ is only slightly bigger than $N$. However, $\tilde{E}$ has the interesting feature that $\Delta_{X,\delta}(\tilde{E})$ depends only on the number of input systems, $N$, but not on the number of clones, $M$, we want to produce. This observation leads immediately to the conjecture that $\tilde{E}$ becomes optimal in the limit $M \to \infty$. A general proof is currently not available, in those cases, however, where optimal cloner and estimater can be explicitly calculated for all $N$ and $M$ (i.e., the cases treated in the sections "Universal pure-state cloning" and "Phase-covariant pure-state cloning") the conjecture is true. A more detailed discussion of this problem together with information about its current status can be found on the web at http://www.imaph.tu-bs.de/qi/problems/problems-html.

## Examples

In this section, we will discuss concrete examples that arise from different choices of the distance measure $\delta$ and the set $X$ of preferred states.

### Universal Pure-State Cloning

The most frequently discussed case arises if $X$ is the set of pure states, that is, the input states are pure, but otherwise unknown. Under this condition, it is sufficient to consider the symmetric part $\mathcal{H}_+^{\otimes N}$ of the tensor product $\mathcal{H}^{\otimes N}$, and only cloning maps $T : \mathcal{B}(\mathcal{H}^{\otimes M}) \to \mathcal{B}(\mathcal{H}_+^{\otimes N})$, because only this part affects the local or the global error. A complete solution for arbitrary $N$, $M$ and all finite-dimensional Hilbert spaces is available for $\Delta_{\mathrm{all}}$ in Werner (1998) and for $\Delta_1$ in Keyl and Werner (1999). Both cases admit the same (surprisingly simple) unique solution

$$\hat{T}_*(\sigma) = \frac{d[N]}{d[M]} S_M \left(\sigma \otimes \mathbb{1}^{\otimes(M-N)}\right) S_M \qquad [14]$$

where $S_M$ is the projection onto the symmetric tensor product $\mathcal{H}_+^{\otimes M}$ and $d[M]$ denotes the dimension of $\mathcal{H}_+^{\otimes M}$. To derive these results, the group-theoretic methods sketched in the section "Covariant cloning maps" are used. The fact that global and local figures of merit are minimized by the same cloning map is surprising and a special feature of pure-state cloning. It implies that correlations and entanglement between the clones does not matter at all.

### Phase-Covariant Pure-State Cloning

Consider a fixed basis $|j\rangle$, $j = 0, \ldots, d-1$, in $\mathcal{H}$ and let $X$ be the set of states given by

$$\psi = |0\rangle + \sum_{j=1}^{d-1} \mathrm{e}^{\mathrm{i}\phi_j}|j\rangle \qquad [15]$$

where the $\phi_j$ denote arbitrary phases. Obviously, this set is invariant under the set of all unitaries which are diagonal in the given basis (i.e., a maximal torus in $U(d)$). Using the methods outlined in the section "Covariant cloning maps," the corresponding cloning problem is (almost) completely solved in Buscemi *et al.* (2005). For arbitrary $d = \dim \mathcal{H}$, $N$ and all $M = N + dk$, with $k \in \mathbb{N}$ a

cloning map which minimizes global as well as local errors is given in terms of the unitary

$$\hat{U}:\mathcal{H}_+^{\otimes N}\to\mathcal{H}_+^{\otimes M},\hat{U}|n_0,\ldots,n_d\rangle = |n_0+k,\ldots,n_d+k\rangle \qquad [16]$$

where $|n_1,\ldots,n_d\rangle, n_j\in\mathbb{N}$, denotes the number basis of $\mathcal{H}^{\otimes N}$ associated with the distinguished basis $|j\rangle$ of $\mathcal{H}$.

### Cloning Finitely Many States

If $X$ is a finite set of pure states, a general solution is not available, but there are several important partial results. The easiest situation arises if the elements of $X$ are mutually orthogonal pure states. In this case, ideal cloning is possible in terms of an appropriately chosen unitary. If the states are linearly independent but nonorthogonal, ideal cloning is possible as well if we consider probabilistic cloning machines (Duan and Guo 1998); that is, there is a nonvanishing probability that the machine fails and does not produce any clones at all (this means $T$ is not unital). Optimal cloning (with deterministic operations) of two nonorthogonal qubit states $\rho_j=|\psi_j\rangle\langle\psi_j|$, $j=1,2$, is considered for all $N$, $M$ in (Bruß *et al.* (1998) and Chefles and Barnett (1999)) (using averaged global fidelity as the figure of merit). The crucial observation in this case is that the optimal clones are pure, that is, $T_*(\rho_j^{\otimes N})=|\Psi_j\rangle\langle\Psi_j|$ and that the $\Psi_j$ lie in the subspace spanned by the (unattainable) ideal clones $\psi_j^{\otimes M}$.

### Universal Mixed-State Cloning

$X=\mathcal{S}(\mathcal{H})$ means that absolutely nothing is known *a priori* about the input state $\rho$. If the distance measure $\delta$ is $U(d)$ and permutation invariant (which is the case for all possible choices discussed in the section "The distance measure") the analysis from the section "Covariant cloning maps" shows that a universal and symmetric minimizer exists. An explicit solution, however, is not known, and even the physically most appropriate choice for $\delta$ is unclear. In contrast to the pure-state case, this is a serious question, because the set of optimal cloners is, in this case, much more sensitive to changes in $\delta$. In particular, correlations among the clones become crucial, and it is very likely that local and global figures of merit lead to very different solutions. To emphasize this difference, an operation which minimizes only local errors is sometimes called "broadcasting," rather than cloning. A related problem with (at least) partial solutions ("purification") will be discussed in the section "Purification."

### Cloning of Gaussian States

If the Hilbert space is infinite dimensional, the restriction to a reasonable small set $X$ of preferred states is crucial, because otherwise the search for minimizers becomes hopeless. A physically relevant class with nice mathematical properties are Gaussian states and in particular coherent states. Cloning of the latter has been studied in Cerf *et al.* (2005) for the case $N=1$ (and $M$ arbitrary). As in the section "Covariant cloning maps," it can be shown that the search for optimal cloners can be restricted to those which are covariant with respect to phase space translations. This simplifies the problem significantly and leads to the result that the global error is minimized by Gaussian cloning maps, while in the local case the best cloner is non-Gaussian.

### Asymmetric Cloning

In all examples discussed up to now, we have considered symmetric cloners, that is, the quality of all clones is measured with equal weight. Alternatively, we can look for asymmetric cloners which produce clones with different quality and ask for the trade-off between them. This problem was first discussed in Cerf (2000) and later in Iblisdir *et al.* (2005). It can be regarded as a constraint optimization problem, where the error of the first $M'<M$ clones should be minimized under the constraint that the error of the rest is bounded by a fixed value. In Iblisdir *et al.* (2005), it is conjectured that for pure input states and local errors the optimal solution to this problem is given by

$$T_*(\sigma) = V^*\left(\sigma\ \otimes \mathbb{1}^{\otimes(M-N)}\right)V \qquad [17]$$

where $V$ is a linear combination of projections in the commutant of $\{U^{\otimes N}\,|\,U\in U(\mathcal{H})\}$. This conjecture is true (at least) for qubits in the case $1\to n+1$ and $1\to 1+n$.

## Related Problems

Instead of cloning, we can also try to approximate other impossible machines by channels which operate on multiple inputs. To this end, we only have to replace the figure of merit [6] by

$$\Delta_{1,\beta}(T) = \sup_{\rho\in X,j}\left|1-\mathcal{F}\left(\hat{\mathrm{tr}}_j T_*(\rho^{\otimes N}),\ \beta(\rho)\right)\right| \qquad [18]$$

where $\beta:\mathcal{S}(\mathcal{H})\to\mathcal{S}(\mathcal{H})$ is a (possibly nonlinear) functional which describes the task we want to approximate. The generalization $\Delta_{\mathrm{all},\beta}$ of $\Delta_{\mathrm{all}}$ can be given similarly. If $\beta$ has the appropriate continuity and symmetry properties, the discussion in the section "General properties" applies completely, that is, we can assume covariance and permutation

invariance, and we can consider operations which use state estimation in an intermediate step.

### Purification

Consider $N$ quantum systems, all originally prepared in the same pure state $\sigma$, and then subsequently exposed to the same (known) decoherence process, described by a depolarizing channel $R$. The task of purification is to produce $M$ output systems which approximate the original pure input state as well as possible. Hence, the corresponding figure of merit arises with $X = \{R(\sigma) \mid \sigma \text{ pure}\}$ and $\beta(\rho) = R^{-1}(\rho)$. This problem is discussed for qubits in Cirac *et al.* (1999), Keyl and Werner (2001) and D'Ariano *et al.* (2005). The optimal purifier can be given explicitly for all $N$, $M$ in terms of irreducible SU(2) representations. Surprisingly, it turns out that the output purity can be improved even if the number of outputs, $M$, is larger than the number of available input systems, $N$ (although $N$ should be large enough). If we measure purity in terms of local errors, it can be shown that, in the limit $N \to \infty$, perfectly purified qubits can be produced at an infinite rate (i.e., the number of output systems per input system can become infinite). However, we have to pay for this result with extremely large correlations between the output systems. Therefore, the global error does not disappear asymptotically, if we insist on a nonvanishing rate.

### Universal Not

"Universal not" (UNOT) is an operation which sends each pure state $\sigma$ to its orthocomplement. This is a positive but not a completely positive operation. Hence, it cannot be performed by any physical device. However, we can try to approximate it by a cloning map $T$ operating on $N$ input systems. The corresponding figure of merit [18] arises if $X$ is the set of pure states and $\beta(\rho) = \mathbb{1} - \rho$. In Bužek *et al.* (1999), it is shown that the optimal solution to this problem (for all $N$ and $M$) is to estimate and reprepare as described in the section "Relationships with quantum state estimation." Approximating UNOT is, therefore, significantly more difficult than (pure-state) cloning, where the optimal solution is always (for finite $M$) better than estimation.

# Optimal Transportation

**Y Brenier**, Université de Nice Sophia Antipolis, Nice, France

The purpose of this article is to introduce some of the main ideas of optimal transportation theory. A lot more can be found in Villani's book (Villani 2003), in a somewhat similar spirit. Supplementary information is also available in Ambrosio *et al.* (2005), Evans and Gangbo (1999), and Rüschendorf and Rachev (1990).

## Transportation Maps

Let us start by a rather abstract definition:

**Definition 1** Let $X$ and $Y$ be two topological spaces with Borel probability measures $\alpha$ and $\beta$, respectively. We say that a Borel map $T : X \to Y$ is a transportation map between $(X, \alpha)$ and $(Y, \beta)$ if, for each Borel subset $A$ of $Y$,

$$\int_{T(x)\in A} \alpha(\mathrm{d}x) = \int_{y\in A} \beta(\mathrm{d}y)$$

It is customary to say that $T$ pushes forward $\alpha$ to $\beta$, or to say that $\beta$ is the image of $\alpha$ by $T$. An abstract measure-theoretic result asserts that there is always such a transportation map $T$, as soon as $\alpha$ has no atom (i.e., the $\alpha$ measure of any point $x \in X$ is zero).

A more concrete situation is when $X = \bar{\Omega}_0, Y = \bar{\Omega}_1$, where $\Omega_0$ and $\Omega_1$ are two smooth bounded open subsets of the $d$-dimensional Euclidean space $\mathbf{R}^d$. In such a case, a classical result, due to Moser and improved by Dacorogna and Moser (1990), reads:

**Theorem 1** *Let $\Omega_0$ and $\Omega_1$ be two smooth bounded open sets in $\mathbf{R}^d$. Let $\rho_0 > 0$ and $\rho_1 > 0$ be two smooth functions on $\mathbf{R}^d$ such that*

$$\int_{\Omega_0} \rho_0(x)\mathrm{d}x = \int_{\Omega_1} \rho_1(x)\mathrm{d}x = 1$$

*Then there is a smooth transportation map $T$ between $(\bar{\Omega}_0, \rho_0(x)\mathrm{d}x)$ and $(\bar{\Omega}_1, \rho_0(y)\mathrm{d}y)$. Furthermore, $T$ is an orientation-preserving diffeomorphism and solves the Jacobian equation:*

$$\rho_1(T(x))\det(DT(x)) = \rho_0(x), \quad \forall x \in \Omega_0 \qquad [1]$$

## Transportation Maps with Convex Potentials

An important property of Moser's construction, which we did not state, is the possibility of prescribing the restriction of $T$ along the boundary $\partial\Omega_0$. If one does not care about this latter property, one can improve Theorem 1 as follows (Caffarelli 1992):

**Theorem 2** *Assume further that $\Omega_1$ is a uniformly strictly convex set. Then, there is a transportation map $T$ with a smooth convex potential, namely*

$$T(x) = D\Phi(x), \quad \forall x \in \Omega_0$$

*for some smooth convex function $\Phi$ defined on $\mathbf{R}^d$ and strictly convex on $\Omega_0$. In addition, among all Borel maps $T$ transporting $(\bar{\Omega}_0, \rho_0(x)\mathrm{d}x)$ to $(\bar{\Omega}_1, \rho_1(y)\mathrm{d}y)$, $D\Phi$ is the unique map that minimizes*

$$\inf_T \int_{\mathbf{R}^d} |T(x) - x|^2 \rho_0(x)\mathrm{d}x \qquad [2]$$

*where $|\cdot|$ denotes the Euclidean norm on $\mathbf{R}^d$.*

Because of its characterization, $T = D\Phi$ is often called the "optimal transportation map" with respect to the "transportation cost" [2]. Notice that, because of the Jacobian equation [1], $\Phi$ automatically is a classical solution to the Monge–Ampère equation:

$$\rho_1(D\Phi(x))\det(D^2\Phi(x)) = \rho_0(x), \quad \forall x \in \Omega_0 \qquad [3]$$

(The Monge–Ampère equation is a famous geometric PDE, related to the seeking of hypersurfaces with prescribed Gaussian curvature.) The main gain with respect to Moser's construction is the property that the optimal map $T$ has, at each $x \in \Omega_0$, a Jacobian matrix $DT(x) = D^2\Phi(x)$ which is a positive-definite symmetric matrix. This property has been first exploited by McCann (1997) and later by many authors (see Villani (2003), for many references) to prove a large series of geometric and functional inequalities. A very fine example can be found in Barthe (1998). Let us just consider, as an elementary illustration, a short and sharp proof of the isoperimetric inequality using the optimal transportation map.

## A Proof of the Isoperimetric Inequality Using Optimal Transportation Maps

Let us recall the isoperimetric inequality:

**Theorem 3** *Let $\Omega$ be a smooth bounded open subset in $\mathbf{R}^d$. Then*

$$|\partial\Omega| \geq \mathrm{d}|B_1|^{1/d}|\Omega|^{1-1/d}$$

*holds true where $B_1$ is the unit ball in $\mathbf{R}^d, |\Omega|$ and $|\partial\Omega|$, respectively, denote the $d$-dimensional volume of $\Omega$ and the $(d-1)$-dimensional Hausdorff measure of the boundary $\partial\Omega$. In addition, the inequality becomes an equality if and only if $\Omega$ is a ball.*

To prove this result, let us define densities:

$$\rho_0(x) = \frac{1}{|\Omega|}, \quad x \in \Omega$$
$$\rho_1(y) = \frac{1}{|B_1|}, \quad y \in B_1$$

and consider the associated optimal transportation map $D\Phi$ from $(\bar{\Omega}_0, \rho_0(x)\mathrm{d}x)$ to $(\bar{\Omega}_1, \rho_0(y)\mathrm{d}y)$. From the Monge–Ampère equation,

$$\rho_1(D\Phi(x))\det(D^2\Phi(x)) = \rho_0(x)$$

we get:

$$\det(D^2\Phi(x)) = \frac{|B_1|}{|\Omega|}, \quad x \in \Omega \qquad [4]$$

Since the range of $D\Phi$ on $\Omega$ is the unit ball $B_1$, we have

$$I = \int_{\partial\Omega} D\Phi(x) \cdot n(x)\mathrm{d}\sigma(x) \leq \int_{\partial\Omega} \mathrm{d}\sigma(x) = |\partial\Omega|$$

where $n(x)$ and $\mathrm{d}\sigma(x)$ respectively, denote the outward unit normal and the $(d-1)$-dimensional

Hausdorff measure along $\partial\Omega$. Using the divergence theorem, we also have:

$$I = \int_\Omega \Delta\Phi(x)\mathrm{d}x$$

where $\Delta\Phi(x) = \mathrm{trace}(D^2\Phi(x))$ is the Laplacian of $\Phi$. From the geometric mean inequality, we know that, for any symmetric matrix $A \geq 0$,

$$(\det A)^{1/d} \leq 1/d \text{ trace } (A)$$

holds true, with equality if and only if $A$ is equal to the identity matrix multiplied by a non-negative scalar factor. Thus,

$$I \geq d\int_\Omega (\det(D^2\Phi(x))^{1/d}\mathrm{d}x$$
$$= d|\Omega|^{1-1/d}|B_1|^{1/d}$$

(because of [4]). So, we have obtained the isoperimetric inequality:

$$|\partial\Omega| \geq \mathrm{d}|B_1|^{1/d}|\Omega|^{1-1/d}$$

Let us now consider the case when this inequality becomes an equality. Then, necessarily, for each $x \in \Omega, A = D^2\Phi(x)$ satisfies $\det A = (\mathrm{trace}(A)/d)^d$ and, therefore, must be the identity matrix multiplied by a scalar factor $\lambda > 0$, possibly depending on $x$. Because of [4], the determinant of $D^2\Phi(x)$ is constant over $\Omega$. Thus, $\lambda > 0$ must be constant. It follows that $D\Phi(x) = \lambda(x - a)$, for some point $a$ in $\boldsymbol{R}^d$. Therefore, $\Omega$ must be the ball centered at $a$ of radius $1/\lambda$.

## Monge's Optimal Transportation Problem

Theorem 2 is one of the numerous avatars of the so-called optimal transportation theory that goes back to Monge's mass transfer problem which addressed in 1781 the 'mémoire sur la théorie des déblais et des remblais' and was completely renewed by Kantorovich in the 1940s (see e.g., Rüschendorf and Rachev (1990) for instance). Let us quote a typical result, similar to Theorem 2, but without regularity assumptions on the data (see Brenier and Caffarelli (1992)):

**Theorem 4** *Let $\rho_0$ be a non-negative Lebesgue integrable function on $\boldsymbol{R}^d$, such that*

$$\int_{\boldsymbol{R}^d} \rho_0(x)\mathrm{d}x = 1$$

*Then for any Borel probability measure $\rho_1(\mathrm{d}y)$ with compact support on $\boldsymbol{R}^d$, there is a unique map $T$ transporting $\rho_0(x)\mathrm{d}x$ to $\rho_1(\mathrm{d}y)$, which minimizes*

$$\int_{\boldsymbol{R}^d} |T(x) - x|^2\rho_0(x)\mathrm{d}x$$

*where $|\cdot|$ denotes the Euclidean norm on $\boldsymbol{R}^d$. In addition, there is a Lipschitz continuous convex function $\Phi$ defined on $\boldsymbol{R}^d$ such that $T(x) = D\Phi(x)$ for $\rho_0$ almost every $x \in \boldsymbol{R}^d$, which implies:*

$$\int_{\boldsymbol{R}^d} f(D\Phi(x))\rho_0(x)\mathrm{d}x = \int_{\boldsymbol{R}^d} f(y)\rho_1(\mathrm{d}y)$$

*for all continuous functions $f$ on $\boldsymbol{R}^d$.*

Theorem 2, which can be interpreted as a regularity result with respect to Theorem 4, is the main output of Caffarelli's regularity theory for transportation maps with convex potentials (Caffarelli 1992). Caffarelli's analysis starts by a proof that $\Phi$ actually is a weak solution of the Monge–Ampère equation [3] in the sense of Alexandrov and is strictly convex. Then, Caffarelli shows that $D^2\Phi$ is Hölder continuous, as soon as $\rho_0$ and $\rho_1$ are Hölder continuous.

Notice that the convexity assumption for $\Omega_1$ is crucial to insure the regularity of the convex potential. Caffarelli provided counter-examples when $\Omega_1$ is made of two separate balls attached together by a sufficiently thin pipe.

Surprisingly enough, results such as Theorem 4 are related to concrete applications in, for example, astrophysics, image processing, etc. (Frisch *et al.* 2002, Haker and Tannenbaum 2003).

## The Kantorovich Optimal Transportation Problem

The Monge optimal transportation problem can be solved using the Kantorovich duality method, based on the key concept of "generalized transportation maps," also called "transportation plans" or "doubly stochastic measures." The abstract definition is:

**Definition 2** Let $X$ and $Y$ be two topological spaces with Borel probability measures $\alpha$ and $\beta$, respectively. We say that a Borel probability measure $\mu$ on $X \times Y$ is a generalized transportation map, or a transportation plan, if its marginals are, respectively, $\alpha$ and $\beta$, namely

$$\begin{aligned}\int_{x\in A, y\in Y} \mu(\mathrm{d}x, \mathrm{d}y) &= \int_{x\in A} \alpha(\mathrm{d}x) \\ \int_{x\in X, y\in B} \mu(\mathrm{d}x, \mathrm{d}y) &= \int_{y\in B} \beta(\mathrm{d}y)\end{aligned} \qquad [5]$$

for all Borel subsets $A$ and $B$ of $X$ and $Y$, respectively.

The Monge–Kantorovich (MK) optimal transportation problem amounts, given a "transportation

cost," that is, a continuous function $c: X \times Y \to \boldsymbol{R}$, to find a minimizer for

$$I_{\mathrm{MK}} = \inf_{\mu} \int c(x, y)\mu(\mathrm{d}x, \mathrm{d}y) \qquad [6]$$

where $\mu$ is subject to be a transportation plan between $(X, \alpha)$ and $(Y, \beta)$. Notice that this problem is convex (and can be seen as an infinite-dimensional linear program) and its dual problem can be easily computed (using, e.g., Rockafellar's theorem in convex analysis and assuming, for simplicity, that both $X$ and $Y$ are compact).

**Theorem 5** *We have*

$$I_{\mathrm{MK}} = \sup_{a,b} \left\{ \int a(x)\alpha(\mathrm{d}x) + \int b(y)\beta(\mathrm{d}y) \right\} \qquad [7]$$

*where $(a, b)$ is any pair of continuous functions, defined on X and Y, respectively, and subject to*:

$$a(x) + b(y) \le c(x, y), \quad \forall x \in X, \forall y \in Y$$

Of course, each transportation map T, in the sense of Definition 1, can be seen as a transportation plan $\mu$ in the Kantorovich framework, just by setting

$$\mu(\mathrm{d}x, \mathrm{d}y) = \delta(y - T(x))\alpha(\mathrm{d}x)$$

which means

$$\int_{x \in A,\, y \in B} \mu(\mathrm{d}x, \mathrm{d}y) = \int_{x \in A, T(x) \in B} \alpha(\mathrm{d}x)$$

for all Borel subsets $A$ and $B$ of $X$ and $Y$, respectively. Then, we have

$$\int c(x, y)\mu(\mathrm{d}x, \mathrm{d}y) = \int c(x, T(x))\alpha(\mathrm{d}x)$$

So, the MK problem can be seen as a "relaxed" version of the "classical" optimal transportation problem à *la* Monge:

$$I_{\mathrm{M}} = \inf_{T} \int c(x, T(x))\alpha(\mathrm{d}x) \qquad [8]$$

where $T$ is subject to be a transportation map between $(X, \alpha)$ and $(Y, \beta)$. Indeed, we have $I_{\mathrm{MK}} \le I_{\mathrm{M}}$. It turns out that, in many important situations, there is no gap between these two values, which makes the MK problem a perfectly convenient convex substitute for the original, nonconvex, Monge transportation problem. This is, in particular, the case of the situation considered in Theorem 4, when the cost function is just

$$c(x, y) = |x - y|^2$$

or, more generally, $c(x, y) = k(x - y)$, where $k$ is a uniformly strictly convex function. A typical result is:

**Theorem 5** *Let $\rho_0$ be a non-negative Lebesgue integrable function on $\boldsymbol{R}^d$, with unit integral, and $\rho_1(\mathrm{d}y)$ be a Borel probability measure with compact support on $\boldsymbol{R}^d$. Let $k$ be a uniformly strictly convex function on $\boldsymbol{R}^d$. Then the MK problem*

$$I_{\mathrm{MK}} = \inf_{\mu} \int k(y - x)\mu(\mathrm{d}x, \mathrm{d}y)$$

*where $\mu$ is subject to be a transportation plan between $\rho_0(x)\mathrm{d}x$ and $\rho_1(\mathrm{d}y)$ on $\boldsymbol{R}^d$, has a unique solution of form*

$$\mu(\mathrm{d}x, \mathrm{d}y) = \delta(y - T(x))\alpha(\mathrm{d}x)$$

*where $T$ is the unique minimizer of the Monge problem*:

$$I_{\mathrm{M}} = \inf_{T} \int k(T(x) - x)\rho_0(x)\mathrm{d}x$$

*among all transportation maps $T$ between $\rho_0(x)\mathrm{d}x$ and $\rho_1(\mathrm{d}y)$ on $\boldsymbol{R}^d$. In addition $I_{\mathrm{MK}} = I_{\mathrm{M}}$.*

**Proof for Theorem 5 (Sketch)** For simplicity, we assume that $\rho_0$ and $\rho_1$ are both compactly supported in a ball $B$ in $\boldsymbol{R}^d$ and we limit ourselves to the simplest cost function $k(x) = |x|^2/2$. We first denote by $M$ the set of all Borel regular probability measures $\nu$ on $B \times B$ having $\rho_0(x)\mathrm{d}x$ and $\rho_1(\mathrm{d}y)$ as marginals, which means

$$\int_{B \times B} f(x)\nu(\mathrm{d}x, \mathrm{d}y) = \int_B f(x)\rho_0(x)\mathrm{d}x$$
$$\int_{B \times B} f(y)\nu(\mathrm{d}x, \mathrm{d}y) = \int_B f(y)\rho_1(\mathrm{d}y)$$

for all continuous functions $f$ on $\boldsymbol{R}^d$. From Theorem 7, we deduce:

$$\max_{\nu \in M} \int_{B \times B} x \cdot y \nu(\mathrm{d}x, \mathrm{d}y) = \inf \int_B [\Phi(x)\rho_0(x) + \Psi(x)\rho_1(x)]\mathrm{d}x$$

where the infimum is taken over all pairs $(\Phi, \Psi)$ of continuous functions on $B$ satisfying

$$\Phi(x) + \Psi(y) \ge x \cdot y, \quad \forall x \in B, \forall y \in B$$

Then, it can be established that the infimum is attained by a pair $(\Phi, \Psi)$ such that $\Phi$ is the restriction of a Lipschitz continuous convex function defined on $\boldsymbol{R}^d$, and for $\rho_0(x)\mathrm{d}x$ almost every point of $\boldsymbol{R}^d$, $\Psi$ coincides with the Legendre–Fenchel transform of $\Phi$,

$$\mathrm{LF}(\Phi)(y) = \sup_{x \in \boldsymbol{R}^d} (x \cdot y - \Phi(x))$$

Moreover, if $\nu = \nu_{\text{opt}} \in M$ maximizes $\int_{B\times B} x \cdot y\nu(\mathrm{d}x, \mathrm{d}y)$, then

$$\Phi(x) + \Psi(y) = x \cdot y$$

holds for $\nu_{\text{opt}}$-almost every $(x, y) \in \boldsymbol{R}^d \times \boldsymbol{R}^d$. Using well-known properties of the Legendre–Fenchel transform in convex analysis, one deduces that $\nu_{\text{opt}}$ is necessarily of the form

$$\nu_{\text{opt}}(\mathrm{d}x, \mathrm{d}y) = \delta(y - D\Phi(x))\rho_0(x)\,\mathrm{d}x$$

which implies

$$\int_{\boldsymbol{R}^d\times\boldsymbol{R}^d} f(y)\nu_{\text{opt}}(\mathrm{d}x, \mathrm{d}y) = \int_{\boldsymbol{R}^d} f(D\Phi(x))\rho_0(x)\,\mathrm{d}x$$

for all continuous functions $f$ on $\boldsymbol{R}^d$ and achieves the proof since the second marginal of $\nu_{\text{opt}}$ is $\rho_1(\mathrm{d}y)$.

## The Wasserstein Distance

Optimal transportation theory is strongly related to the geometric analysis of probability measures. For simplicity, let us just consider the space Prob($B$) of all Borel probability measures $\rho$ supported by some fixed ball $B$ in $\boldsymbol{R}^d$. This space is compact for the weak topology of measures. An equivalent definition of this topology is provided by the distance $d$, naturally attached to the MK problem:

$$\mathrm{d}(\rho_0, \rho_1) = \inf_{\nu}\left(\int_{B\times B} |x - y|^2\mu(\mathrm{d}x, \mathrm{d}y)\right)^{1/2} \qquad [9]$$

where $\mu$ is subject to be a transportation plan between $\rho_0$ and $\rho_1$ on $B$. (Of course, more general convex functions $k$ can be used to define the cost function.) It has become popular to call this distance as Wasserstein distance (or its generalizations for various $k$). It turns out that Prob($B$) equipped with this distance has a formal Riemannian structure (Otto 2001, Ambrosio *et al.* 2005). For instance, given two probability measures $\rho_0(x)\mathrm{d}x$ and $\rho_1(x)\mathrm{d}x$, we can define a "shortest path" $t \to \rho(t, \cdot) \in$ Prob($B$) such that $\rho(0) = \rho_0$, $\rho(1) = \rho_1$, just by setting:

$$\rho(t, \mathrm{d}x) = \int_B \delta(a + (D\Phi(a) - a)t - x)\rho_0(a)\mathrm{d}a, \quad \forall t \in [0, 1]$$

where $D\Phi$ is the optimal transportation map between $\rho_0$ and $\rho_1$ on $B$. This idea, which is somewhat related to the geometric analysis of hydrodynamics and various concepts of generalized flows Arnol'd and Khesin 1998, Brenier, was successfully used by McCann (1997) and Otto (2001). In particular, the concept of convexity along these geodesic paths on Prob($B$) has been pointed out by McCann (1997) to be a crucial tool for new proofs of geometric and functional inequalities. Otto, and other contributors (see Ambrosio *et al.* (2005) for a comprehensive discussion), observed that many important parabolic or dissipative evolution PDEs can be described as "gradient flows" (or "steepest descent") of such functionals, with respect to the Wasserstein metric.

# Ordinary Special Functions

**W Van Assche**, Katholieke Universiteit Leuven, Leuven, Belgium

## Introduction

The exponential function, the logarithm, the trigonometric functions, and various other functions are often used in mathematics and physics. They are transcendental functions in the sense that they cannot be obtained by a finite number of operations as a solution of an algebraic (polynomial) equation. Typically, they are obtained by a Taylor series expansion. Many other higher transcendental functions arise in mathematical physics, often as solutions of differential equations. A precise knowledge of the behavior of such functions, their relation with other functions, addition, multiplication and composition properties, representations as an infinite series, or as an integral, often shed a lot of light onto the problem in which they arise. If they are sufficiently useful to a large audience, then they usually get a name and they will be called special functions. In what follows, we describe a few of these special functions of one variable, but clearly this is just a tip of the iceberg. Many other special functions exist and we refer to the classical tables of Abramowitz and Stegun (1964) and the Bateman manuscript project (Erdélyi *et al.* 1953–55) for more special functions. Nowadays, there have been numerous $q$-extensions of special functions (*see* q-Special Functions).

## Gamma and Beta Function

The gamma function is defined by

$$\Gamma(z) = \int_0^\infty t^{z-1} \mathrm{e}^{-t}\, \mathrm{d}t, \quad \Re z > 0. \qquad [1]$$

It satisfies the functional equation $\Gamma(z+1) = z\Gamma(z)$ and since $\Gamma(1) = 1$ we have $\Gamma(n+1) = n!$ for $n \in \mathbb{N}$. The gamma function therefore extends the factorial function for integers to complex numbers. The functional equation

$$\Gamma(z)\Gamma(1-z) = \frac{\pi}{\sin \pi z} \qquad [2]$$

allows to continue the gamma function analytically to $\Re z < 0$ and the gamma function becomes an analytic function in the complex plane, with a simple pole at 0 and at all the negative integers. The residue of $\Gamma(z)$ at $z = -n$ is equal to $(-1)^n/n!$. Legendre's duplication formula is

$$\Gamma(2z) = \frac{2^{2z-1}}{\sqrt{\pi}} \Gamma(z)\Gamma(z+1/2) \qquad [3]$$

from which one can obtain the special value $\Gamma(1/2) = \sqrt{\pi}$. Finally, two useful infinite product representations are

$$\Gamma(z) = \lim_{n\to\infty} \frac{n!n^z}{z(z+1)\cdots(z+n)}$$

and

$$\frac{1}{\Gamma(z)} = z\mathrm{e}^{\gamma z} \prod_{n=1}^{\infty} \left( (1+z/n)\mathrm{e}^{-z/n} \right)$$

where $\gamma$ is Euler's constant:

$$\gamma = \lim_{n\to\infty} \left( \sum_{k=1}^{n} \frac{1}{k} - \log n \right) = 0.577\,215\,664\,9\ldots \qquad [4]$$

The beta function is a function of two variables given by

$$\mathrm{B}(x,y) = \int_0^1 t^{x-1}(1-t)^{y-1}\, \mathrm{d}t$$
$$\Re x > 0, \Re y > 0 \qquad [5]$$

Clearly it satisfies $\mathrm{B}(x,y) = \mathrm{B}(y,x)$ and it is related to the gamma function by

$$\mathrm{B}(x,y) = \frac{\Gamma(x)\Gamma(y)}{\Gamma(x+y)} \qquad [6]$$

The gamma and beta function are quite useful in probability theory. One of the most common probability distributions on the positive real line is the gamma distribution

$$\Pr(X \le x) = \frac{1}{\beta^\alpha \Gamma(\alpha)} \int_0^x \mathrm{e}^{-t/\beta} t^{\alpha-1}\, \mathrm{d}t, \quad x \ge 0$$

The case $\alpha = 3/2$ is the Maxwell–Boltzmann distribution. The most common probability distribution on the interval [0, 1] is the beta distribution

$$\Pr(Y \le x) = \frac{1}{\mathrm{B}(\alpha,\beta)} \int_0^x t^{\alpha-1}(1-t)^{\beta-1} \mathrm{d}t$$

where $0 \le x \le 1$.

The psi function is the logarithmic derivative of the gamma function

$$\psi(z) = \frac{\Gamma'(z)}{\Gamma(z)} \qquad [7]$$

It is meromorphic with simple poles at 0 and at the negative integers. Special values are $\psi(1) = -\gamma$ and

$$\psi(n+1) = \sum_{k=1}^{n} \frac{1}{k} - \gamma$$

where $\gamma$ is Euler's constant. These can be obtained from the functional equation

$$\psi(z) = \psi(z+1) - \frac{1}{z}$$

## Bessel Functions

Bessel's differential equation is

$$x^2 y'' + xy' + (x^2 - \nu^2)y = 0 \qquad [8]$$

where derivatives are with respect to $x$ and $\nu$ is a complex number. This differential equation has a regular singularity at $x = 0$ and an irregular singularity at $x = \infty$. The standard method of finding a solution in the neighborhood of a regular singularity gives the solution

$$J_\nu(x) = (x/2)^\nu \sum_{k=0}^{\infty} \frac{(-x^2/4)^k}{k!\Gamma(k+\nu+1)}$$

and $J_{-\nu}(x)$ is another solution (if $\nu \neq 0$). The function $J_\nu$ is called the "Bessel function of the first kind" and $\nu$ is the "order" of the Bessel function. The series $x^{-\nu} J_\nu(x)$ is an entire function of the variable $x$. The function

$$Y_\nu(x) = \frac{J_\nu(x)\cos(\nu\pi) - J_{-\nu}(x)}{\sin(\nu\pi)}$$

is also a solution of Bessel's differential equation and is known as the "Bessel function of the second kind of order $\nu$." Two other solutions that are often used are

$$H_\nu^{(1)}(x) = J_\nu(x) + \mathrm{i}Y_\nu(x)$$
$$H_\nu^{(2)}(x) = J_\nu(x) - \mathrm{i}Y_\nu(x)$$

which are the first and second "Hankel functions."

Bessel functions appear if one solves the wave equation in cylindrical or spherical coordinates, using separation of variables. The Helmholtz equation $\nabla^2 F + k^2 F = 0$ in cylindrical coordinates $\rho, \phi, z$ is

$$\frac{\partial^2 F}{\partial \rho^2} + \frac{1}{\rho}\frac{\partial F}{\partial \rho} + \frac{1}{\rho^2}\frac{\partial^2 F}{\partial \phi^2} + \frac{\partial^2 F}{\partial z^2} + k^2 F = 0$$

and if we look for a solution of the form $f(\rho)g(\phi)h(z)$, then this leads to a differential equation for $f$ of the form

$$\frac{\mathrm{d}^2 f}{\mathrm{d}\rho^2} + \frac{1}{\rho}\frac{\mathrm{d}f}{\mathrm{d}\rho} + [k^2 - a^2 - (\nu/\rho)^2]f = 0$$

where $a$ and $\nu$ are separation constants. The general solution is $f(\rho) = Z_\nu(\rho(k^2 - a^2))$, where $Z_\nu$ is any of the Bessel functions given higher or linear combinations of them. In spherical coordinates $r$, $\theta$, $\phi$ the Helmholtz equation is

$$\frac{\partial^2 F}{\partial r^2} + \frac{2}{r}\frac{\partial F}{\partial r} + \frac{1}{r^2}\frac{\partial^2 F}{\partial \theta^2} + \frac{\cot\theta}{r^2}\frac{\partial F}{\partial \theta} + \frac{1}{r^2 \sin^2 \phi}\frac{\partial^2 F}{\partial \phi^2} + k^2 F = 0$$

and for a solution of the form $f(r)g(\theta)h(\phi)$ one obtains a differential equation for $f$ of the form

$$\frac{1}{r}\frac{\mathrm{d}^2(rf)}{\mathrm{d}r^2} + [k^2 - \nu(\nu+1)/r^2]f = 0$$

with general solution $f(r) = Z_{\nu+(1/2)}(kr)/\sqrt{r}$.

Bessel functions have very simple differentiation formulas:

$$[z^\nu J_\nu(z)]' = z^\nu J_{\nu-1}(z)$$
$$[z^{-\nu} J_\nu(z)]' = -z^{-\nu} J_{\nu+1}(z)$$

The first formula can be seen as a lowering operation, the second as a raising operation. Some integral representations are

$$J_\nu(z) = \frac{(z/2)^\nu}{\sqrt{\pi}\,\Gamma(\nu+1/2)} \int_0^\pi \sin^{2\nu}\theta \cos(z\cos\theta)\mathrm{d}\theta$$

or

$$J_\nu(z) = \frac{(z/2)^\nu}{\sqrt{\pi}\,\Gamma(\nu+1/2)} \int_{-1}^{1} (1-x^2)^{\nu-1/2} \cos zx \,\mathrm{d}x$$

which hold for $\Re\nu > -1/2$. For real $\nu$ the Bessel function $J_\nu$ has infinitely many real zeros, and when $\nu > -1$, then all the zeros are real. All the zeros are simple (except possibly at the origin). Each of the functions $J_\nu(z), Y_\nu(z), H_\nu^{(1)}(z)$, or $H_\nu^{(2)}(z)$ satisfies the recurrence relation

$$za_{\nu-1}(z) + za_{\nu+1}(z) = 2\nu a_\nu(z)$$

and the differential–recurrence relation

$$a_{\nu-1}(z) - a_{\nu-1}(z) = 2a'_\nu(z)$$

### Modified Bessel Functions

The modified Bessel equation is

$$x^2y'' + xy' - (x^2 + \nu^2)y = 0 \quad [9]$$

Clearly $J_\nu(\mathrm{i}x)$ is a solution of this equation. The "modified Bessel function of the first kind" is defined as

$$I_\nu(x) = \mathrm{e}^{-\nu\pi\mathrm{i}/2} J_\nu(x\mathrm{e}^{\pi\mathrm{i}/2}), \quad -\pi < \arg x \leq \pi/2 \quad [10]$$

so that

$$I_\nu(x) = (x/2)^\nu \sum_{k=0}^{\infty} \frac{(x/2)^{2k}}{k!\Gamma(\nu + k + 1)}$$

If $\nu$ is not an integer, then $I_\nu(x)$ and $I_{-\nu}(x)$ are two linearly independent solutions of [9], and when $\nu = n$ is an integer one has $I_n(x) = I_{-n}(x)$. The "modified Bessel function of the second kind" is defined by

$$K_\nu(x) = \frac{\pi}{2\sin\nu\pi}[I_{-\nu}(x) - I_\nu(x)]$$

Some special cases of modified Bessel functions are

$$I_{1/2}(x) = \sqrt{\frac{2}{\pi x}}\sinh x$$
$$I_{-1/2}(x) = \sqrt{\frac{2}{\pi x}}\cosh x$$

and

$$K_{1/2}(x) = \sqrt{\frac{\pi}{2x}}\mathrm{e}^{-x}$$

One has the integral representation

$$K_\nu(z) = \int_0^\infty \mathrm{e}^{-z\cosh x}\cosh\nu x\,\mathrm{d}x$$

and

$$I_\nu(z) = \frac{(z/2)^\nu}{\sqrt{\pi}\,\Gamma(\nu + 1/2)}\int_{-1}^{1}(1 - x^2)^{\nu - 1/2}\mathrm{e}^{\pm zx}\,\mathrm{d}x$$

whenever $\Re\nu > -1/2$. The "Airy functions" are given by

$$\mathrm{Ai}(z) = \frac{\sqrt{z}}{3}\left[I_{-1/3}(\zeta) - I_{1/3}(\zeta)\right] = \frac{\sqrt{z/3}}{\pi}K_{1/3}(\zeta)$$
$$\mathrm{Bi}(z) = \sqrt{z/3}\left[I_{-1/3}(\zeta) + I_{1/3}(\zeta)\right]$$

where $\zeta = 2z^{2/3}/3$. They are both a solution of Airy's differential equation

$$y''(z) - zy(z) = 0$$

## Hypergeometric Series

A power series $\sum_{n=0}^{\infty} c_n z^n$ is said to be hypergeometric when the ratio $c_{n+1}/c_n$ is a rational function of the index $n$. Most series that one finds in calculus textbooks are hypergeometric series and some of them define important special functions. When

$$\frac{c_{n+1}}{c_n} = \frac{(n + a_1)(n + a_2)\cdots(n + a_p)}{(n + b_1)(n + b_2)\cdots(n + b_q)(n + 1)}$$

then we write the corresponding series as

$$ {}_pF_q\left(\left.\begin{matrix} a_1, a_2, \ldots, a_p \\ b_1, b_2, \ldots, b_q \end{matrix}\right| z\right) = \sum_{n=0}^{\infty} \frac{(a_1)_n(a_2)_n\cdots(a_p)_n}{(b_1)_n(b_2)_n\cdots(b_q)_n}\frac{z^n}{n!} \quad [11]$$

where $(a)_n = a(a + 1)(a + 2)\cdots(a + n - 1)$, with $(a)_0 = 1$, is the rising factorial or Pochhammer symbol. When $p$ and $q$ are small, one also uses the notation ${}_pF_q(a_1, \ldots, a_p; b_1, \ldots, b_q; z)$ where a semicolon (;) is used to separate the parameters in the numerator from the parameters in the denominator and also to separate the parameters from the variable $z$. Some special cases are:

- the exponential series

$$ {}_0F_0(-; -; z) = \sum_{n=0}^{\infty}\frac{z^n}{n!} = \exp(z)$$

- the geometric series

$$ {}_1F_0(1; -; z) = \sum_{n=0}^{\infty} z^n = \frac{1}{1 - z}$$

- the binomial series

$$ {}_1F_0(-\alpha; -; -z) = \sum_{n=0}^{\infty}\binom{\alpha}{n}z^n = (1 + z)^\alpha$$

- the logarithmic function

$$ {}_2F_1(1, 1; 2; z) = \sum_{n=0}^{\infty}\frac{z^n}{n + 1} = -\frac{1}{z}\log(1 - z)$$

- the Bessel function

$$(z/2)^\nu {}_0F_1(-; \nu + 1; -z^2/4) = \Gamma(\nu + 1)J_\nu(z)$$

For generic values of the parameters, we see that the hypergeometric series converges everywhere in the complex plane when $q \geq p$, it converges for $|z| < 1$ when $p = q + 1$, and for $p > q + 1$ it is only defined at

$z = 0$. When one of the numerator parameters is a negative integer, say $a_1 = -m$, then the series is terminating and defines a polynomial of degree $m$. None of the denominator parameters is allowed to be a negative integer $-m$, unless there is a numerator parameter which is a negative integer $-k$ with $k < m$. For $q \geq p$, the hypergeometric series therefore defines an entire function which is the corresponding hypergeometric function. For $p = q + 1$, the hypergeometric series only converges in the open unit disk, but sometimes it can be continued analytically to a larger domain in the complex plane. The analytic continuation of the hypergeometric series is then called the hypergeometric function. Take for example the geometric series, then it is clear that the hypergeometric series converges in the open unit disk, but the corresponding hypergeometric function is defined in the whole complex plane with a simple pole at $z = 1$. The logarithmic function $-\log(1 - z)$ has a hypergeometric series in the open unit disk, but it can be continued analytically to the complex plane with a cut along $[1, \infty)$ and a branch point at $z = 1$.

### Gauss Hypergeometric Function

The most famous hypergeometric function is the Gauss hypergeometric function defined for $|z| < 1$ by the hypergeometric series

$$ {}_2F_1(a, b; c; z) = \sum_{n=0}^{\infty} \frac{(a)_n (b)_n}{(c)_n n!} z^n \qquad [12] $$

which is often denoted by $F(a, b; c; z)$. It is a solution of the hypergeometric equation

$$ z(1 - z)y''(z) + [c - (a + b + 1)z]y'(z) - aby(z) = 0 \qquad [13] $$

and this solution is regular at $z = 0$. Obviously, ${}_2F_1(a, b; \; c; z) = {}_2F_1(b, a; c; z)$. The six functions ${}_2F_1(a \pm 1, b; \; c; z)$, ${}_2F_1(a, b \pm 1; c; z)$, and ${}_2F_1(a, b; c \pm 1; z)$ are called contiguous to ${}_2F_1(a, b; c; z)$ and there are 15 linear relations (with coefficients which are linear functions of $z$) between ${}_2F_1(a, b; c; z)$ and any two contiguous functions. Two of these relations are

$$ (2a - c - az + bz)F(a, b; c; z) + (c - a)F(a - 1, b; c; z) + a(z - 1)F(a + 1, v; c; z) = 0 $$

and

$$ c(a - (c - b)z)F(a, b; c; z) - ac(1 - z)F(a + 1, b; c; z) + (c - a)(c - b)zF(a, b; c + 1; z) = 0 $$

Euler gave the integral representation

$$ {}_2F_1(a, b; c; z) = \frac{\Gamma(c)}{\Gamma(b)\Gamma(c - b)} \int_0^1 \frac{x^{b-1}(1 - x)^{c-b-1}}{(1 - zx)^a} \mathrm{d}x \qquad [14] $$

for $\Re c > 0$ and $\Re b > 0$. This allows to find the analytic continuation from the open unit disk to the complex plane. A useful result is the Gauss summation formula

$$ {}_2F_1(a, b; c; 1) = \frac{\Gamma(c)\Gamma(c - a - b)}{\Gamma(c - a)\Gamma(c - b)} \quad \Re(c - a - b) > 0 $$

The special case for a terminating series is known as the Chu–Vandermonde sum

$$ {}_2F_1(-n, a; c; 1) = \frac{(c - a)_n}{(c)_n} $$

Pfaff's transformation is

$$ {}_2F_1(a, b; c; z) = (1 - z)^{-a} {}_2F_1\left(a, c - b; c; \frac{z}{z - 1}\right) $$

and Euler's transformation is

$$ {}_2F_1(a, b; c; z) = (1 - z)^{c-a-b} {}_2F_1(c - a, c - b; c; z) $$

### Confluent Hypergeometric Function

The hypergeometric series ${}_1F_1(a; c; z)$ defines an entire function in the complex plane and satisfies the differential equation

$$ zy''(z) + (c - z)y'(z) - ay(z) = 0 \qquad [15] $$

This hypergeometric series (and the differential equation) are formally obtained from ${}_2F_1(a, b; c; z/b)$ by letting $b \to \infty$, which gives a confluence of two of the singularities at $z = \infty$. This is the reason why the differential equation [15] is known as the confluent hypergeometric equation. The solution

$$ \Phi(a, c; z) = {}_1F_1(a; c; z) \qquad [16] $$

is called a confluent hypergeometric function, and a second linearly independent solution of [15] is $z^{1-c}\Phi(c - a + 1, 2 - c; z)$. The function

$$ \Psi(a, c; z) = \frac{\Gamma(1 - c)}{\Gamma(a - c + 1)} \Phi(a, c; z) + \frac{\Gamma(c - 1)}{\Gamma(a)} z^{1-c} \Phi(a - c + 1, 2 - c; z) \qquad [17] $$

is therefore also a solution of eqn [15]. The following integral representations hold:

$$\Phi(a,c;z)=\frac{\Gamma(c)}{\Gamma(a)\Gamma(c-a)}\int_0^1 \mathrm{e}^{zx}x^{a-1}(1-x)^{c-a-1}\mathrm{d}x$$

whenever $\Re c > \Re a > 0$, and

$$\Psi(a,c;z)=\frac{1}{\Gamma(a)}\int_0^\infty \mathrm{e}^{-zx}x^{a-1}(1+x)^{c-a-1}\mathrm{d}x$$

whenever $\Re a > 0$.

The "Whittaker functions" are defined as

$$M_{\lambda,\mu}(z)=\mathrm{e}^{-z/2}z^{c/2}\Phi(a,c;z)$$
$$W_{\lambda,\mu}(z)=\mathrm{e}^{-z/2}z^{c/2}\Psi(a,c;z)$$

with $\lambda=-a+c/2$ and $\mu=(c-1)/2$. They are a solution of the Whittaker equation

$$y''(z)+\left(-\frac{1}{4}+\frac{\lambda}{z}+\frac{1-4\mu^2}{4z^2}\right)y(z)=0$$

The "parabolic cylinder functions" are also confluent hypergeometric functions. They are given by

$$\begin{aligned}D_\nu(z)&=2^{\nu/2}\mathrm{e}^{-z^2/4}\Psi(-\nu/2,1/2;z^2/2)\\&=2^{(\nu-1)/2}\mathrm{e}^{-z^2/4}z\Psi((1-\nu)/2,3/2;z^2/2)\end{aligned}$$

When $\nu$ is a non-negative integer, one finds Hermite polynomials

$$H_n(z)=2^{n/2}\mathrm{e}^{z^2/2}D_n(\sqrt{2}z)$$

## Classical Orthogonal Polynomials

A family of polynomials $\{p_n(x), n\in\mathbb{N}\}$, where $p_n$ has degree $n$, is orthogonal on the real line if there is a positive measure $\mu$ on the real line for which

$$\int_{\mathbb{R}} p_n(x)p_m(x)\mathrm{d}\mu(x)=h_n\delta_{m,n} \qquad [18]$$

Usually the measure $\mu$ is absolutely continuous, in which case $\mathrm{d}\mu(x)=w(x)\,\mathrm{d}x$ with $w$ a non-negative density function on the real line, or $\mu$ is discrete and supported on a finite or at most countable set. Any family of orthogonal polynomials satisfies a "three-term recurrence relation"

$$xp_n(x)=A_np_{n+1}(x)+B_np_n(x)+C_np_{n-1}(x) \qquad [19]$$

with $C_nA_{n-1}>0$ for every $n\geq 1$. For the monic polynomials $P_n(x)=p_n(x)/k_n$, with $k_n=1/(A_0A_1A_2\cdots A_{n-1})$ this relation becomes

$$P_{n+1}(x)=(x-b_n)P_n(x)-a_n^2P_{n-1}(x)$$

with $b_n=B_n$ and $a_n^2=A_{n-1}C_n$. This recurrence relation gives rise to a tridiagonal matrix

$$J=\begin{pmatrix} b_0 & a_1 & 0 & 0 & 0 & 0\\ a_1 & b_1 & a_2 & 0 & 0 & 0\\ 0 & a_2 & b_2 & a_3 & 0 & 0\\ 0 & 0 & a_3 & b_3 & a_4 & 0\\ 0 & 0 & 0 & a_4 & \ddots & \ddots\\ 0 & 0 & 0 & 0 & \ddots & \end{pmatrix}$$

which is formally symmetric and which is called the "Jacobi matrix." The spectral measure of this operator, acting on $\ell_2(\mathbb{N})$, is equal to the orthogonality measure $\mu$ whenever this symmetric operator can be extended to a self-adjoint operator. If this is not possible in a unique way – a situation which can occur for unbounded operators only – then every self-adjoint extension of $J$ gives rise to a spectral measure which can be used for the orthogonality conditions [18]. In this case, there are infinitely many positive measures which can be used in the orthogonality relations and all these measures have the same moments

$$m_n=\int_{\mathbb{R}} x^n\,\mathrm{d}\mu(x)$$

Some families of orthogonal polynomials have additional properties which are quite useful in many practical and physical applications, such as the following:

- The derivatives $p_n'$ are again a family of orthogonal polynomials (Hahn property).
- The polynomials $p_n$ satisfy a second-order linear differential equation of the form

  $$\sigma(x)y''(x)+\tau y'(x)=\lambda_ny(x)$$

  where $\sigma$ is a polynomial of degree at most 2, $\tau$ is a polynomial of degree 1, both independent of $n$, and $\lambda_n$ is a real number (Bochner property).
- The polynomials can be obtained by a Rodrigues formula

  $$w(x)p_n(x)=C_n\frac{\mathrm{d}^n}{\mathrm{d}x^n}(w(x)\sigma^n(x))$$

  where $w$ is a non-negative function and $\sigma$ a polynomial of degree at most 2 (Hildebrand property).

There are three families of orthogonal polynomials on the real line which have these three properties, and

each of these three properties characterizes these families. These are the Hermite polynomials, the Laguerre polynomials, and the Jacobi polynomials. In a more general situation when the orthogonality relation is described by a linear functional and the functional is not required to be positive, one has an additional family of Bessel polynomials. The densities $w(x)$ for these families all satisfy a first-order differential equation $[\sigma(x)w(x)]' = \tau(x)w(x)$, where $\sigma$ is a polynomial of degree at most 2 and $\tau$ a polynomial of degree 1. This equation is known as the "Pearson equation."

### Hermite Polynomials

Hermite polynomials $H_n(x)$ are orthogonal with respect to the normal density $w(x) = e^{-x^2}$:

$$\int_{-\infty}^{\infty} H_n(x)H_m(x)e^{-x^2}\,dx = 2^n n!\delta_{n,m}$$

Observe that the density satisfies $w' = -2xw$ so that $\sigma = 1$ and $\tau(x) = -2x$. The recurrence relation is

$$H_{n+1}(x) = 2xH_n(x) - 2nH_{n-1}(x)$$

and the polynomials satisfy the second-order differential equation

$$y''(x) - 2xy'(x) + 2ny(x) = 0$$

The functions $h_n(x) = e^{-x^2/2}H_n(x)$ satisfy the differential equation

$$h_n''(x) + (2n + 1 - x^2)h_n(x) = 0$$

The derivatives satisfy $H_n'(x) = 2nH_{n-1}(x)$ (lowering operation) and one also has $[e^{-x^2}H_n(x)]' = -e^{-x^2}H_{n+1}(x)$ (raising operation). The Rodrigues formula is

$$e^{-x^2}H_n(x) = (-1)^n \frac{d^n}{dx^n} e^{-x^2}$$

The polynomials can be written as a hypergeometric series

$$H_n(x) = (2x)^n {}_2F_0(-n/2, -(n-1)/2; -; -1/x^2)$$

or alternatively as

$$H_n(x) = n! \sum_{k=0}^{\lfloor n/2 \rfloor} \frac{(-1)^k (2x)^{n-2k}}{k!(n-2k)!}$$

Their generating function is

$$\sum_{n=0}^{\infty} H_n(x)\frac{t^n}{n!} = \exp(2xt - t^2)$$

Hermite polynomials are relevant for the analysis of the quantum harmonic oscillator, and the lowering and raising operators there correspond to creation and annihilation.

### Laguerre Polynomials

Laguerre polynomials $L_n^\alpha(x)$ are for $\alpha > -1$ orthogonal with respect to the gamma density $w(x) = x^\alpha e^{-x}$ on $[0, \infty)$:

$$\int_0^{\infty} L_n^\alpha(x)L_m^\alpha(x)x^\alpha e^{-x}\,dx = \frac{\Gamma(n+\alpha)}{n!}\delta_{m,n}$$

The Pearson equation is $[xw]' = (\alpha + 1 - x)w$ so that $\sigma(x) = x$ and $\tau(x) = \alpha + 1 - x$. The recurrence relation is

$$\begin{aligned}(n+1)L_{n+1}^\alpha(x) \\ &= (2n + \alpha + 1 - x)L_n^\alpha(x) - (n+\alpha)L_{n-1}^\alpha(x)\end{aligned}$$

and the differential equation is

$$xy''(x) + (\alpha + 1 - x)y'(x) + ny(x) = 0$$

The functions $\ell_n(x) = x^{\alpha/2}e^{-x/2}L_n^\alpha(x)$ satisfy

$$(x\ell_n')' + \left(n + \frac{\alpha+1}{2} - \frac{x}{4} - \frac{\alpha^2}{4x}\right)\ell_n = 0$$

Differentiation has the effect that

$$\left[L_n^\alpha(x)\right]' = -L_{n-1}^{\alpha+1}(x)$$

and

$$\left[x^\alpha e^{-x}L_n^\alpha(x)\right]' = (n+1)x^{\alpha-1}e^{-x}L_{n+1}^{\alpha-1}(x)$$

The Rodrigues formula is

$$x^\alpha e^{-x}L_n^\alpha(x) = \frac{1}{n!}\frac{d^n}{dx^n}[x^{n+\alpha}\,e^{-x}]$$

The hypergeometric expression is

$$n!L_n^\alpha(x) = (\alpha+1)_n {}_1F_1(-n; \alpha+1; x)$$

and the generating function is

$$\sum_{n=0}^{\infty} L_n^\alpha(x)t^n = (1-t)^{-\alpha-1}\exp\left(\frac{xt}{t-1}\right)$$

Laguerre polynomials occur as eigenfunctions of the hydrogen atom.

### Jacobi Polynomials

Jacobi polynomials $P_n^{(\alpha,\beta)}(x)$ are orthogonal for the beta density $w(x) = (1-x)^\alpha(1+x)^\beta$ on $[-1,1]$ whenever $\alpha > -1$ and $\beta > -1$:

$$\int_{-1}^{1} P_n^{(\alpha,\beta)}(x)P_m^{(\alpha,\beta)}(x)(1-x)^\alpha(1+x)^\beta\,\mathrm{d}x = \frac{2^{\alpha+\beta+1}}{2n+\alpha+\beta+1}\frac{\Gamma(n+\alpha+1)\Gamma(n+\beta+1)}{\Gamma(n+\alpha+\beta+1)}\delta_{n,m}$$

The Pearson equation is $[(1-x^2)w]' = [\beta-\alpha-(\alpha+\beta+2)x]w$ and the differential equation is

$$(1-x^2)y''(x) + [\beta-\alpha-(\alpha+\beta+2)x]y'(x) + n(n+\alpha+\beta+1)y(x) = 0$$

Differentiation has the effect

$$\left[P_n^{(\alpha,\beta)}(x)\right]' = (n+\alpha+\beta+1)/2P_{n-1}^{(\alpha+1,\beta+1)}(x)$$

and

$$\left[(1-x)^\alpha(1+x)^\beta P_n^{(\alpha,\beta)}(x)\right]' = -2(n+1)(1-x)^{\alpha-1}(1+x)^{\beta-1}P_{n+1}^{(\alpha-1,\beta-1)}(x)$$

The Rodrigues formula is

$$(1-x)^\alpha(1+x)^\beta P_n^{(\alpha,\beta)}(x) = \frac{(-1)^n}{2^n n!}\frac{\mathrm{d}^n}{\mathrm{d}x^n}\left[(1-x)^{n+\alpha}(1+x)^{n+\beta}\right]$$

In terms of hypergeometric series, one has

$$P_n^{(\alpha,\beta)}(x) = \frac{(\alpha+1)_n}{n!} \times {}_2F_1\left(\begin{matrix}-n, n+\alpha+\beta+1\\ \alpha+1\end{matrix}\,\middle|\,\frac{1-x}{2}\right)$$

Observe that one has $P_n^{(\alpha,\beta)}(-x) = (-1)^n P_n^{(\beta,\alpha)}(x)$.

Special cases of the Jacobi polynomials are as follows:

- The "Legendre polynomials" $P_n(x) = P_n^{(0,0)}(x)$. They appear when the Laplacian is separated in spherical coordinates as functions of the polar angle $\theta$, for which $x = \cos\theta$.
- The "Chebyshev polynomials" of the first kind

  $$T_n(x) = P_n^{(-1/2,-1/2)}(x)/P_n^{(-1/2,-1/2)}(1)$$

  and of the second kind

  $$U_n(x) = (n+1)P_n^{(1/2,1/2)}(x)/P_n^{(1/2,1/2)}(1)$$

  These functions are more easily written by using the change of variable $x = \cos\theta$ and then $T_n(\cos\theta) = \cos n\theta$ and $U_n(\cos\theta) = \sin(n+1)\theta/\sin\theta$.
- The "Gegenbauer polynomials" or ultraspherical polynomials are Jacobi polynomials with equal parameters:

  $$C_n^\lambda(x) = (2\lambda)_n/(\lambda+1/2)_n P_n^{(\lambda-1/2,\lambda-1/2)}(x)$$

Gegenbauer polynomials are involved in the angular or spatial part of the wave function of physical systems in a central potential in both position and momentum space, and in the spatial part of the wave function of hydrogenic systems in momentum space, as well as in the eigenfunctions of several quantum-mechanical potentials, such as the relativistic harmonic oscillator.

### Other Classical Orthogonal Polynomials

Instead of restricting attention to the differential operator $D = \mathrm{d}/\mathrm{d}x$, one can also use the (forward) difference operator $\Delta$ for which $\Delta f(x) = f(x+1) - f(x)$, the divided difference operator $\Delta_\lambda$ for which $\Delta_\lambda f(x) = \Delta f(\lambda(x))/\Delta\lambda(x)$ with a quadratic function $\lambda$, or certain $q$-difference operators and look for orthogonal polynomials that satisfy difference equations in the variable $x$. Together with the three-term recurrence relation (in the degree $n$), one then has families of polynomials satisfying a bispectral problem. For the difference operator and the divided difference operator, this gives several important families of orthogonal polynomials which all have a hypergeometric representation. These hypergeometric polynomials are usually listed in a table, and each level indicates the number of parameters and/or the order of the hypergeometric function. This table is known as Askey's table and is given in Figure 1. The extension with $q$-difference operators involves basic hypergeometric series and $q$-extensions of classical orthogonal polynomials.

"Charlier polynomials" $C_n(x;a)$ are orthogonal with respect to the Poisson distribution

$$\sum_{k=0}^{\infty} C_n(k;a)C_m(k;a)\frac{a^k}{k!} = \mathrm{e}^a/a^n\delta_{n,m}$$

The recurrence relation is

$$aC_{n+1}(x;a) + (x-n-a)C_n(x;a) + nC_{n-1}(x;a) = 0$$

and the second-order difference equation is

$$ay(x+1) + (n-x-a)y(x) + xy(x-1) = 0$$

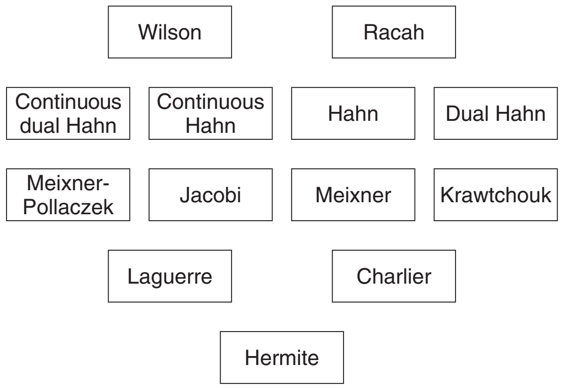

**Figure 1** Askey's table.

The forward difference operator has the effect $\Delta C_n(x;a) = -n/aC_{n-1}(x;a)$ and the backward difference operator $\nabla f(x) = f(x) - f(x-1)$ has the effect $\nabla[a^x/x!C_n(x;a)] = a^x/x!C_{n+1}(x;a)$. The hypergeometric representation is $C_n(x;a) = {}_2F_0(-n-x;\ -;\ -1/a)$. Observe that the variable $x$ appears as a parameter of the hypergeometric series.

"Krawtchouk polynomials" $K_n(x;p,N)$ are orthogonal with respect to the binomial distribution:

$$\sum_{k=0}^{N} K_n(k;p,N)K_m(k;p,N)\binom{N}{k}p^k(1-p)^{N-k} = \frac{(-1)^n n!}{(-N)_n}p^{-n}(1-p)^n\delta_{n,m}$$

where $N$ is a positive integer and $0 < p < 1$. They are given by $K_n(x;p,N) = {}_2F_1(-n,\ -x;\ -N;1/p)$ and correspond to Meixner polynomials for which the parameter $\beta$ is a negative integer.

"Meixner polynomials" $m_n(x;\beta,c)$ are orthogonal with respect to the negative binomial distribution (Pascal distribution)

$$\sum_{k=0}^{\infty} m_n(k;\beta,c)m_j(k;\beta,c)\frac{(\beta)_k c^k}{k!} = \frac{n!}{c^n(\beta)_n(1-c)^\beta}\delta_{n,j}$$

where $\beta > 0$ and $0 < c < 1$. They are given by $m_n(x;\beta,c) = {}_2F_1(-n,\ -x;\beta;1-1/c)$.

"Meixner–Pollaczek polynomials" $P_n^\lambda(x;\phi)$ are orthogonal on $(-\infty,\infty)$:

$$\int_{-\infty}^{\infty} P_m^\lambda(x;\phi)P_n^\lambda(x;\phi)e^{(2\phi-\pi)x}|\Gamma(\lambda+ix)|^2\,dx = \frac{2\pi\Gamma(n+2\lambda)}{(2\sin\phi)^{2\lambda}n!}\delta_{m,n}$$

where $\lambda > 0$ and $0 < \phi < \pi$. The appropriate difference operator $\delta$ has an imaginary shift $\delta f(x) = f(x+i/2) - f(x-i/2)$ and one has $\delta P_n^\lambda(x;\phi) = 2\sin\phi P_{n-1}^{\lambda+1/2}(x;\phi)$. They are given by

$$P_n^\lambda(x;\phi) = \frac{(2\lambda)_n}{n!}e^{in\phi}{}_2F_1\left(\begin{matrix}-n,\lambda+ix\\2\lambda\end{matrix}\middle|1-e^{-2i\phi}\right)$$

"Hahn and dual Hahn polynomials" are orthogonal on a finite set of points. Hahn polynomials are given by

$$Q_n(x;\alpha,\beta,N) = {}_3F_2\left(\begin{matrix}-n,n+\alpha+\beta+1,-x\\\alpha+1,-N\end{matrix}\middle|1\right)$$

and their orthogonality is with respect to a hypergeometric distribution on $\{0,1,\ldots,N\}$. The appropriate difference operator is the (forward) difference operator $\Delta$. They are related to the $3-j$ symbols or Wigner coefficients that arise when considering angular momenta in two quantum systems. Dual Hahn polynomials are given by

$$R_n(\lambda(x);\gamma,\delta,N) = {}_3F_2\left(\begin{matrix}-n,-x,x+\gamma+\delta+1\\\gamma+1,-N\end{matrix}\middle|1\right)$$

where $\lambda(x) = x(x+\gamma+\delta+1)$. They are obtained from the Hahn polynomials by interchanging the roles of $n$ and $x$. They are orthogonal on the set $\{\lambda(0),\lambda(1),\ldots,\lambda(N)\}$. The appropriate difference operator is the divided difference operator which acts on $f$ as $\Delta f(\lambda(x))/\Delta\lambda(x)$.

"Continuous Hahn and dual Hahn polynomials" are orthogonal on the real line. The continuous Hahn polynomials are

$$p_n(x;a;b;c;d) = i^n\frac{(a+c)_n(a+d)_n}{n!} \times {}_3F_2\left(\begin{matrix}-n,n+a+b+c+d-1,a+ix\\a+c,a+d\end{matrix}\middle|1\right)$$

and the appropriate difference operator is the difference operator $\delta$ with imaginary shift. The continuous dual Hahn polynomials are

$$S_n(x^2;a,b,c) = (a+b)_n(a+c)_n \times {}_3F_2\left(\begin{matrix}-n,a+ix,a-ix\\a+b,a+c\end{matrix}\middle|1\right)$$

and the appropriate difference operator is the divided difference operator which acts on $f$ as $\delta f(x^2)/\delta x^2$.

"Wilson polynomials" are the most general system of hypergeometric polynomials satisfying a bispectral problem. All the other classical orthogonal polynomials can be obtained from them by taking

appropriate parameters or as limiting cases. They are given by

$$\frac{W_n(x^2;a,b,c,d)}{(a+b)_n(a+c)_n(a+d)_n} = {}_4F_3\left(\begin{matrix}-n, n+a+b+c+d-1, a+\mathrm{i}x, a-\mathrm{i}x\\ a+b, a+c, a+d\end{matrix}\middle| 1\right)$$

and for $\Re(a,b,c,d) > 0$ (with nonreal parts appearing in conjugate pairs) they are orthogonal on the positive real line with respect to the weight function

$$w(x) = \left|\frac{\Gamma(a+\mathrm{i}x)\Gamma(b+\mathrm{i}x)\Gamma(c+\mathrm{i}x)\Gamma(d+\mathrm{i}x)}{\Gamma(2\mathrm{i}x)}\right|$$

"Racah polynomials" can be obtained from Wilson polynomials when the parameters are such that one of $a+b$, $a+c$, or $a+d$ is a negative integer $-N$. They are given by

$$R_n(\lambda(x);\alpha,\beta,\gamma,\delta) = {}_4F_1\left(\begin{matrix}-n, n+\alpha+\beta+1, -x, x+\gamma+\delta+1\\ \alpha+1, \beta+\delta+1, \gamma+1\end{matrix}\middle| 1\right)$$

where $\alpha+1=-N$ or $\beta+\delta+1=-N$ or $\gamma+1=-N$, and $N$ is a non-negative integer. They are orthogonal on the finite set $\{\lambda(0), \lambda(1), \ldots, \lambda(N)\}$, where $\lambda(x) = x(x+\gamma+\delta+1)$. They arise as $6-j$ symbols in the coupling of three angular momenta.

## Painlevé Equations

**N Joshi**, University of Sydney, Sydney, NSW, Australia

### Introduction

The Painlevé equations $P_I$–$P_{VI}$ are six classical second-order ordinary differential equations that appear widely in modern physical applications. Their conventional forms (governing $y(x)$ with derivatives $y' = dy/dx$, $y'' = d^2y/dx^2$) are:

$$P_I: \quad y'' = 6y^2 + x$$

$$P_{II}: \quad y'' = 2y^3 + xy + \alpha$$

$$P_{III}: \quad y'' = \frac{y'^2}{y} - \frac{y'}{x} + \frac{1}{x}(\alpha y^2 + \beta) + \gamma y^3 + \frac{\delta}{y}$$

$$P_{IV}: \quad y'' = \frac{y'^2}{2y} + \frac{3}{2}y^3 + 4xy^2 + 2(x^2 - \alpha)y + \frac{\beta}{y}$$

$$P_V: \quad y'' = \left(\frac{1}{2y} + \frac{1}{y-1}\right)y'^2 - \frac{y'}{x} + \frac{(y-1)^2}{x^2}\left(\alpha y + \frac{\beta}{y}\right) + \frac{\gamma y}{x} + \frac{\delta y(y+1)}{y-1}$$

$$P_{VI}: \quad y'' = \frac{1}{2}\left(\frac{1}{y} + \frac{1}{y-1} + \frac{1}{y-x}\right)y'^2 - \left(\frac{1}{x} + \frac{1}{x-1} + \frac{1}{y-x}\right)y' + \frac{y(y-1)(y-x)}{x^2(x-1)^2}\left\{\alpha + \frac{\beta x}{y^2} + \frac{\gamma(x-1)}{(y-1)^2} + \frac{\delta x(x-1)}{(y-x)^2}\right\}$$

where $\alpha$, $\beta$, $\gamma$, $\delta$ are constants. They were identified and studied by Painlevé and his school in their search for ordinary differential equations (in the class $y'' = R(x, y, y')$, where $R$ is rational in $y'$, $y$ and analytic in $x$) that define new transcendental functions. Painlevé focussed his search on equations that possess what is now known as the Painlevé property: that all solutions are single-valued around all movable singularities (a singularity is "movable" if its location changes with initial conditions).

For the Painlevé equations, all movable singularities are poles. For $P_I$ and $P_{II}$, all solutions are meromorphic functions. However, the solutions of each of the remaining equations have other singularities called "fixed" singularities, with locations that are determined by the singularities of the coefficient functions of the equation. $P_{III}$–$P_{VI}$ have a fixed singularity at $x = \infty$. $P_{III}$ and $P_V$ have additional fixed singularities at $x = 0$, and $P_{VI}$ has them at $x = 0$ and 1. Although each solution of $P_{III}$–$P_{VI}$ is single-valued around a movable singularity, it may be multivalued around a fixed singularity.

Painlevé's school considered canonical classes of ordinary differential equations equivalent under linear fractional transformations of $y$ and $x$. Of the fifty canonical classes of equations they found, all except six were found to be solvable in terms of already known functions. These six lead to the Painlevé equations $P_I$–$P_{VI}$ as their canonical representatives.

A resurgence of interest in the Painlevé equations came about from the observation (due to Ablowitz and Segur) that they arise as similarity reductions of well-known integrable partial differential equations (PDEs), or soliton equations, such as the Korteweg–de Vries equation, the sine-Gordon equation, and the self-dual Yang–Mills equations.

As this connection suggests, the Painlevé equations possess many of the special properties that are commonly associated with soliton equations. They have associated linear problems (i.e., Lax pairs) for which they act as compatibility conditions. There exist special transformations (called Bäcklund transformations) mapping a solution of one equation to a solution of another Painlevé equation (or the same equation with changed parameters). There exist Hamiltonian forms that are related to existence of tau-functions, that are analytic everywhere except at the fixed singularities. They also possess multilinear forms (or Hirota forms) that are satisfied by tau-functions. In the following subsections, for conciseness, we give examples of these properties for the first or second Painlevé equations and briefly indicate differences, in any, with other Painlevé equations.

## Complex Analytic Structure of Solutions

Consider the two-(complex-)parameter manifold of solutions of a Painlevé equation. Each solution is globally determined by two initial values given at a regular point of the solution. However, the solution can also be determined by two pieces of data given at a movable pole. The location $x_0$ of such a pole provides one of the two free parameters. The other free parameter occurs as a coefficient in the Laurent expansion of the solution in a domain punctured at $x_0$. For $P_I$, the Laurent expansion of a solution at a movable singularity $x_0$ is

$$y(x) = \frac{1}{(x-x_0)^2} + \frac{x_0}{10}(x-x_0)^2 + \frac{1}{6}(x-x_0)^3 + c_I(x-x_0)^4 + \cdots \quad [1]$$

where $c_I$ is arbitrary. This second free parameter is normally called a "resonance parameter." For $P_{II}$, the Laurent expansion of a solution at a movable singularity $x_0$ is

$$y(x) = \frac{\pm 1}{(x-x_0)} + \frac{\mp x_0}{6}(x-x_0) + \frac{\mp 1 - \alpha}{4}(x-x_0)^2 + c_{II}(x-x_0)^3 + \cdots \quad [2]$$

where $c_{II}$ is arbitrary. The symmetric solution of $P_I$ that has a pole at the origin and corresponding resonance parameter $c_I = 0$ has a distribution of poles in the complex $x$-plane shown in Figure 1. (This figure was obtained by searching for zeros of truncated Taylor expansions of the tau-function $\tau_I$ described in the section "Bäcklund and Miura transformations." One hundred and sixty numerical zeros are shown. The two pairs of closely spaced zeros near the imaginary axis (between $8 < \pm\Im x < 12$) may be numerical artifacts. We used the command NSolve to 32 digits in MATHEMATICA4.)

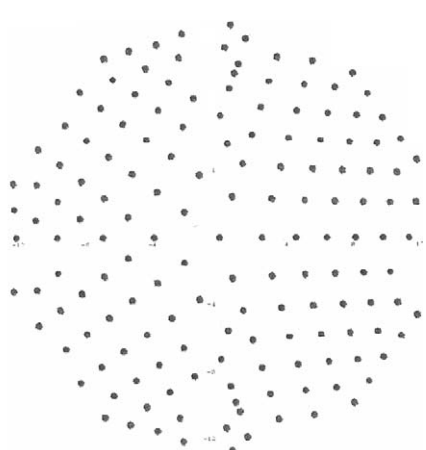

**Figure 1** Poles of a symmetric solution of $P_I$ in the complex $x$-plane, with a pole at the origin and zero corresponding resonance parameter, i.e., $x_0 = 0$, $c_I = 0$.

The rays of symmetry evident in Figure 1 reflect discrete symmetries of $P_I$. The solutions of $P_I$ and $P_{II}$ are invariant under the respective discrete symmetries,

$$P_I: \quad y_n(x) = e^{2\pi i n/5} y(e^{4\pi i n/5} x), \quad n = \pm 1, \pm 2$$

$$P_{II}: \quad y_n(x) = e^{\pi i n/3} y(e^{2\pi i n/3} x), \quad \alpha \mapsto e^{-\pi i n}\alpha \quad n = \pm 1, \pm 2, 3$$

The rays of angle $2\pi n/5$ for $P_I$ and $\pi n/3$ for $P_{II}$ related to these symmetries play special roles in the asymptotic behaviors of the corresponding solutions for $|x| \to \infty$.

## Linear Problems

The Painlevé equations are regarded as completely integrable because they can be solved through an associated system of linear equations (Jimbo and Miwa 1981).

$$\frac{d\varphi}{d\zeta} = L(x,\zeta)\varphi \quad [3a]$$

$$\frac{d\varphi}{dx} = M(x,\zeta)\varphi \quad [3b]$$

The compatibility condition, that is,

$$L_x - M_\zeta + [L, M] = 0 \quad [4]$$

is equivalent to the corresponding Painlevé equation. The matrices $L$, $M$ for $P_I$ and $P_{II}$ are listed below:

$$P_I: \quad L_I(x,\zeta) = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}\zeta^2 + \begin{pmatrix} 0 & y \\ 4 & 0 \end{pmatrix}\zeta + \begin{pmatrix} -z & y^2 + x/2 \\ -4y & z \end{pmatrix}$$

$$M_I(x,\zeta) = \begin{pmatrix} 0 & 1/2 \\ 0 & 0 \end{pmatrix}\zeta + \begin{pmatrix} 0 & y \\ 2 & 0 \end{pmatrix}$$

$$\text{where } z = y', \quad z' = 6y^2 + x$$

$$P_{II}: \quad L_{II}(x,\zeta) = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}\zeta^2 + \begin{pmatrix} 0 & u \\ -2z/u & 0 \end{pmatrix}\zeta + \begin{pmatrix} z + x/2 & -uy \\ -2(\vartheta + zy)/u & -(z + x/2) \end{pmatrix}$$

$$M_{II}(x,\zeta) = \begin{pmatrix} 1/2 & 0 \\ 0 & -1/2 \end{pmatrix}\zeta + \begin{pmatrix} 0 & u/2 \\ -z/u & 0 \end{pmatrix}$$

$$\text{where } u' = -uy, \; z = y' - y^2 - x/2$$

$$\vartheta := \frac{1}{2} - \alpha$$

Alternative linear problems also exist for each equation. For example, for $P_{II}$, an alternative choice of $L$ and $M$ is (Flaschka and Newell 1980):

$$P_{II}: \quad L_{II'}(x,\zeta) = \begin{pmatrix} -4\,i & 0 \\ 0 & 4\,i \end{pmatrix}\zeta^2 + \begin{pmatrix} 0 & 4y \\ 4y & 0 \end{pmatrix}\zeta + \begin{pmatrix} -i(x+2y^2) & 2\,iy' \\ -2\,iy' & i(x+2y^2) \end{pmatrix} + \frac{\alpha}{\zeta}\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$$

$$M_{II'}(x,\zeta) = \begin{pmatrix} -i\zeta & y \\ y & i\zeta \end{pmatrix}$$

The matrix $L$ for each Painlevé equation is singular at a finite number of points $a_i(x)$ in the $\zeta$-plane. For the above choices of $L$ for $P_I$ and $P_{II}$, the point $\zeta = \infty$ is clearly a singularity. For $L_{II'}$, the origin $\zeta = 0$ is also a singularity. The analytic continuation of a fundamental matrix of solutions $\Phi$ around $a_i$ gives a new solution $\widetilde{\Phi}$ which must be related to the original solution: $\widetilde{\Phi} = \Phi A$. $A$ is called the monodromy matrix and its trace and determinant are called the monodromy data. In general, the data will change with $x$. However, eqn [4] ensures that the monodromy data remain constant in $x$. For this reason, the system [3] is called an isomonodromy problem.

## Bäcklund and Miura Transformations

Bäcklund transformations are those that map a solution of a Painlevé equation with one choice of parameter to a solution of the same equation with different parameters. For $P_I$ no such transformation is known. For $P_{II}$, there is one Bäcklund transformation. Let $y = y(x;\alpha)$ denote a solution of $P_{II}$ with parameter $\alpha$. Then $\tilde{y} = y(x;\alpha - 1)$, which solves $P_{II}$ with parameter $\alpha - 1$, is given by

$$\tilde{y} := -y + \frac{\alpha - \frac{1}{2}}{y' - y^2 - x/2} \quad \text{if } \alpha \neq 1/2 \qquad [5]$$

If $\alpha = 1/2$, then $y' = y^2 + x/2$ and $\tilde{y} = -y$ (see the next section for this case). Combined with the symmetry $y \mapsto -y, \alpha = -\alpha$, we can write down another version of this Bäcklund transformation which maps $y$ to $\hat{y} = y(x;\alpha + 1)$:

$$\hat{y} := -y - \frac{\alpha + \frac{1}{2}}{y' + y^2 + x/2}, \quad \text{if } \alpha \neq -\frac{1}{2} \qquad [6]$$

If we parametrize $\alpha$ by $c + n$ for arbitrary $c$, and denote the solution for corresponding parameter as $y_n$, we can write a difference equation relating $y_{n-1}$ and $y_{n+1}$ (by eliminating $y'$ from the two transformations $\tilde{y}$, $\hat{y}$) as

$$\frac{c + \frac{1}{2} + n}{y_{n+1} + y_n} + \frac{c - \frac{1}{2} + n}{y_{n-1} + y_n} + 2y_n^2 + x = 0$$

This is an example of a discrete Painlevé equation (called "alternate" $dP_I$ in the literature). In such a discrete Painlevé equation, $x$ is fixed while $n$ varies. Another lesser known Bäcklund transformation for $P_{II}$ is

$$y' - y^2 - \frac{x}{2} - \delta\, v^2 = 0 \qquad [7]$$

$$v' + y\, v = 0 \qquad [8]$$

between $P_{II}$ with $\alpha = 1/2$ and

$$v'' + \delta\, v^3 + \frac{x}{2}\, v = 0$$

which can be scaled (take $v(x) = y(\sqrt{2}x)/\sqrt{\sqrt{2}\delta}$) to the usual form of $P_{II}$ with $\alpha = 0$.

Miura transformations are those that map a solution of a Painlevé equation to another equation in the 50 canonical types classified by Painlevé's school. If $y$ is a solution of $P_{II}$ with parameter $\alpha \neq 1/2$, then

$$(2\alpha - 1)w = 2(y' - y^2 - x/2), \quad y = \frac{1 - w'}{2w}$$

maps between $P_{II}$ and

$$w'' = \frac{(w')^2}{2\,w} - (2\alpha - 1)\,w^2 - xw - \frac{1}{2\,w}$$

which represents the 34th canonical class in the Painlevé classification listed in Ince (1927).

The Painlevé equations do not possess continuous symmetries other than Bäcklund and Miura transformations described here. However, they do possess discrete symmetries described in the section "Complex analytic structure of solutions."

## Classical Special Solutions

Painlevé showed that there can be no explicit first integral that is rational in $y$ and $y'$ for his eponymous equations. It is known that this statement can be extended to say that no such algebraic first integral exists. But the question whether the Painlevé equations define new transcendental functions remained open until recently.

Form a class of functions consisting of those satisfying linear second-order differential equations, such as the Airy, Bessel, and hypergeometric functions, as well as rational, algebraic, and exponential functions. Extend this class to include arithmetic operations, compositions under such functions, and

solutions of linear equations with these earlier functions as coefficients. Members of this class are called classical functions. For general values of the constants $\alpha, \beta, \gamma, \delta$, it is now known (Umemura 1990, Umemura and Watanabe 1997) that the six Painlevé equations cannot be solved in terms of classical functions. However, there are special values of the constant parameters $\alpha$, $\beta$, $\gamma$, $\delta$ for which classical functions do solve the Painlevé equations. Each Painlevé equation, except $P_I$, has special solutions given by classical functions when the parameters in the Painlevé equation take on special values. For $P_{II}$, with $\alpha = 1/2$ we have the special integral

$$I_{1/2} \equiv y' - y^2 - \frac{x}{2} = 0 \qquad [9]$$

which, modulo $P_{II}$ with $\alpha = 1/2$, satisfies the relation

$$\left(\frac{\mathrm{d}}{\mathrm{d}x} + 2y\right) I_{1/2} = 0$$

The Riccati eqn [9] can be linearized via $y = -\psi'/\psi$ to yield

$$\psi'' + \frac{x}{2}\psi = 0$$

which gives

$$\psi(x) = a\,\mathrm{Ai}(-2^{-1/3}x) + b\,\mathrm{Bi}(-2^{-1/3}\,x)$$

for arbitrary constants $a$ and $b$, that is, the well-known Airy function solutions of $P_{II}$. Iterations of the Bäcklund transformations $\tilde{y}$ and $\hat{y}$, [5]–[6] give further classical solutions in terms of Airy functions for the case when $\alpha = (2N+1)/2$ for integer $N$.

Similarly, there is a sequence of rational solutions of the family of equations $P_{II}$ with $\alpha = N$, for integer $N$, if we iterate the Bäcklund transformations $\tilde{y}, \hat{y}$ by starting with the trivial solution $y \equiv 0$ for the case $\alpha = 0$. For example, for $\alpha = 1$, we have $\hat{y} = -1/x$. The transformations [7]–[8] give a mapping that shows that this family of rational solutions and the above family of Airy-type solutions of $P_{II}$ both exist for the cases when $\alpha$ is half-integer and when it is integer.

## Hamiltonians and Tau-Functions

Each Painlevé equation has a Hamiltonian form. For $P_I$ and $P_{II}$, these can be found by integrating each equation after multiplying by $y'$. These give

$$P_I: \qquad \frac{y'^2}{2} = 2y^3 + xy - \int^x y(\xi)\mathrm{d}\xi + E_I$$

$$P_{II}: \qquad \frac{y'^2}{2} = \frac{y^4}{2} + \frac{x}{2}y^2 - \frac{1}{2}\int^x y(\xi)^2\mathrm{d}\xi + \alpha\, y + E_{II}$$

where $E_{II}$ and $E_{II}$ are constants. We choose canonical variables $q_1(t) = y(x), p_1(t) = y'(x)$, where $t = x$. Furthermore, for $P_I$, we take

$$q_2(t) = x, \qquad p_2(t) = \int^x y(\xi)\mathrm{d}\xi$$

and the Hamiltonian

$$H_I := \frac{p_1^2}{2} - 2{q_1}^3 - q_2 q_1 + p_2$$

so that the Hamiltonian equations of motion $\dot{q}_i = \partial H/\partial p_i$ and $\dot{p}_i = -\partial H/\partial q_i$ are satisfied. For $P_{II}$, we take

$$q_2(t) = x/2, \qquad p_2(t) = \int^x y(\xi)^2\mathrm{d}\xi$$

and the Hamiltonian

$$H_{II} := \frac{{p_1}^2}{2} - \frac{{q_1}^4}{2} - q_2{q_1}^2 + \frac{1}{2}p_2 - \alpha q_1$$

We note that these Hamiltonians govern systems with two degrees of freedom and each is conserved. However, no explicit second conserved quantity is known (see comments on first integrals in the last section).

Painlevé's viewpoint of the transcendental solutions of the Painlevé equations as natural generalizations of elliptic functions also led him to search for entire functions that play the role of theta functions in this new setting. He found that analogous functions could be defined which have only zeros at the locations of the movable singularities of the Painlevé transcendents. These functions are now commonly known as tau-functions (also denoted $\tau$-functions). For $P_I$ and $P_{II}$, the corresponding tau-functions are entire functions (i.e., they are analytic everywhere in the complex $x$-plane). However, for the remaining Painlevé equations, they are singular at the fixed singularities of the respective equation.

For $P_I$, all movable singularities of $P_I$ are double poles of strength unity (see eqn [1]). Therefore, the function given by

$$P_I: \quad \tau_I(x) = \exp\left(-\int^x\int^s y(t)\mathrm{d}t\mathrm{d}s\right)$$

has Taylor expansion with leading term $(x - x_0)$. In other words, $\tau_I(x)$ is analytic at all the poles of the corresponding solution of $P_I$. Since $y(x)$ has no other singularity (other than at infinity), $\tau_I(x)$ must be analytic everywhere in the complex $x$-plane. Differentiation and substitution of $P_I$ shows that $\tau_I(x)$ satisfies the fourth-order equation

$$P_I: \quad \tau_I^{(4)}(x)\tau_I(x) = 4\tau_I'(x)\tau_I^{(3)}(x) - 3\tau_I''(x)^2 - x\tau_I(x)^2$$

Note that this equation is bilinear in $\tau$ and its derivatives. Such bilinear, or in general, multilinear, equations are called Hirota-type forms of the Painlevé equations. The special nature of such equations is most simply expressed in terms of the Hirota $D(\equiv D_x)$ operator, an antisymmetric differential operator defined here on products of functions of $x$:

$$D^n f \cdot g = (\partial_\xi - \partial_\eta)^n f(\xi) g(\eta)|_{\xi=\eta=x}$$

Notice that

$$D^2 \tau \cdot \tau = \tau\tau'' - \tau'^2,$$

$$D^4 \tau \cdot \tau = \tau\tau^{(4)} - 4\tau'\tau^{(3)} + 3\tau''^2$$

Hence the equation satisfied by $\tau_{\rm I}(x)$ can be rewritten more succinctly as

$$(D^4 + x)\tau_{\rm I} \cdot \tau_{\rm I} = 0$$

For $P_{\rm II}$, a generic solution $y(x)$ has movable simple poles of residue $\pm 1$ (see eqn [2]). Painlevé pointed out that if we square the function $y(x)$, multiply by $-1$ and integrate twice, we obtain a function with Taylor expansion with leading term $(x - x_0)$. However, the square is not invertible and to construct an invertible mapping to entire functions, we need two $\tau$-functions. We denote these by $\tau(x)$ and $\sigma(x)$:

$$P_{\rm II}: \qquad \tau_{\rm II}(x) = \exp\left(-\int^x \int^s y(t)^2 {\rm d}t{\rm d}s\right)$$

$$\sigma_{\rm II}(x) = y(x)\tau_{\rm II}(x)$$

The equations satisfied by these tau-functions are

$$P_{\rm II}: \qquad \tau''(x)\tau(x) = \tau'(x)^2 - \sigma(x)^2$$

$$\sigma''(x)\tau(x)^2 = 2\tau(x)\tau'(x)\sigma'(x) - \tau'(x)^2\tau(x) + \sigma(x)^3 + x\tau(x)^2\sigma(x) + \alpha\tau(x)^3$$

## Hierarchies

Each Painlevé equation is associated with at least one infinite sequence of ordinary differential equations (ODEs) indexed by order. These sequences are called hierarchies and arise from symmetry reductions of PDE hierarchies that are associated with soliton equations.

Define the operator $\mathcal{L}_n\{v(z)\}$ (the Lenard recursion operator) recursively by

$$\frac{\rm d}{{\rm d}z}\mathcal{L}_{n+1}\{v\} = \left(\frac{{\rm d}^3}{{\rm d}z^3} + 4v\frac{\rm d}{{\rm d}z} + 2v'\right)\mathcal{L}_n\{v\}$$

$$\mathcal{L}_1\{v\} = v$$

where primes denote $z$-derivatives. Note that

$$\mathcal{L}_2\{v\} = v'' + 3v^2$$

$$\mathcal{L}_3\{v\} = v^{(4)} + 10vv'' + 5v'^2 + 10v^3$$

This operator is intimately related to the Korteweg–de Vries equation. (It was first discovered as a method of generating the infinite number conservation laws associated with this soliton equation.)

The scaling $v(z) = \lambda y(\mu x)$, with $\lambda = (-2)^{1/3}$, $\mu = (-2)^{-1/3}$, shows that the case $n = 2$ of the sequence of ODEs defined recursively by

$$\mathcal{L}_n\{v\} = z$$

is $P_{\rm I}$. Hence this is called the first Painlevé hierarchy.

A second Painlevé hierarchy is given recursively by

$$\left(\frac{\rm d}{{\rm d}x} + 2y\right)\mathcal{L}_n\{y' - y^2\} = xy + \alpha_n, \quad n \geq 1$$

where $\alpha_n$ are constants.

Each Painlevé equation may arise as a reduction of more than one PDE. Since different soliton equations have different hierarchies, this means that more than one hierarchy may be associated with each Painlevé equation.

## Introduction

Many physical laws are mathematically expressed in terms of partial differential equations (PDEs); this is, for instance, the case in the realm of classical mechanics and physics of the laws of conservation of angular momentum, mass, and energy.

The object of this short article is to provide an overview and make a few comments on the set of PDEs appearing in classical mechanics, which is tremendously rich and diverse. From the mathematical point of view the PDEs appearing in mechanics range from well-understood PDEs to equations which are still at the frontier of sciences as far as their mathematical theory is concerned. The mathematical theory of PDEs deals primarily with their "well-posedness" in the sense of Hadamard. A well-posed PDE problem is a problem for which existence and uniqueness of solutions in suitable function spaces and continuous dependence on the data have been proved.

For simplicity, let us restrict ourselves to space dimension 2. Several interesting and important PDEs are of the form

$$a\frac{\partial^2 u}{\partial x^2} + b\frac{\partial^2 u}{\partial x \partial y} + c\frac{\partial^2 u}{\partial y^2} = 0 \qquad [1]$$

Here $a$, $b$, $c$ may depend on $x$ and $y$ or they may be constants, and then eqn [1] is linear: they may also depend on $u$, $\partial u/\partial x$, and $\partial u/\partial y$, in which case the equation is nonlinear.

Such an equation is

- elliptic when (where) $b^2 - 4ac < 0$,
- hyperbolic when (where) $b^2 - 4ac > 0$,
- parabolic when (where) $b^2 - 4ac = 0$.

Among the simplest linear equations, we have the elliptic equation

$$\Delta u = 0 \qquad [2]$$

which governs the following phenomena: equation for the potential or stream function of plane, incompressible irrotational fluids; equation for some potential in linear elasticity, or the equation for the temperature in suitable conditions (stationary case; see below for the time-dependent case).

Another eqn of the form [1] is the hyperbolic equation

$$\frac{\partial^2 u}{\partial t^2} - \frac{\partial^2 u}{\partial x^2} = 0 \qquad [3]$$

which governs, for example, linear acoustics in one dimension (sound pipes) or the propagation of an elastic wave along an elastic string.

A third equation of type [1] is the linear parabolic equation

$$\frac{\partial u}{\partial t} - \frac{\partial^2 u}{\partial x^2} = 0 \qquad [4]$$

also called the heat equation, which governs, under appropriate circumstances, the temperature ($u(x,t) =$ temperature at $x$ at time $t$).

All these equations are well understood from the mathematical viewpoint and many well-posedness results are available. A fundamental difference between eqns [2], [3], and [4] is that for [2] and [4] the solution is as smooth as allowed by the data (forcing terms, boundary data not mentioned here), whereas the solutions of [3] usually present some discontinuities corresponding to the propagation of a wave or wave front.

A considerable jump of complexity occurs if we consider the equation of transonic flows in which

$$\begin{aligned} a &= \left(1 - \frac{1}{v^2}\left(\frac{\partial u}{\partial x}\right)^2\right) \\ b &= -\frac{2}{v^2}\frac{\partial u}{\partial x}\frac{\partial u}{\partial y} \\ c &= 1 - \frac{1}{v^2}\left(\frac{\partial u}{\partial y}\right)^2 \end{aligned} \qquad [5]$$

where $v = v(x,y)$ is the local speed of sound. This is a mixed second-order equation: it is elliptic in the subsonic region where $M < 1, M$ the Mach number being the ratio of the velocity

$$|\text{grad } u| = \left(\left(\frac{\partial u}{\partial x}\right)^2 + \left(\frac{\partial u}{\partial y}\right)^2\right)^{1/2}$$

to the local velocity of sound $v = v(x,y)$; eqn [1] (with [5]) is hyperbolic in the supersonic region, where $M > 1$ and parabolic on the sonic line $M = 1$. Essentially no result of well-posedness is available for this problem, and it is not even totally clear what are the boundary conditions that one should associate to [1]–[5] to obtain a well-posed problem.

Intermediate mathematical situations are encountered with the Navier–Stokes and Euler equations, which govern the motion of fluids in the viscous and inviscid cases, respectively. A number of mathematical results are available for these equations (*see* Compressible Flows: Mathematical Theory, Incompressible Euler Equations: Mathematical Theory, Viscous Incompressible Fluids: Mathematical Theory, Inviscid Flows); but other questions are still open, including the famous Clay prize problem, which is: to show that the solutions of the (viscous, incompressible) Navier–Stokes equations, in space dimension three, remain smooth for all time, or to exhibit an example of appearance of singularity. A prize of US$ 1 million will be awarded by the Clay Foundation for the solution of this problem.

For compressible fluids, the Navier–Stokes equations expressing conservation of angular momentum and mass read

$$\rho\left(\frac{\partial \boldsymbol{u}}{\partial t} + (\boldsymbol{u}\cdot\nabla)\boldsymbol{u}\right) - \mu\Delta\boldsymbol{u} + \nabla p - (\lambda+\mu)\nabla(\nabla\cdot\boldsymbol{u}) = 0 \qquad [6]$$

$$\frac{\partial \rho}{\partial t} + \nabla(\rho\boldsymbol{u}) = 0 \qquad [7]$$

Here $\boldsymbol{u} = \boldsymbol{u}(\boldsymbol{x}, t)$ is the velocity at $\boldsymbol{x}$ at time $t$, $p = p(\boldsymbol{x}, t)$ the pressure, $\rho$ the density; $\lambda, \mu$ are viscosity coefficients, $\mu > 0, 3\lambda + 2\mu \geq 0$. When $\mu = \lambda = 0$, we obtain the Euler equation (*see* Compressible Flows: Mathematical Theory). If the fluid is incompressible and homogeneous, then the density is constant, $\rho = \rho_0$ and

$$\nabla\cdot\boldsymbol{u} = 0 \qquad [8]$$

so that eqn [8] replaces eqn [7] and eqn [6] simplifies accordingly.

Finally, let us mention still different nonlinear PDEs corresponding to nonlinear wave phenomena, namely the Korteweg–de Vries (*see* Korteweg–de Vries Equation and Other Modulation Equations)

$$\frac{\partial u}{\partial t} + u\frac{\partial u}{\partial x} + \frac{\partial^3 u}{\partial x^3} = 0 \qquad [9]$$

and the nonlinear Schrödinger equation (*see* Nonlinear Schrödinger Equations)

$$\frac{\partial u}{\partial z} + i\beta\frac{\partial^2 A}{\partial t^2} - \mathrm{i}\,\gamma|A|^2 A + \alpha A = 0 \qquad [10]$$

$\alpha, \gamma > 0$. These equations are very different from eqns [1]–[8] and are reasonably well understood from the mathematical point of view; they produce and describe the amazing physical wave phenomenon known as the soliton (*see* Solitons and Kac–Moody Lie Algebras).

This article is based on the Appendix of the book by Miranville and Temam quoted below, with the authorization of Cambridge University Press.

## Introduction

Let us recall that there are basically two algebraic infinite-dimensional distribution theories:

- The first one is white-noise analysis (Hida *et al.* 1993, Berezansky and Kondratiev 1995), and uses Fock spaces and the algebra of creation and annihilation operators.
- The second one is the noncommutative differential geometry of Connes (1988) and uses the entire cyclic complex.

If we disregard the differential operations, these two distribution theories are very similar. Let us recall quickly their background on geometrical examples. Let $V$ be a compact Riemannian manifold and $E$ a Hermitian bundle on it. We consider an elliptic Laplacian $\Delta_E$ acting on sections $\omega$ of this bundle. We consider the Sobolev space $H_k, k > 0$, of sections $\omega$ of $E$ such that:

$$\int_V \left\langle \left(\Delta_E^k + 1\right)\omega, \omega \right\rangle \mathrm{d}m_V < \infty \qquad [1]$$

where $\mathrm{d}m_V$ is the Riemannian measure on $V$ and $\langle\,,\rangle$ the Hermitian structure on $V$. $H_{k+1}$ is included in $H_k$ and the intersection of all $H_k$ is nothing other than the space of smooth sections of the bundle $E$, by the Sobolev embedding theorem.

Let us quickly recall Connes' distribution theory: let $\alpha(n)$ be a sequence of real strictly positive numbers. Let

$$\sigma = \sum \sigma_n \qquad [2]$$

where $\sigma_n$ belongs to $H_k^{\otimes n}$ with the Hilbert structure naturally inherited from the Hilbert structure of $H_k$. We put, for $C > 0$,

$$\|\sigma\|_{1,C,k} = \sum C^n \alpha(n) \|\sigma_n\|_{H_k^{\otimes n}} \qquad [3]$$

The set of $\sigma$ such that $\|\sigma\|_{1,C,k} < \infty$ is a Banach space called $\mathrm{Co}_{C,k}$. The space of Connes functionals $\mathrm{Co}_{\infty-}$ is the intersection of these Banach spaces for $C > 0$ and $k > 0$ endowed with its natural topology. Its topological dual $\mathrm{Co}_{-\infty}$ is the space of distributions in Connes' sense.

**Remark** We do not give the original version of the space of Connes where tensor products of Banach algebras appear but we use here the presentation of Jones and Léandre (1991).

Let us now quickly recall the theory of distributions in the white-noise sense. The main tools are Fock spaces. We consider interacting Fock spaces (Accardi and Bożejko (1998)) constituted of $\sigma$ written as in [2] such that

$$\|\sigma\|_{2,C,k}^2 = \sum C^n \alpha(n)^2 \|\sigma_n\|_{H_k^{\otimes n}}^2 < \infty \qquad [4]$$

The space of white-noise functionals $\mathrm{WN}_{\infty-}$ is the intersection of these interacting Fock spaces $\Lambda_{k,C}$ for $C > 0, k > 0$. Its topological dual $\mathrm{WN}_{-\infty}$ is called the space of white-noise distributions.

Traditionally, in white-noise analysis, one considers in [2] the case where $\sigma_n$ belongs to the symmetric tensor product of $H_k$ endowed with its natural Hilbert structure. We get a symmetric Fock space $\Lambda^{\mathrm{s}}_{C,k}$ and another space of white-noise distributions $\mathrm{WN}_{\mathrm{s},-\infty}$. The interest in considering symmetric Fock spaces, instead of interacting Fock spaces, arises from the characterization theorem of Potthoff–Streit. For the sake of simplicity, let us consider the case where $\alpha(n) = 1$. If $\omega$ if a smooth section of $E$, we can consider its exponential $\exp[\omega] = \sum n!^{-1}\omega^{\otimes n}$. If we consider an element $\Phi$ of $\mathrm{WN}_{\mathrm{s},-\infty}$, $\langle\Phi, \exp[\omega]\rangle$ satisfies two natural conditions:

1. $|\langle\Phi, \exp[\omega]\rangle| \le C\exp[C\|\omega\|_{H_k}^2]$ for some $k > 0$.
2. $z \to \langle\Phi, \exp[\omega_1 + z\omega_2]\rangle$ is entire.

The Potthoff–Streit theorem states the opposite: a functional which sends a smooth section of $V$ into a Hilbert space and which satisfies the two previous requirements defines an element of $\mathrm{WN}_{\mathrm{s},-\infty}$ with values in this Hilbert space. Moreover, if the functional depends holomorphically on a complex parameter, then the distribution depends holomorphically on this complex parameter as well.

The Potthoff–Streit theorem allows us to define flat Feynman path integrals as distributions. It is the opposite point of view, from the traditional point of view of physicists, where generally path integrals are defined by convergence of the finite-dimensional lattice approximations. Hida–Streit have proposed replacing the approach of physicists by defining path integrals as infinite-dimensional distributions, and by using Wiener chaos. Getzler was the first who thought of replacing Wiener chaos by other functionals on path spaces, that is, Chen iterated integrals. In this article, we review the recent

developments of path integrals in this framework. We will mention the following topics:

- infinite-dimensional volume element
- Feynman path integral on a manifold
- Bismut–Chern character and path integrals
- fermionic Brownian motion

The reader who is interested in various rigorous approaches to path integrals should consult the review of Albeverio (1996).

## Infinite-Dimensional Volume Element

Let us recall that the Lebesgue measure does not exist generally as a measure in infinite dimensions. For instance, the Haar measure on a topological group exists if and only if the topological group is locally compact. Our purpose in this section is to define the Lebesgue measure as a distribution.

We consider the set $C^\infty(M;N)$ of smooth maps $x(.)$ from a compact Riemannian manifold $M$ into a compact Riemannian manifold $N$ endowed with its natural Fréchet topology. $S$ is the generic point of $M$ and $x$ the generic point of $N$. We would like to say that the law of $x(S_i)$ for a finite set of $n$ different points $S_i$ under the formal Lebesgue measure $\mathrm{d}D(x(.))$ on $C^\infty(M;N)$ is the product law of $n\,\mathrm{d}m_N$ (This means that the Lebesgue measure on $C^\infty(M;N)$ is a cylindrical measure). Let us consider a smooth function $\sigma_n$ from $(M\times N)^n$ into $C$. We introduce the associated functional $F(\sigma_n)(x(.))$ on $C^\infty(M;N)$:

$$F(\sigma_n)(x(.)) = \int_{M^n} \sigma_n(S_1,\ldots,S_n,x(S_1),\ldots,x(S_n))\mathrm{d}m_{M^n} \qquad [5]$$

If we use formally the Fubini formula, we get

$$\int_{C^\infty(M;N)} F(\sigma_n)(x(.))\mathrm{d}D(x(.)) = \int_{M^n\times N^n} F(S_1,\ldots,S_n,x_1,\ldots,x_n)\mathrm{d}m_{M^n\times N^n} \qquad [6]$$

We will interpret this formal remark in the framework of the distribution theories of the introduction. We consider $V = M\times N$ and $E$ the trivial complex line bundle endowed with the trivial metric and $\alpha(n)=1$. We can define the associated algebraic spaces $\mathrm{Co}_{-\infty}$ and $\mathrm{WN}_{-\infty}$ and we can extend to $\mathrm{Co}_{\infty-}$ and $\mathrm{WN}_{\infty-}$ the map $F$ of [5]. $F$ sends elements of $\mathrm{Co}_{\infty-}$ and $\mathrm{WN}_{\infty-}$ into the set of continuous bounded maps of $C^\infty(M;N)$ where we can extend [6]. We obtain:

**Theorem 1** $\sigma\to\int_{C^\infty(M;N)}F(\sigma)(x(.))\mathrm{d}D(x(.))$ *defines an element of* $\mathrm{Co}_{-\infty}$ *or* $\mathrm{WN}_{-\infty}$.

## Feynman Path Integral on a Manifold

Let us introduce the flat Brownian motion $s\to B(s)$ in $\boldsymbol{R}^d$ starting from 0. It has formally the Gaussian law

$$Z^{-1}\exp\left[-\frac{1}{2}\int_0^1\left|\frac{\mathrm{d}}{\mathrm{d}s}B(s)\right|^2\mathrm{d}s\right]\mathrm{d}D(B(.))$$

where $\mathrm{d}D(B(.))$ is the formal Lebesgue measure on finite-energy paths starting from 0 in $\boldsymbol{R}^d$ (the partition function $Z$ is infinite!). Let $N$ be a compact Riemannian manifold of dimension $d$ endowed with the Levi–Civita connection. The stochastic parallel transport on semimartingales for the Levi-Civita connection exists almost surely (Ikeda and Watanabe 1981). Let us introduce the Laplace–Beltrami operator $\Delta_N$ on $N$ and the Eells–Elworthy–Malliavin equation starting from $x$ (Ikeda and Watanabe 1981):

$$\mathrm{d}x_s(x) = \tau_s(x)\mathrm{d}B(s) \qquad [7]$$

where $B(.)$ is a Brownian motion in $T_x(M)$ starting from 0 and $s\to\tau_s(x)$ is the stochastic parallel transport associated to the solution. $s\to x_s(x)$ is called the Brownian motion on $N$. The heat semigroup associated to $\Delta_N$ satisfies $\exp[-t\Delta_N]f(x)=E[f(x_t(x))]$ for $f$ continuous on $N$. Formally, there is a Jacobian which appears in the transformation of the formal path integral which governs $B(.)$ into the formal path integral which governs $x_.(x)$

$$\mathrm{d}\mu_x(1) = Z_x^{-1}\exp[-I(x_.(x))/2]\mathrm{d}D(x_.(x)) \qquad [8]$$

It was shown by B DeWitt, in a formal way, that the action in [8] is not the energy of the path and that there are some counter-terms in the action where the scalar curvature $K$ of $N$ appears (see Andersson and Driver (1999) and Sidorova *et al.* (2004) for rigorous results). In order to describe Feynman path integrals, we perform, as it is classical in physics, analytic continuation on the semigroup and on the "measure" $\mathrm{d}\mu_x(1)$ such that we get a distribution $\mathrm{d}\mu_x(\alpha)$ which depends holomorphically on $\alpha$, $\mathrm{Re}\,\alpha\geq 0$.

In order to return to the formalism of the introduction, we consider $V=N$, $E$ the trivial complex line bundle and the symmetric Fock space and $\alpha(n)=1$. To $\sigma_n/n!$ belonging to $H_k^{\otimes\mathrm{sym}\,n}$ we associate the functional on $P(N)$, the smooth path space on $N$:

$$F(\sigma_n/n!)(x(.)) = \int_{\Delta_n}\sigma_n(x(s_1),\ldots,x(s_n))\mathrm{d}s_1\cdots\mathrm{d}s_n \qquad [9]$$

where $\Delta_n$ is the $n$-dimensional simplex of $[0,1]^n$ constituted of times $0<s_1<\cdots<s_n<1$ (Léandre (2003)). We remark that $F$ maps $\mathrm{WN}_{s,\infty-}$ into the set of bounded continuous functionals on $P(N)$. We

introduce an element $h$ of $L^2(N)$. The map which to $\omega$, a smooth function on $N$, associates $\exp[\alpha(\Delta_N + \omega)]h(\mathrm{Re}\,\alpha \le 0)$ satisfies the requirements (1) and (2) of the introduction and depends holomorphically on $\alpha$. This defines by the Potthoff–Streit theorem a distribution $\Phi_\alpha$ which depends holomorphically on $\alpha$, $\mathrm{Re}\,\alpha \le 0$ with values in $L^2(N)$. By uniqueness of analytic continuation, we obtain:

**Theorem 2** *If $P_x(N)$ is the space of smooth paths starting from $x$ in $N$, we have*

$$\langle \Phi_\alpha, \sigma \rangle = \left\{ x \to \int_{P_x(N)} F(\sigma) h(x(1)) \mathrm{d}\mu_x(-\alpha) \right\} \quad [10]$$

Instead of taking functions, we can consider as bundle $E$ the space of complex 1-forms on $N$. We then consider Chen (1973) iterated integrals:

$$F(\sigma_n)(x(.)) = \int_{\Delta_n} \langle \sigma_n(x(s_1), \ldots, x(s_n)), \mathrm{d}x(s_1), \ldots, \mathrm{d}x(s_n) \rangle \quad [11]$$

such that $F$ maps $\mathrm{WN}_{s,\infty-}$ into the set of measurable maps on $P(N)$. These maps are generally not bounded. Namely,

$$F(\exp[\omega]) = \exp\left[\int_0^1 \langle \omega(x(s)), \mathrm{d}x(s) \rangle\right] \quad [12]$$

instead of $\exp[\int_0^1 \omega(x(s))\mathrm{d}s]$ in the previous case. By using the Cameron–Martin–Girsanov–Maruyama formula and Kato perturbation theory, we get an analog of Theorem 2 for Chen iterated integrals, but for $\mathrm{Re}\,\alpha < 0$, because we have to deal with a perturbation of $\Delta_N$ by a drift when we want to check (1) and (2). The interest of this formalism is that the parallel transport belongs in some sense to the domain of the distribution and that we get the flat Feynman path integral from the curved one by using an analog of [7].

## Bismut–Chern Character and Path Integrals

Since we are concerned in this part with index theory, we replace the free path space of $N$ by the free smooth loop space $L(N)$. We consider the case where $V = N$ is a compact oriented Riemannian spin manifold and $E = E_- \oplus E_+$. $E_-$ is the bundle of complexified odd forms and $E_+$ is the bundle of complexified even forms. To $\sigma_n = n!^{-1}(\omega_1 + \omega_1^1) \otimes \cdots \otimes (\omega_n + \omega_n^1)$, we associate the even Chen (1973) iterated integral

$$F(\sigma_n) = \int_{\Delta_n} \left(\omega_1(\mathrm{d}x(s_1), .) + \omega_1^1 \mathrm{d}s_1\right) \wedge \cdots \wedge \left(\omega_n(\mathrm{d}x(s_n), .) + \omega_n^1 \mathrm{d}s_n\right) \quad [13]$$

where $s \to x(s)$ is a smooth loop in $N$, $\omega_i$ is of odd degree and $\omega_i^1$ is of even degree. Let us recall that even forms on the free loop space commute. $F(\sigma_n)$ is built from even forms on the free loop space, which commute. This explains why we have to consider the symmetric Fock space. Therefore, if $\sigma$ belongs to $\mathrm{WN}_{s,\infty-}$, then $F(\sigma) = \sum F^{2r}(\sigma)$, where $F^{2r}(\sigma)$ is a measurable form on $L(N)$ of degree $2r$ (see Jones and Léandre (1991) for an analogous statement in the stochastic context).

Let us explain why the free loop space is important in this context. Let $\mathrm{d}\nu_x(1)$ be the law of the Brownian bridge on $N$ starting from $x$ and coming back at $x$ at time 1: this is the law of the Brownian motion $x_.(x)$ subject to return in time 1 at its departure. Let $p_t(x, y)$ be the heat kernel associated with $x_t(x)$: the law of $x_t(x)$ is namely $p_t(x, y)\,\mathrm{d}m_N(y)$ (Ikeda and Watanabe 1981). We consider the Bismut–Høegh–Krohn measure on the continuous free loop space $L_0(N)$:

$$\mathrm{d}P = p_1(x, x)\mathrm{d}x \otimes \mathrm{d}\nu_x(1) \quad [14]$$

This satisfies

$$\mathrm{tr}[\exp[-s_1\Delta_N] f_1 \cdots f_n \exp[-(1 - s_n)\Delta_N]] = \int_{L_0(N)} f_1(x(s_1)) \cdots f_n(x(s_n)) \mathrm{d}P \quad [15]$$

(We are interested in the trace of the heat semigroup instead of the heat semigroup itself unlike in the previous section.)

Since $N$ is spin, we can consider the spin bundle $\mathrm{Sp} = \mathrm{Sp}_+ \oplus \mathrm{Sp}_-$ on it, the Clifford bundle Cl on it with its natural $\mathbb{Z}/2\mathbb{Z}$ gradation (Gilkey 1995). Let us recall that the Clifford algebra acts on the spinors. A form $\omega$ can be associated with an element $\tilde{\omega}$ of the Clifford bundle (Gilkey 1995). We consider the Brownian loop $x(.)$ associated to the Bismut–Høegh–Krohn measure. If $s < t$, we can define the stochastic parallel transport $\tilde{\tau}_{s,t}$ from $x(t)$ to $x(s)$ (we identify a loop to a path from $[0, 1]$ into $N$ with the same end values). We remark that with the notations of [13]

$$\int_{\Delta_n} \tilde{\tau}_{0,s_1}(\tilde{\omega}_1(\mathrm{d}x(s_1)) + \tilde{\omega}_1 \mathrm{d}s_1)\tilde{\tau}_{s_1,s_2} \ldots \times \tilde{\tau}_{s_{n-1},s_n}(\tilde{\omega}_n(\mathrm{d}x(s_n)) + \tilde{\omega}_n^1 \mathrm{d}s_n)\tilde{\tau}_{s_n,1} = A \quad [16]$$

is a random almost surely defined even element of the Clifford bundle over $x(0)$. Acting on $\mathrm{Sp}(x(0))$, it thus preserves the gradation. We consider its supertrace $\mathrm{tr}_s A = \mathrm{tr}_{\mathrm{Sp}_+} A - \mathrm{tr}_{\mathrm{Sp}_-} A$. This becomes a random variable on $L_0(N)$. We introduce the scalar curvature $K$ of the Levi–Civita connection on $N$, whose introduction arises from the Lichnerowicz formula given the square of the Dirac operator in terms of the horizontal

Laplacian on the spin bundle (Gilkey 1995). We consider the expression $\int_{L_0(N)} \exp[-\int_0^1 K(x(s)\,\mathrm{d}s/8]$ $\mathrm{tr}_s A\,\mathrm{d}P$. This expression can be extended to $\mathrm{WN}_{s,\infty-}$ and therefore defines an element Wi of $\mathrm{WN}_{s,-\infty}$ called by Getzler (Léandre 2002) the Witten current.

Bismut has introduced a Hermitian bundle $\xi$ on $M$. He deduces a bundle $\xi_\infty$ on $L(N)$: the fiber on a loop $x(.)$ is the space of smooth sections along the loop of $\xi$. We can suppose that $\xi$ is a sub-bundle given by a projector $p$ of a trivial bundle. We can suppose that the Hermitian connection on $\xi$ is the projection connection $A = p\mathrm{d}p$ such that its curvature is $R = p\mathrm{d}p \wedge p\mathrm{d}p$. Bismut (1985, 1987) has introduced the Bismut–Chern character:

$$\mathrm{Ch}(\xi_\infty) = \mathrm{tr}\left( \int_{\Delta_n} (A\mathrm{d}x(s_1) - R\mathrm{d}s_1) \wedge \cdots \wedge (A\mathrm{d}x(s_n) - R\mathrm{d}s_n) \right) \qquad [17]$$

$\mathrm{Ch}(\xi_\infty)$ is a collection of even forms equal to $F(\sigma(\xi))$, where $\sigma(\xi)$ belongs to $\mathrm{WN}_{s,\infty-}$. We obtain:

**Theorem 3** *Let us consider the index* $\mathrm{Ind}(D_\xi)$ *of the Dirac operator on N with auxiliary bundle* $\xi$ (Hida *et al.* 1993). *We have*

$$\langle \mathrm{Wi}, \sigma(\xi)\rangle = \mathrm{Ind}\ D_\xi \qquad [18]$$

The proof arises from the Lichnerowicz formula, the matricial Feynman–Kac formula, and the decomposition of the solution of a stochastic linear equation into the sum of iterated integrals.

By using the Potthoff–Streit theorem, we can do the analytic continuation of [18], as is suggested by the path-integral interpretation of Atiyah (1985) or Bismut (1985, 1987) of [18], motivated by the Duistermaat–Heckman or Berline–Vergne localization formulas on the free loop space. For this, these authors consider the Atiyah–Witten even form on the free loop space given by $I(x(.)) = \int_{S^1} |(\mathrm{d}/\mathrm{d}s)x(s)|^2 \mathrm{d}s + \mathrm{d}X_\infty$, where $\mathrm{d}X_\infty$ is the exterior derivative of the Killing form $X_\infty$ which to a vector $X(.)$ on the loop associates $\langle X_\infty, X(.)\rangle = \int_{S^1} \langle X(s), \mathrm{d}x(s)\rangle$. We should obtain the heuristic formula

$$\langle \mathrm{Wi}, \sigma\rangle = Z^{-1} \int_{L(M)} F(\sigma) \wedge \exp\left[-\frac{1}{2} I(x(.))\right] \qquad [19]$$

We refer to Léandre (2002) for details.

Let us remark that Bismut (1987) and Léandre (2003) has continued his formal considerations to the case of the index theorem for a family of Dirac operators. We consider a fibration $\pi: N \to B$ of compact manifolds. Bismut replaces [19] by an integral of forms on the set of loops of $N$ which project to a given loop of $B$. Bismut remarks that this integration in the fiber is related to filtering theory in stochastic analysis.

## Fermionic Brownian Motion

Alvarez-Gaumé has given a supersymmetric proof of the index theorem: the path representation of the index of the Dirac operator involves infinite-dimensional Berezin integrals, while in the previous section only integrals of forms on the free loop space were concerned. Rogers (1987) has given an interpretation of the work of Alvarez-Gaumé, which begins with the study of fermionic Brownian motion. Let us interpret the considerations of Rogers (1987) in this framework.

We consider $\mathbf{C}^d$. $H$ is the space of $L^2$-maps from $[0,1]$ into $\mathbf{C}^d$. We denote such a path by $\phi(s) = (\phi_1(s), \ldots, \phi_d(s))$, where $\phi_i(s) = q_i(s) + \sqrt{-1}p_i(s)$. $p_i(s)$ is the $i$th momentum and $q_i(s)$ the $i$th position. We denote by $\hat{\Lambda}(H)$ the fermionic Fock space associated with $H$.

We introduce the bilinear antisymmetric form on $H$:

$$\Omega(\phi^1, \phi^2) = \sqrt{-1} \sum_{i=1}^d \int_0^1 -p_i^1(s)\,\mathrm{d}q_i^2(s) + p_i^2(s)\,\mathrm{d}q_i^1(s) \qquad [20]$$

and we consider the formal expression $\exp[\Omega] = \sum_{n=0}^\infty n!^{-1}\Omega^{\wedge n}$. We define a state on $\hat{\Lambda}^2(H)$ by $\omega(\phi^1 \wedge \phi^2) = \Omega(\phi^1, \phi^2)$. We put $\hat{\phi}_i(s) = 1_{[0,s]} + \sqrt{-1}1_{[0,s]}$ where we take the $i$th coordinate in $\mathbf{C}^d$. We obtain, if $s_1 < s_2$,

$$\omega(\hat{\phi}_i(s_1) \wedge \hat{\phi}_j(s_2)) = -\sqrt{-1}\delta_{i,j} \qquad [21]$$

where $\delta_{i,j}$ is the Kronecker symbol. We change the sign if $s_2 > s_1$ and we write 0 if $s_1 = s_2$.

We consider the finite-dimensional space Pol of fermionic polynomials on $\mathbf{C}^d$. Pol is endowed with a suitable norm, and we consider $\mathrm{Pol}^{\otimes n}$ endowed with the induced norm. We consider a formal series $\sigma = \sum \sigma_n$, where $\sigma_n$ belongs to $\mathrm{Pol}^{\otimes n}$. In order to simplify the treatment, we suppose that our fermionic polynomials do not contain constant terms. We introduce the following Banach norm:

$$\|\sigma\|_C = \sum \frac{C^n}{n!}\|\sigma_n\| \qquad [22]$$

We obtain the notion of Connes space $\mathrm{Co}_{\infty-}$ in this simpler context: $\sigma$ belongs to $\mathrm{Co}_{\infty-}$ if $\|\sigma\|_C < \infty$ for all C. If $\sigma_n = P_1 \otimes \cdots \otimes P_n$, we associate

$$F(\sigma_n) = \int_{\Delta_n} P_1(\hat{\phi}(s_1)) \wedge \cdots \wedge P_n(\hat{\phi}(s_n))\,\mathrm{d}s_1 \cdots \mathrm{d}s_n \qquad [23]$$

$F$ can be extended in an injective continuous map from $\mathrm{Co}_{\infty-}$ into $\hat{\Lambda}(H)$. By using [21], we get:

**Theorem 4** $\exp[\Omega]$ *is a distribution in the sense of Connes.*

We have only to use the formula [21] and

$$\langle \exp[\Omega], \phi^1 \wedge \phi^2 \cdots \wedge \phi^{2n} \rangle = \mathrm{Pf}\{\omega(\phi^i \wedge \phi^j)\} \qquad [24]$$

and to estimate the obtained Pfaffians when $n \to \infty$.

Theorem 4 allows us to give a rigorous interpretation of the fermionic Feynman–Kac formula of Rogers (1987). We refer to Roepstorff (1994) for details.

$\exp[\Omega]$ should give a rigorous interpretation to the Gaussian Berezin integral with formal density $\exp[\sqrt{-1}\int_0^1 \sum p_i(s)\, \mathrm{d}q_i(s)]$.

# Peakons

**D D Holm**, Imperial College, London, UK

## Introduction

Peakons are singular solutions of the dispersionless Camassa–Holm (CH) shallow-water wave equation in one spatial dimension. These are reviewed in the context of asymptotic expansions and Euler–Poincaré (EP) variational principles. The dispersionless CH equation generalizes to the EPDiff equation (defined subsequently in this article), whose singular solutions are peakon wave fronts in higher dimensions. The reduction of these singular solutions of CH and EPDiff to canonical Hamiltonian dynamics on lower-dimensional sets may be understood, by realizing that their solution ansatz is a momentum map, and momentum maps are Poisson.

Camassa and Holm (1993) discovered the "peakon" solitary traveling-wave solution for a shallow-water wave:

$$u(x,t) = c\mathrm{e}^{-|x-ct|/\alpha} \qquad [1]$$

whose fluid velocity $u$ is a function of position $x$ on the real line and time $t$. The peakon traveling wave

moves at a speed equal to its maximum height, at which it has a sharp peak (jump in derivative). Peakons are an emergent phenomenon, solving the initial-value problem for a partial differential equation (PDE) derived by an asymptotic expansion of Euler's equations using the small parameters of shallow-water dynamics. Peakons are nonanalytic solitons, which superpose as

$$u(x,t) = \sum_{a=1}^{N} p_a(t)\mathrm{e}^{-|x-q_a(t)|/\alpha} \qquad [2]$$

for sets $\{p\}$ and $\{q\}$ satisfying canonical Hamiltonian dynamics. Peakons arise for shallow-water waves in the limit of zero linear dispersion in one dimension. Peakons satisfy a PDE arising from Hamilton's principle for geodesic motion on the smooth invertible maps (diffeomorphisms) with respect to the $H^1$ Sobolev norm of the fluid velocity. Peakons generalize to higher dimensions, as well. We explain how peakons were derived in the context of shallow-water asymptotics and describe some of their remarkable mathematical properties.

## Shallow-Water Background for Peakons

Euler's equations for irrotational incompressible ideal fluid motion under gravity with a free surface have an asymptotic expansion for shallow-water waves that contains two small parameters, $\epsilon$ and $\delta^2$, with ordering $\epsilon \geq \delta^2$. These small parameters are $\epsilon = a/h_0$ (the ratio of wave amplitude to mean depth) and $\delta^2 = (h_0/l_x)^2$ (the squared ratio of mean depth to horizontal length, or wavelength). Euler's equations are made nondimensional by introducing $x = l_x x'$ for horizontal position, $z = h_0 z'$ for vertical position, $t = (l_x/c_0)t'$ for time, $\eta = a\eta'$ for surface elevation, and $\varphi = (gl_x a/c_0)\varphi'$ for velocity potential, where $c_0 = \sqrt{gh_0}$ is the mean wave speed and $g$ is the constant gravity. The quantity $\sigma = \sigma'/(h_0 \rho c_0^2)$ is the dimensionless Bond number, in which $\rho$ is the mass density of the fluid and $\sigma'$ is its surface tension, both of which are taken to be constants. After dropping primes, this asymptotic expansion yields the nondimensional Korteweg–de Vries (KdV) equation for the horizontal velocity variable $u = \varphi_x(x,t)$ at "linear" order in the small dimensionless ratios $\epsilon$ and $\delta^2$, as the left-hand side of

$$u_t + u_x + \frac{3\epsilon}{2}uu_x + \frac{\delta^2}{6}(1-3\sigma)u_{xxx} = \mathrm{O}(\epsilon\delta^2) \qquad [3]$$

Here, partial derivatives are denoted using subscripts, and boundary conditions are $u = 0$ and $u_x = 0$ at spatial infinity on the real line. The famous $\mathrm{sech}^2(x-t)$ traveling-wave solutions (the solitons) for KdV [3] arise in a balance between its (weakly) nonlinear steepening and its third-order linear dispersion, when the quadratic terms in $\epsilon$ and $\delta^2$ on its right-hand side are neglected.

In eqn [3], a normal-form transformation due to Kodama (1985) has been used to remove the other possible quadratic terms of order $O(\epsilon^2)$ and $O(\delta^4)$. The remaining quadratic correction terms in the KdV equation [3] may be collected at order $O(\epsilon\delta^2)$. These terms may be expressed, after introducing a "momentum variable,"

$$m = u - \nu\delta^2 u_{xx} \qquad [4]$$

and neglecting terms of cubic order in $\epsilon$ and $\delta^2$, as

$$m_t + m_x + \frac{\epsilon}{2}(um_x + bmu_x) + \frac{\delta^2}{6}(1-3\sigma)u_{xxx} = 0 \qquad [5]$$

In the momentum variable $m = u - \nu\delta^2 u_{xx}$, the parameter $\nu$ is given by Dullin *et al.* (2001):

$$\nu = \frac{19 - 30\sigma - 45\sigma^2}{60(1-3\sigma)} \qquad [6]$$

Thus, the effects of $\delta^2$-dispersion also enter the nonlinear terms. After restoring dimensions in eqn [5] and rescaling velocity $u$ by $(b+1)$, the following "$b$-equation" emerges,

$$m_t + c_0 m_x + um_x + bmu_x + \Gamma u_{xxx} = 0 \qquad [7]$$

where $m = u - \alpha^2 u_{xx}$ is the dimensional momentum variable, and the constants $\alpha^2$ and $\Gamma/c_0$ are squares of length scales. When $\alpha^2 \to 0$, one recovers KdV from the $b$-equation [7], up to a rescaling of velocity. Any value of the parameter $b \neq -1$ may be achieved in eqn [7] by an appropriate Kodama transformation (Dullin *et al.* 2001).

As already emphasized, the values of the coefficients in the asymptotic analysis of shallow-water waves at quadratic order in their two small parameters only hold, modulo the Kodama normal-form transformations. Hence, these transformations may be used to advance the analysis and thereby gain insight, by optimizing the choices of these coefficients. The freedom introduced by the Kodama transformations among asymptotically equivalent equations at quadratic order in $\epsilon$ and $\delta^2$ also helps to answer the perennial question, "Why are integrable equations so ubiquitous when one uses asymptotics in modeling?"

### Integrable Cases of the *b*-equation [7]

The cases $b = 2$ and $b = 3$ are special values for which the $b$-equation becomes a completely integrable Hamiltonian system. For $b = 2$, eqn [7]

specializes to the integrable CH equation of Camassa and Holm (1993). The case $b = 3$ in [7] recovers the integrable equation of Degasperis and Procesi (1999) (henceforth DP equation). These two cases exhaust the integrable candidates for [7], as was shown using Painlevé analysis. The $b$-family of eqns [7] was also shown in Mikhailov and Novikov (2002) to admit the symmetry conditions necessary for integrability, only in the cases $b = 2$ for CH and $b = 3$ for DP.

The $b$-equation [7] with $b = 2$ was first derived in Camassa and Holm (1993) by using asymptotic expansions directly in the Hamiltonian for Euler's equations governing inviscid incompressible flow in the shallow-water regime. In this analysis, the CH equation was shown to be bi-Hamiltonian and thereby was found to be completely integrable by the inverse-scattering transform (IST) on the real line. Reviews of IST may be found, for example, in Ablowitz and Clarkson (1991), Dubrovin (1981), and Novikov *et al.* (1984). For discussions of other related bi-Hamiltonian equations, see Degasperis and Procesi (1999).

Camassa and Holm (1993) also discovered the remarkable peaked soliton (peakon) solutions of [1], [2] for the CH equation on the real line, given by [7] in the case $b = 2$. The peakons arise as solutions of [7], when $c_0 = 0$ and $\Gamma = 0$ in the absence of linear dispersion. Peakons move at a speed equal to their maximum height, at which they have a sharp peak (jump in derivative). Unlike the KdV soliton, the peakon speed is independent of its width ($\alpha$). Periodic peakon solutions of CH were treated in Alber *et al.* (1999). There, the sharp peaks of periodic peakons were associated with billiards reflecting at the boundary of an elliptical domain. These billiard solutions for the periodic peakons arise from geodesic motion on a triaxial ellipsoid, in the limit that one of its axes shrinks to zero length.

Before Camassa and Holm (1993) derived their shallow-water equation, a class of integrable equations existed, which was later found to contain eqn [7] with $b = 2$. This class of integrable equations was derived using hereditary symmetries in Fokas and Fuchssteiner (1981). However, eqn [7] was not written explicitly, nor was it derived physically as a shallow-water equation and its solution properties for $b = 2$ were not studied before Camassa and Holm (1993). (See Fuchssteiner (1996) for an insightful history of how the shallow-water equation [7] in the integrable case with $b = 2$ relates to the mathematical theory of hereditary symmetries.)

Equation [7] with $b = 2$ was recently re-derived as a shallow-water equation by using asymptotic methods in three different approaches in Dullin *et al.* (2001), in Fokas and Liu (1996), and also in Johnson [2002]. All the three derivations used different variants of the method of asymptotic expansions for shallow-water waves in the absence of surface tension. Only the derivation in Dullin *et al.* (2001) used the Kodama normal-form transformations to take advantage of the nonuniqueness of the asymptotic expansion results at quadratic order.

The effects of the parameter $b$ on the solutions of eqn [7] were investigated in Holm and Staley (2003), where $b$ was treated as a bifurcation parameter, in the limiting case when the linear dispersion coefficients are set to $c_0 = 0$ and $\Gamma = 0$. This limiting case allows several special solutions, including the peakons, in which the two nonlinear terms in eqn [7] balance each other in the "absence" of linear dispersion.

## Peakons: Singular Solutions without Linear Dispersion in One Spatial Dimension

Peakons were first found as singular soliton solutions of the completely integrable CH equation. This is eqn [7] with $b = 2$, now rewritten in terms of the velocity as

$$\begin{aligned} u_t + c_0 u_x + 3uu_x + \Gamma u_{xxx} \\ = \alpha^2(u_{xxt} + 2u_x u_{xx} + uu_{xxx}) \end{aligned} \qquad [8]$$

Peakons were found in Camassa and Holm (1993) to arise in the absence of linear dispersion. That is, they arise when $c_0 = 0$ and $\Gamma = 0$ in CH [8]. Specifically, peakons are the individual terms in the peaked $N$-soliton solution of CH [8] for its velocity

$$u(x,t) = \sum_{b=1}^{N} p_b(t) e^{-|x - q_b(t)|/\alpha} \qquad [9]$$

in the absence of linear dispersion. Each term in the sum is a soliton with a sharp peak at its maximum, hence the name "peakon." Expressed using its momentum, $m = (1 - \alpha^2 \partial_x^2)u$, the peakon velocity solution [9] of dispersionless CH becomes a sum over a delta functions, supported on a set of points moving on the real line. Namely, the peakon velocity solution [9] implies

$$m(x,t) = 2\alpha \sum_{b=1}^{N} p_b(t)\delta(x - q_b(t)) \qquad [10]$$

because of the relation $(1 - \alpha^2\partial_x^2)e^{-|x|/\alpha} = 2\alpha\delta(x)$. These solutions satisfy the $b$-equation [7] for any value of $b$, provided $c_0 = 0$ and $\Gamma = 0$.

Thus, peakons are "singular momentum solutions" of the dispersionless $b$-equation, although

they are not stable for every value of $b$. From numerical simulations (Holm and Staley 2003), peakons are conjectured to be stable for $b > 1$. In the integrable cases $b=2$ for CH and $b=3$ for DP, peakons are stable singular soliton solutions. The spatial velocity profile $e^{-|x|/\alpha}/2\alpha$ of each separate peakon in [9] is the Green's function for the Helmholtz operator on the real line, with vanishing boundary conditions at spatial infinity. Unlike the KdV soliton, whose speed and width are related, the width of the peakon profile is set by its Green's function, independently of its speed.

### Integrable Peakon Dynamics of CH

Substituting the peakon solution ansatz [9] and [10] into the dispersionless CH equation

$$m_t + um_x + 2mu_x = 0, \quad m = u - \alpha^2 u_{xx} \qquad [11]$$

yields Hamilton's canonical equations for the dynamics of the discrete set of peakon parameters $q_a(t)$ and $p_a(t)$:

$$\dot{q}_a(t) = \frac{\partial h_N}{\partial p_a} \quad \text{and} \quad \dot{p}_a(t) = -\frac{\partial h_N}{\partial q_a} \qquad [12]$$

for $a = 1, 2, \ldots, N$, with Hamiltonian given by (Camassa and Holm 1993):

$$h_N = \frac{1}{2}\sum_{a,\, b=1}^{N} p_a p_b e^{-|q_a - q_b|/\alpha} \qquad [13]$$

Thus, one finds that the points $x = q^a(t)$ in the peakon solution [9] move with the flow of the fluid velocity $u$ at those points, since $u(q^a(t), t) = \dot{q}^a(t)$. This means the $q^a(t)$ are Lagrangian coordinates. Moreover, the singular momentum solution ansatz [10] is the Lagrange-to-Euler map for an invariant manifold of the dispersionless CH equation [11]. On this finite-dimensional invariant manifold for the PDE [11], the dynamics is canonically Hamiltonian.

With Hamiltonian [13], the canonical equations [12] for the $2N$ canonically conjugate peakon parameters $p_a(t)$ and $q_a(t)$ were interpreted in Camassa and Holm (1993) as describing "geodesic motion" on the $N$-dimensional Riemannian manifold whose co-metric is $g^{ij}(\{q\}) = e^{-|q_i - q_j|/\alpha}$. Moreover, the canonical geodesic equations arising from Hamiltonian [13] comprise an integrable system for any number of peakons $N$. This integrable system was studied in Camassa and Holm (1993) for solutions on the real line, and in Alber *et al.* (1999) and Mckean and Constantin (1999) and references therein, for spatially periodic solutions.

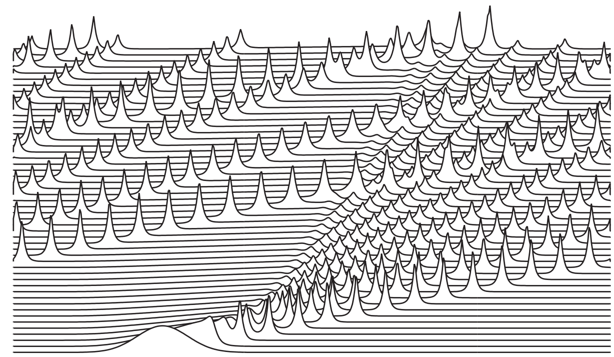

**Figure 1** A smooth localized (Gaussian) initial condition for the CH equation breaks up into an ordered train of peakons as time evolves (the time direction being vertical). The peakon train eventually wraps around the periodic domain, thereby allowing the leading peakons to overtake the slower emergent peakons from behind in collisions that cause phase shifts as discussed in Camassa and Holm (1993). Courtesy of Staley M.

Being a completely integrable Hamiltonian soliton equation, the continuum CH equation [8] has an associated isospectral eigenvalue problem, discovered in Camassa and Holm (1993) for any values of its dispersion parameters $c_0$ and $\Gamma$. Remarkably, when $c_0 = 0$ and $\Gamma = 0$, this isospectral eigenvalue problem has a purely "discrete" spectrum. Moreover, in this case, each discrete eigenvalue corresponds precisely to the time-asymptotic velocity of a peakon. This discreteness of the CH isospectrum in the absence of linear dispersion implies that only the singular peakon solutions [10] emerge asymptotically in time, in the solution of the initial-value problem for the dispersionless CH equation [11]. This is borne out in numerical simulations of the dispersionless CH equation [11], starting from a smooth initial distribution of velocity (Fringer and Holm 2001, Holm and Staley 2003).

**Figure 1** shows the emergence of peakons from an initially Gaussian velocity distribution and their subsequent elastic collisions in a periodic one-dimensional domain. This figure demonstrates that singular solutions dominate the initial-value problem and, thus, that it is imperative to go beyond smooth solutions for the CH equation; the situation is similar for the EPDiff equation.

### Peakons as Mechanical Systems

Being governed by canonical Hamiltonian equations, each $N$-peakon solution can be associated with a mechanical system of moving particles. Calogero (1995) further extended the class of mechanical systems of this type. The $r$-matrix approach was applied to the Lax pair formulation of the $N$-peakon system for CH by Ragnisco and Bruschi (1996), who also pointed out the connection

of this system with the classical Toda lattice. A discrete version of the Adler–Kostant–Symes factorization method was used by Suris (1996) to study a discretization of the peakon lattice, realized as a discrete integrable system on a certain Poisson submanifold of gl($N$) equipped with an $r$-matrix Poisson bracket. Beals *et al.* (1999) used the Stieltjes theorem on continued fractions and the classical moment problem for studying multipeakon solutions of the CH equation. Generalized peakon systems are described for any simple Lie algebra by Alber *et al.* (1999).

#### Pulsons: Generalizing the Peakon Solutions of the Dispersionless $b$-Equation for Other Green's Functions

The Hamiltonian $h_N$ in eqn [13] depends on the Green's function for the relation between velocity $u$ and momentum $m$. However, the singular momentum solution ansatz [10] is "independent" of this Green's function. Thus, as discovered in Fringer and Holm (2001), the singular momentum solution ansatz [10] for the dispersionless equation

$$m_t + um_x + 2mu_x = 0, \quad \text{with } u = g * m \qquad [14]$$

provides an invariant manifold on which canonical Hamiltonian dynamics occurs, for any choice of the Green's function $g$ relating velocity $u$ and momentum $m$ by the convolution $u = g * m$.

The fluid velocity solutions corresponding to the singular momentum ansatz [10] for eqn [14] are the "pulsons". Pulsons are given by the sum over $N$ velocity profiles determined by the Green's function $g$, as

$$u(x, t) = \sum_{a=1}^{N} p_a(t) g(x, q_a(t)) \qquad [15]$$

Again for [14], the singular momentum ansatz [10] results in a finite-dimensional invariant manifold of solutions, whose dynamics is canonically Hamiltonian. The Hamiltonian for the canonical dynamics of the $2N$ parameters $p_a(t)$ and $q_a(t)$ in the "pulson" solutions [15] of eqn [14] is

$$h_N = \frac{1}{2} \sum_{a,\, b=1}^{N} p_a p_b \, g(q_a, q_b) \qquad [16]$$

Again, for the pulsons, the canonical equations for the invariant manifold of singular momentum solutions provide a phase-space description of geodesic motion, this time with respect to the co-metric given by the Green's function $g$. Mathematical analysis and numerical results for the dynamics of these pulson solutions are given in Fringer and Holm (2001). These results describe how the collisions of pulsons [15] depend upon their shape.

#### Compactons in the $1/\alpha^2 \to 0$ Limit of CH

As mentioned earlier, in the limit that $\alpha^2 \to 0$, the CH equation [8] becomes the KdV equation. In contrast, when $1/\alpha^2 \to 0$, CH becomes the Hunter–Zheng equation (Hunter and Zheng 1994):

$$(u_t + uu_x)_{xx} = \tfrac{1}{2}\left(u_x^2\right)_x$$

This equation has "compacton" solutions, whose collision dynamics was studied numerically and put into the present context in Fringer and Holm (2001). The corresponding Green's function satisfies $-\partial_x{}^2 g(x) = 2\delta(x)$, so it has the triangular shape, $g(x) = 1 - |x|$ for $|x| < 1$, and vanishes otherwise, for $|x| \geq 1$. That is, the Green's function in this case has compact support, hence the name "compactons" for these pulson solutions, which as a limit of the integrable CH equations are true solitons, solvable by IST.

#### Pulson Solutions of the Dispersionless $b$-Equation

Holm and Staley (2003) give the pulson solutions of the traveling-wave problem and their elastic collision properties for the dispersionless $b$-equation:

$$m_t + um_x + bmu_x = 0, \quad \text{with } u = g * m \qquad [17]$$

with any (symmetric) Green's function $g$ and for any value of the parameter $b$. Numerically, pulsons and peakons are both found to be stable for $b > 1$ (Holm and Staley 2003). The reduction to "noncanonical" Hamiltonian dynamics for the invariant manifold of singular momentum solutions [10] of the other integrable case $b = 3$ with peakon Green's function $g(x, y) = \mathrm{e}^{-|x-y|/\alpha}$ is found in Degasperis and Procesi (1999) and Degasperis *et al.* (2002).

### Euler–Poincaré Theory in More Dimensions

#### Generalizing the Peakon Solutions of the CH Equation to Higher Dimensions

In Holm and Staley (2003), weakly nonlinear analysis and the assumption of columnar motion in the variational principle for Euler's equations are found to produce the two-dimensional generalization of the dispersionless CH equation [11]. This generalization is the EP equation (Holm *et al.* 1998a, b) for the Lagrangian consisting of the kinetic energy:

$$\ell = \frac{1}{2} \int \left[ |\boldsymbol{u}|^2 + \alpha^2 (\operatorname{div} \boldsymbol{u})^2 \right] \mathrm{d}x \, \mathrm{d}y \qquad [18]$$

in which the fluid velocity $\boldsymbol{u}$ is a two-dimensional vector. Evolution generated by kinetic energy in

Hamilton's principle results in geodesic motion, with respect to the velocity norm $\|\boldsymbol{u}\|$, which is provided by the kinetic-energy Lagrangian. For ideal incompressible fluids governed by Euler's equations, the importance of geodesic flow was recognized by Arnol'd (1966) for the $L^2$ norm of the fluid velocity. The EP equation generated by any choice of kinetic-energy norm without imposing incompressibility is called "EPDiff," for "Euler–Poincaré equation for geodesic motion on the diffeomorphisms." EPDiff is given by (Holm *et al.* 1998a):

$$\left(\frac{\partial}{\partial t} + \boldsymbol{u} \cdot \nabla\right)\boldsymbol{m} + \nabla \boldsymbol{u}^{\mathrm{T}} \cdot \boldsymbol{m} + \boldsymbol{m}(\operatorname{div} \boldsymbol{u}) = 0 \qquad [19]$$

with momentum density $\boldsymbol{m} = \delta\ell/\delta\boldsymbol{u}$, where $\ell = (1/2)\|\boldsymbol{u}\|^2$ is given by the kinetic energy, which defines a norm in the fluid velocity $\|\boldsymbol{u}\|$, yet to be determined. By design, this equation has no contribution from either potential energy or pressure. It conserves the velocity norm $\|\boldsymbol{u}\|$ given by the kinetic energy. Its evolution describes geodesic motion on the diffeomorphisms with respect to this norm (Holm *et al.* 1998a).

An alternative way of writing the EPDiff equation [19] in either two or three dimensions is

$$\frac{\partial}{\partial t}\boldsymbol{m} - \boldsymbol{u} \times \operatorname{curl} \boldsymbol{m} + \nabla(\boldsymbol{u} \cdot \boldsymbol{m}) + \boldsymbol{m}(\operatorname{div} \boldsymbol{u}) = 0 \qquad [20]$$

This form of EPDiff involves all three differential operators: curl, gradient, and divergence. For the kinetic-energy Lagrangian $\ell$ given in [18], which is a norm for "irrotational" flow (with $\operatorname{curl} \boldsymbol{u} = 0$), we have the EPDiff equation [19] with momentum $\boldsymbol{m} = \delta\ell/\delta\boldsymbol{u} = \boldsymbol{u} - \alpha^2\nabla(\operatorname{div} \boldsymbol{u})$.

EPDiff [19] may also be written intrinsically as

$$\frac{\partial}{\partial t}\frac{\delta\ell}{\delta\boldsymbol{u}} = -\mathrm{ad}^*_{\boldsymbol{u}}\frac{\delta\ell}{\delta\boldsymbol{u}} \qquad [21]$$

where $\mathrm{ad}^*$ is the $L^2$ dual of the ad-operation (commutator) for vector fields (see Arnol'd and Khesin (1998) and Marsden and Ratiu (1999) for additional discussions of the beautiful geometry underlying this equation).

### Reduction to the Dispersionless CH Equation in One Dimension

In one dimension, the EPDiff equations [19]–[21] with Lagrangian $\ell$ given in [18] simplify to the dispersionless CH equation [11]. The dispersionless limit of the CH equation appears, because potential energy and pressure have been ignored.

### Strengthening the Kinetic-Energy Norm to Allow for Circulation

The kinetic-energy Lagrangian [18] is a norm for irrotational flow, with $\operatorname{curl} \boldsymbol{u} = 0$. However, inclusion of rotational flow requires the kinetic-energy norm to be strengthened to the $H^1_\alpha$ norm of the velocity, defined as

$$\begin{aligned}\ell &= \frac{1}{2}\int\left[|\boldsymbol{u}|^2 + \alpha^2(\operatorname{div} \boldsymbol{u})^2 + \alpha^2(\operatorname{curl} \boldsymbol{u})^2\right]\mathrm{d}x\,\mathrm{d}y \\ &= \frac{1}{2}\int\left[|\boldsymbol{u}|^2 + \alpha^2|\nabla\boldsymbol{u}|^2\right]\mathrm{d}x\,\mathrm{d}y = \frac{1}{2}\|\boldsymbol{u}\|^2_{H^1_\alpha}\end{aligned} \qquad [22]$$

Here, we assume boundary conditions that give no contributions upon integrating by parts. The corresponding EPDiff equation is [19] with $\boldsymbol{m} \equiv \delta\ell/\delta\boldsymbol{u} = \boldsymbol{u} - \alpha^2\Delta\boldsymbol{u}$. This expression involves inversion of the familiar Helmholtz operator in the (nonlocal) relation between fluid velocity and momentum density. The $H^1_\alpha$ norm $\|\boldsymbol{u}\|^2_{H^1_\alpha}$ for the kinetic energy [22] also arises in three dimensions for turbulence modeling based on Lagrangian averaging and using Taylor's hypothesis that the turbulent fluctuations are "frozen" into the Lagrangian mean flow (Foias *et al.* 2001).

### Generalizing the CH Peakon Solutions to *n* Dimensions

Building on the peakon solutions [9] for the CH equation and the pulsons [15] for its generalization to other traveling-wave shapes in Fringer and Holm (2001), Holm and Staley (2003) introduced the following measure-valued singular momentum solution ansatz for the $n$-dimensional solutions of the EPDiff equation [19]:

$$\boldsymbol{m}(\boldsymbol{x}, t) = \sum_{a=1}^{N}\int \boldsymbol{P}^a(s,t)\delta(\boldsymbol{x} - \boldsymbol{Q}^a(s,t))\,\mathrm{d}s \qquad [23]$$

These singular momentum solutions, called "diffeons," are vector density functions supported in $\mathbb{R}^n$ on a set of $N$ surfaces (or curves) of codimension $(n-k)$ for $s \in \mathbb{R}^k$ with $k < n$. They may, for example, be supported on sets of points (vector peakons, $k = 0$), one-dimensional filaments (strings, $k = 1$), or two-dimensional surfaces (sheets, $k = 2$) in three dimensions.

Figure 2 shows the results for the EPDiff equation when a straight peakon segment of finite length is created initially moving rightward (East). Because of propagation along the segment in adjusting to the condition of zero speed at its ends and finite speed in its interior, the initially straight segment expands outward as it propagates and curves into a peakon "bubble."

Figure 3 shows an initially straight segment whose velocity distribution is exponential in the transverse

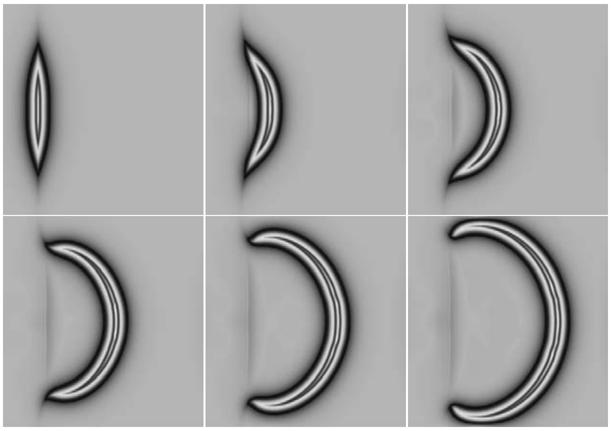

**Figure 2** A peakon segment of finite length is initially moving rightward (east). Because its speed vanishes at its ends and it has fully two-dimensional spatial dependence, it expands into a peakon "bubble" as it propagates. (The various shades indicate different speeds. Any transverse slice will show a wave profile with a maximum at the center of the wave, which falls exponentially with distance away from the center.)

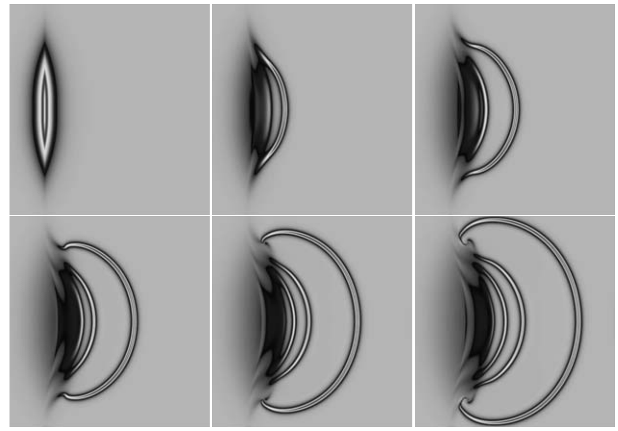

**Figure 3** An initially straight segment of velocity distribution whose exponential profile is wider than the width $\alpha$ for the peakon solution breaks up into a train of curved peakon "bubbles," each of width $\alpha$. This example illustrates the emergent property of the peakon solutions in two dimensions.

direction, but is wider than $\alpha$ for the peakon solution. This initial-velocity distribution evolves under EPDiff to separate into a train of curved peakon "bubbles," each of width $\alpha$. This example illustrates the emergent property of the peakon solutions in two dimensions. This phenomenon is observed in nature, for example, as trains of internal wave fronts in the South China Sea (Liu *et al.* 1998).

Substitution of the singular momentum solution ansatz [23] into the EPDiff equation [19] implies the following integro-partial-differential equations (IPDEs) for the evolution of the parameters $\{\boldsymbol{P}\}$ and $\{\boldsymbol{Q}\}$:

$$\begin{aligned}\frac{\partial}{\partial t}\boldsymbol{Q}^a(s,t) &= \sum_{b=1}^{N}\int \boldsymbol{P}^b(s',t)\, G\Big(\boldsymbol{Q}^a(s,t) - \boldsymbol{Q}^b(s',t)\Big)\,\mathrm{d}s' \\ \frac{\partial}{\partial t}\boldsymbol{P}^a(s,t) &= -\sum_{b=1}^{N}\int \Big(\boldsymbol{P}^a(s,t)\cdot\boldsymbol{P}^b(s',t)\Big) \times \frac{\partial}{\partial \boldsymbol{Q}^a(s,t)} G\Big(\boldsymbol{Q}^a(s,t) - \boldsymbol{Q}^b(s',t)\Big)\,\mathrm{d}s'\end{aligned} \quad [24]$$

Importantly for the interpretation of these solutions, the coordinates $s \in \mathbb{R}^k$ turn out to be Lagrangian coordinates. The velocity field corresponding to the momentum solution ansatz [23] is given by

$$\begin{aligned}\boldsymbol{u}(\boldsymbol{x},t) &= G * \boldsymbol{m} \\ &= \sum_{b=1}^{N}\int \boldsymbol{P}^b(s',t)\, G\Big(\boldsymbol{x} - \boldsymbol{Q}^b(s',t)\Big)\,\mathrm{d}s'\end{aligned} \quad [25]$$

for $\boldsymbol{u} \in \mathbb{R}^n$. When evaluated along the curve $\boldsymbol{x} = \boldsymbol{Q}^a(s,t)$, this velocity satisfies

$$\begin{aligned}\boldsymbol{u}(\boldsymbol{Q}^a(s,t),t) &= \sum_{b=1}^{N}\int \boldsymbol{P}^b(s',t) \times G\Big(\boldsymbol{Q}^a(s,t) - \boldsymbol{Q}^b(s',t)\Big)\,\mathrm{d}s' \\ &= \frac{\partial \boldsymbol{Q}^a(s,t)}{\partial t}\end{aligned} \quad [26]$$

Consequently, the lower-dimensional support sets defined on $\boldsymbol{x} = \boldsymbol{Q}^a(s,t)$ and parametrized by coordinates $s \in \mathbb{R}^k$ move with the fluid velocity. This means that the $s \in \mathbb{R}^k$ are Lagrangian coordinates. Moreover, eqns [24] for the evolution of these support sets are canonical Hamiltonian equations:

$$\frac{\partial}{\partial t}\boldsymbol{Q}^a(s,t) = \frac{\delta H_N}{\delta \boldsymbol{P}^a}, \qquad \frac{\partial}{\partial t}\boldsymbol{P}^a(s,t) = -\frac{\delta H_N}{\delta \boldsymbol{Q}^a} \quad [27]$$

The corresponding Hamiltonian function $H_N : (\mathbb{R}^n \times \mathbb{R}^n)^N \to \mathbb{R}$ is

$$H_N = \frac{1}{2}\iint \sum_{a,b=1}^{N}\Big(\boldsymbol{P}^a(s,t)\cdot\boldsymbol{P}^b(s',t)\Big) \times G(\boldsymbol{Q}^a(s,t), \boldsymbol{Q}_j(s',t))\,\mathrm{d}s\,\mathrm{d}s' \quad [28]$$

This is the Hamiltonian for geodesic motion on the cotangent bundle of a set of curves $\boldsymbol{Q}^a(s,t)$ with respect to the metric given by $G$. This dynamics was investigated numerically in Holm and Staley (2003) which can be referred to for more details of the solution properties. One important result found "numerically" in Holm and Staley (2003) is that only codimension-1 singular momentum solutions

appear to be stable under the evolution of the EPDiff equation. Thus,

*Stability for codimension-1 solutions: the singular momentum solutions of EPDiff are stable, as points on the line (peakons), as curves in the plane (filaments, or wave fronts), or as surfaces in space (sheets).*

Proving this stability result analytically remains an outstanding problem. The stability of peakons on the real line is proven in Constantin and Strauss (2000).

### Reconnections in Oblique Overtaking Collisions of Peakon Wave Fronts

Figures 4 and 5 show results of oblique wave front collisions producing reconnections for the EPDiff equation in two dimensions. Figure 4 shows a single oblique overtaking collision, as a faster expanding peakon wave front overtakes a slower one and reconnects with it at the collision point. Figure 5 shows a series of reconnections involving the oblique overtaking collisions of two trains of curved peakon filaments, or wave fronts.

### The Peakon Reduction is a Momentum Map

As shown in Holm and Marsden (2004), the singular solution ansatz [23] is a momentum map from the cotangent bundle of the smooth embeddings of lower-dimensional sets $\mathbb{R}^s \in \mathbb{R}^n$, to the dual of the Lie algebra of vector fields defined on these sets. (Momentum maps for Hamiltonian dynamics are reviewed in Marsden and Ratiu (1999), for example.) This geometric feature underlies the remarkable reduction properties of the EPDiff equation, and it also explains why the reduced equations must be Hamiltonian on the invariant manifolds of the singular solutions; namely, because

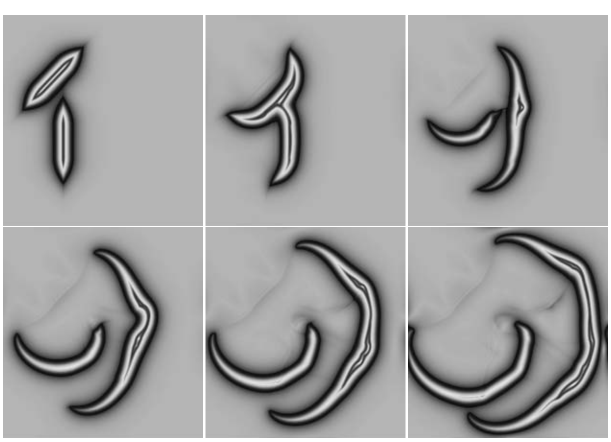

**Figure 4** A single collision is shown involving reconnection as the faster peakon segment initially moving southeast along the diagonal expands, curves, and obliquely overtakes the slower peakon segment initially moving rightward (east). This reconnection illustrates one of the collision rules for the strongly two-dimensional EPDiff flow.

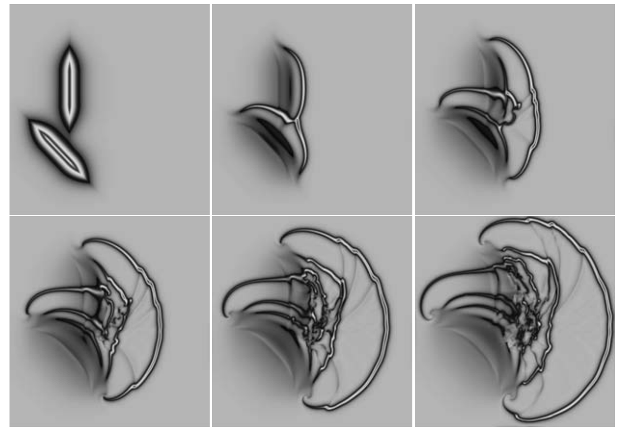

**Figure 5** A series of multiple collisions is shown involving reconnections as the faster wider peakon segment initially moving northeast along the diagonal expands, breaks up into a wave train of peakons, each of which propagates, curves, and obliquely overtakes the slower wide peakon segment initially moving rightward (east), which is also breaking up into a train of wave fronts. In this series of oblique collision, the now-curved peakon filaments exchange momentum and reconnect several times.

momentum maps are Poisson maps. This geometric feature also underlies the singular momentum solution [23] and its associated velocity [25] which generalize the peakon solutions, both to higher dimensions and to arbitrary kinetic-energy metrics. The result that the singular solution ansatz [23] is a momentum map helps to organize the theory, to explain previous results, and to suggest new avenues of exploration.

## Acknowledgment

The author is grateful to R Camassa, J E Marsden, T S Ratiu, and A Weinstein for their collaboration, help, and inspiring discussions over the years. He also thanks M F Staley for providing the figures obtained from his numerical simulations in the collaborations. ## Introduction

Percolation as a mathematical theory was introduced by Broadbent and Hammersley (1957), as a stochastic way of modeling the flow of a fluid or gas through a porous medium of small channels which may or may not let gas or fluid pass. It is one of the simplest models exhibiting a phase transition, and the occurrence of a critical phenomenon is central to the appeal of percolation. Having truly applied origins, percolation has been used to model the fingering and spreading of oil in water, to estimate whether one can build nondefective integrated circuits, and to model the spread of infections and forest fires. From a mathematical point of view, percolation is attractive because it exhibits relations between probabilistic and algebraic/topological properties of graphs.

To make the mathematical construction of such a system of channels, take a graph $\mathcal{G}$ (which originally was taken as $\mathbb{Z}^d$), with vertex set $\mathcal{V}$ and edge set $\mathcal{E}$, and make all the edges independently open (or passable) with probability $p$ or closed (or blocked) with probability $1-p$. Write $P_p$ for the corresponding probability measure on the set of configurations of open and closed edges – that model is called bond percolation. The collection of open edges thus forms a random subgraph of $\mathcal{G}$, and the original question stated by Broadbent was whether the connected component of the origin in that subgraph is finite or infinite.

A path on $\mathcal{G}$ is a sequence $v_1, v_2, \ldots$ of vertices of $\mathcal{G}$, such that for all $i \geq 1$, $v_i$ and $v_{i+1}$ are adjacent on $\mathcal{G}$. A path is called open if all the edges $\{v_i, v_{i+1}\}$ between successive vertices are open. The infiniteness of the cluster of the origin is equivalent to the existence of an unbounded open path starting from the origin.

There is an analogous model, called "site percolation," in which all edges are assumed to be passable, but the vertices are independently open or closed with probability $p$ or $1-p$, respectively. An open path is then a path along which all vertices are open. Site percolation is more general than bond percolation in the sense that the existence of a path for bond percolation on a graph $\mathcal{G}$ is equivalent to the existence of a path for site percolation on the covering graph of $\mathcal{G}$. However, site percolation on a given graph may not be equivalent to bond percolation on any other graph.

All graphs under consideration will be assumed to be connected, locally finite and quasitransitive. If $A, B \subset \mathcal{V}$, then $A \leftrightarrow B$ means that there exists an open path from some vertex of $A$ to some vertex of $B$; by a slight abuse of notation, $u \leftrightarrow v$ will stand for the existence of a path between sites $u$ and $v$, that is, the event $\{u\} \leftrightarrow \{v\}$. The open cluster $C(v)$ of the vertex $v$ is the set of all open vertices which are connected to $v$ by an open path:

$$C(v) = \{u \in \mathcal{V} : u \leftrightarrow v\}$$

The central quantity of the percolation theory is the percolation probability:

$$\theta(p) := P_p\{\mathbf{0} \leftrightarrow \infty\} = P_p\{|C(\mathbf{0})| = \infty\}$$

The most important property of the percolation model is that it exhibits a phase transition, that is, there exists a threshold value $p_c \in [0,1]$, such that the global behavior of the system is substantially different in the two regions $p < p_c$ and $p > p_c$. To make this precise, observe that $\theta$ is a nondecreasing function. This can be seen using Hammersley's joint construction of percolation systems for all $p \in [0,1]$ on $\mathcal{G}$: let $\{U(v), v \in \mathcal{V}\}$ be independent random variables, uniform in [0,1]. Declare $v$ to be $p$-open if $U(v) \leq p$, otherwise it is declared $p$-closed. The configuration of $p$-open vertices has the distribution $P_p$ for each $p \in [0,1]$. The collection of $p$-open vertices is nondecreasing in $p$, and therefore $\theta(p)$ is nondecreasing as well. Clearly, $\theta(0) = 0$ and $\theta(1) = 1$ (**Figure 1**).

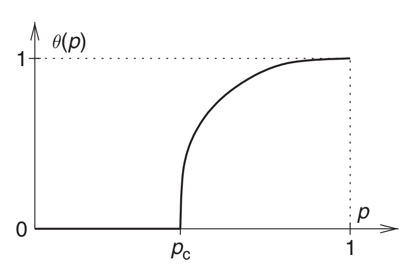

**Figure 1** The behavior of $\theta(p)$ around the critical point (for bond percolation).

The critical probability is defined as

$$p_c := p_c(\mathcal{G}) = \sup\{p : \theta(p) = 0\}$$

By definition, when $p < p_c$, the open cluster of the origin is $P_p$-a.s. finite; hence, all the clusters are also finite. On the other hand, for $p > p_c$ there is a strictly positive $P_p$-probability that the cluster of the origin is infinite. Thus, from Kolmogorov's zero–one law it follows that

$$P_p\{|C(v)| = \infty \text{ for some } v \in \mathcal{V}\} = 1 \quad \text{for } p > p_c$$

Therefore, if the intervals $[0, p_c)$ and $(p_c, 1]$ are both nonempty, there is a phase transition at $p_c$.

Using a so-called Peierls argument it is easy to see that $p_c(\mathcal{G}) > 0$ for any graph $\mathcal{G}$ of bounded degree. On the other hand, Hammersley proved that $p_c(\mathbb{Z}^d) < 1$ for bond percolation as soon as $d \geq 2$, and a similar argument works for site percolation and various periodic graphs as well. But for some graphs $\mathcal{G}$, it is not so easy to show that $p_c(\mathcal{G}) < 1$. One says that the system is in the subcritical (resp. supercritical) phase if $p < p_c$ (resp. $p > p_c$).

It was one of the most remarkable moments in the history of percolation when Kesten (1980) proved, based on results by Harris, Russo, Seymour and Welsh, that the critical parameter for bond percolation on $\mathbb{Z}^2$ is equal to 1/2. Nevertheless, the exact value of $p_c(\mathcal{G})$ is known only for a handful of graphs, all of them periodic and two dimensional – see below.

## Percolation in $\mathbb{Z}^d$

The graph on which most of the theory was originally built is the cubic lattice $\mathbb{Z}^d$, and it was not before the late twentieth century that percolation was seriously considered on other kinds of graphs (such as Cayley graphs), on which specific phenomena can appear, such as the coexistence of multiple infinite clusters for some values of the parameter $p$. In this section, the underlying graph is thus assumed to be $\mathbb{Z}^d$ for $d \geq 2$, although most of the results still hold in the case of a periodic $d$-dimensional lattice.

### The Subcritical Regime

When $p < p_c$, all open clusters are finite almost surely. One of the greatest challenges in percolation theory has been to prove that $\chi(p) := E_p\{|C(v)|\}$ is finite if $p < p_c$ ($E_p$ stands for the expectation with respect to $P_p$). For that one can define another critical probability as the threshold value for the finiteness of the expected cluster size of a fixed vertex:

$$p_T(\mathcal{G}) := \sup\{p : \chi(p) < \infty\}$$

It was an important step in the development of the theory to show that $p_T(\mathcal{G}) = p_c(\mathcal{G})$. The fundamental estimate in the subcritical regime, which is a much stronger statement than $p_T(\mathcal{G}) = p_c(\mathcal{G})$, is the following:

**Theorem 1** (Aizenman and Barsky, Menshikov). *Assume that $\mathcal{G}$ is periodic. Then for $p < p_c$ there exist constants $0 < C_1, C_2 < \infty$, such that*

$$P_p\{|C(v)| \geq n\} \leq C_1\, e^{-C_2 n}$$

The last statement can be sharpened to a "local limit theorem" with the help of a subadditivity argument: for each $p < p_c$, there exists a constant $0 < C_3(p) < \infty$, such that

$$\lim_{n\to\infty} -\frac{1}{n}\log P_p\{|C(v)| = n\} = C_3(p)$$

### The Supercritical Regime

Once an infinite open cluster exists, it is natural to ask how it looks like, and how many infinite open clusters exist. It was shown by Newman and Schulman that for periodic graphs, for each $p$, exactly one of the following three situations prevails: if $N \in \mathbb{Z}_+ \cup \{\infty\}$ is the number of infinite open clusters, then $P_p(N = 0) = 1$, or $P_p(N = 1) = 1$, or $P_p(N = \infty) = 1$.

Aizenman, Kesten, and Newman showed that the third case is impossible on $\mathbb{Z}^d$. By now several proofs exist, perhaps the most elegant of which is due to Burton and Keane, who prove that indeed there cannot be infinitely many infinite open clusters on any amenable graph. However, there are some graphs, such as regular trees, on which coexistence of several infinite clusters is possible.

The geometry of the infinite open cluster can be explored in some depth by studying the behavior of a random walk on it. When $d = 2$, the random walk is recurrent, and when $d \geq 3$ is a.s. transient. In all dimensions $d \geq 2$, the walk behaves diffusively, and the "central limit theorem" and the "invariance principle" were established in both the annealed and quenched cases.

**Wulff droplets** In the supercritical regime, aside from the infinite open cluster, the configuration contains finite clusters of arbitrary large sizes. These large finite open clusters can be thought of as droplets swimming in the areas surrounded by an infinite open cluster. The presence at a particular location of a large finite cluster is an event of low probability, namely, on $\mathbb{Z}^d, d \geq 2$, for $p > p_c$, there exist positive constants $0 < C_4(p), C_5(p) < \infty$, such that

$$C_4(p) \leq -\frac{1}{n^{(d-1)/d}}\log P_p\{|C(v)| = n\} \leq C_5(p)$$

for all large $n$. This estimate is based on the fact that the occurrence of a large finite cluster is due to a surface effect. The typical structure of the large finite cluster is described by the following theorem:

**Theorem 2** *Let $d \geq 2$, and $p > p_c$. There exists a bounded, closed, convex subset $W$ of $\mathbb{R}^d$ containing the origin, called the* normalized *Wulff crystal of the Bernoulli percolation model, such that, under the conditional probability $P_p\{\cdot\, | n^d \leq |C(0)| < \infty\}$, the random measure*

$$\frac{1}{n^d}\sum_{x\in C(\mathbf{0})} \delta_{x/n}$$

*(where $\delta_x$ denotes a Dirac mass at $x$) converges weakly in probability toward the random measure $\theta(p)\mathbb{1}_W(x-M)\,dx$ (where $M$ is the rescaled center of mass of the cluster $C(\mathbf{0})$). The deviation probabilities behave as $\exp\{-cn^{d-1}\}$ (i.e., they exhibit large deviations of surface order; in dimensions 4 and more it holds up to re-centering).*

This result was proved in dimension 2 by Alexander et al. (1990), and in dimensions 3 and more by Cerf (2000).

### Percolation Near the Critical Point

**Percolation in Slabs** The main macroscopic observable in percolation is $\theta(p)$, which is positive above $p_c$, 0 below $p_c$, and continuous on $[0,1]\backslash\{p_c\}$. Continuity at $p_c$ is an open question in the general case; it is known to hold in two dimensions (cf. below) and in high enough dimension (at the moment $d \geq 19$ though the value of the critical dimension is believed to be 6) using lace expansion methods. The conjecture that $\theta(p_c) = 0$ for $3 \leq d \leq 18$ remains one of the major open problems.

Efforts to prove that led to some interesting and important results. Barsky, Grimmett, and Newman solved the question in the half-space case, and simultaneously showed that the slab percolation and half-space percolation thresholds coincide. This was complemented by Grimmett and Marstrand showing that

$$p_c(\text{slab}) = p_c(\mathbb{Z}^d)$$

**Critical exponents** In the subcritical regime, exponential decay of the correlation indicates that there is a finite correlation length $\xi(p)$ associated to the system, and defined (up to constants) by the relation

$$P_p(0 \leftrightarrow nx) \approx \exp\left(-\frac{n\varphi(x)}{\xi(p)}\right)$$

where $\varphi$ is bounded on the unit sphere (this is known as Ornstein–Zernike decay). The phase transition can then also be defined in terms of the divergence of the correlation length, leading again to the same value for $p_c$; the behavior at or near the critical point then has no finite characteristic length, and gives rise to scaling exponents (conjecturally in most cases).

The most usual critical exponents are defined as follows, if $\theta(p)$ is the percolation probability, $C$ the cluster of the origin, and $\xi(p)$ the correlation length:

$$\frac{\partial^3}{\partial p^3}E_p[|C|^{-1}] \approx |p-p_c|^{-1-\alpha}$$
$$\theta(p) \approx (p-p_c)_+^{\beta}$$
$$\chi^f(p) := E_p[|C|\mathbb{1}_{|C|<\infty}] \approx |p-p_c|^{-\gamma}$$
$$P_{p_c}[|C| = n] \approx n^{-1-1/\delta}$$
$$P_{p_c}[x \in C] \approx |x|^{2-d-\eta}$$
$$\xi(p) \approx |p-p_c|^{\nu}$$
$$P_{p_c}[\text{diam}(C) = n] \approx n^{-1-1/\rho}$$
$$\frac{E_p[|C|^{k+1}\mathbb{1}_{|C|<\infty}]}{E_p[|C|^{k}\mathbb{1}_{|C|<\infty}]} \approx |p-p_c|^{-\Delta}$$

These exponents are all expected to be universal, that is, to depend only on the dimension of the lattice, although this is not well understood at the mathematical level; the following scaling relations between the exponents are believed to hold:

$$2-\alpha = \gamma + 2\beta = \beta(\delta+1), \quad \Delta = \delta\beta,\ \gamma = \nu(2-\eta)$$

In addition, in dimensions up to $d_c = 6$, two additional hyperscaling relations involving $d$ are strongly conjectured to hold:

$$d\rho = \delta + 1, \qquad d\nu = 2 - \alpha$$

while above $d_c$ the exponents are believed to take their mean-field value, that is, the ones they have for percolation on a regular tree:

$$\alpha = -1,\ \beta = 1,\ \gamma = 1,\ \delta = 2$$
$$\eta = 0,\ \nu = \tfrac{1}{2},\ \rho = \tfrac{1}{2},\ \Delta = 2$$

Not much is known rigorously on critical exponents in the general case. Hara and Slade (1990) proved that mean field behavior does happen above dimension 19, and the proof can likely be extended to treat the case $d \geq 7$. In the two-dimensional case on the other hand, Kesten (1987) showed that, assuming that the exponents $\delta$ and $\rho$ exist, then so do $\beta, \gamma, \eta$, and $\nu$, and they satisfy the scaling and hyperscaling relations where they appear.

**The incipient infinite cluster** When studying long-range properties of a critical model, it is useful to have an object which is infinite at criticality, and such is not the case for percolation clusters. There are two ways to condition the cluster of the origin to

be infinite when $p = p_c$: The first one is to condition it to have diameter at least $n$ (which happens with positive probability) and take a limit in distribution as $n$ goes to infinity; the second one is to consider the model for parameter $p > p_c$, condition the cluster of 0 to be infinite (which happens with positive probability) and take a limit in distribution as $p$ goes to $p_c$. The limit is the same in both cases; it is known as the incipient infinite cluster.

As in the supercritical regime, the structure of the cluster can be investigated by studying the behavior of a random walk on it, as was suggested by de Gennes; Kesten proved that in two dimensions, the random walk on the incipient infinite cluster is subdiffusive, that is, the mean square displacement after $n$ steps behaves as $n^{1-\varepsilon}$ for some $\varepsilon > 0$.

The construction of the incipient infinite cluster was done by Kesten (1986) in two dimensions, and a similar construction was performed recently in high dimension by van der Hofstad and Jarai (2004).

## Percolation in Two Dimensions

As is the case for several other models of statistical physics, percolation exhibits many specific properties when considered on a two-dimensional lattice: duality arguments allow for the computation of $p_c$ in some cases, and for the derivation of *a priori* bounds for the probability of crossing events at or near the critical point, leading to the fact that $\theta(p_c) = 0$. On another front, the scaling limit of critical site percolation on the two-dimensional triangular lattice can be described in terms of Stochastic Loewner evolutions (SLE) processes.

### Duality, Exact Computations, and RSW Theory

Given a planar lattice $\mathcal{L}$, define two associated graphs as follows. The dual lattice $\mathcal{L}'$ has one vertex for each face of the original lattice, and an edge between two vertices if and only if the corresponding faces of $\mathcal{L}$ share an edge. The star graph $\mathcal{L}^*$ is obtained by adding to $\mathcal{L}$ an edge between any two vertices belonging to the same face ($\mathcal{L}^*$ is not planar in general; $(\mathcal{L}, \mathcal{L}^*)$ is commonly known as a matching pair). Then, a result of Kesten is that, under suitable technical conditions,

$$p_c^{\text{bond}}(\mathcal{L}) + p_c^{\text{bond}}(\mathcal{L}') = p_c^{\text{site}}(\mathcal{L}) + p_c^{\text{site}}(\mathcal{L}^*) = 1$$

Two cases are of particular importance: the lattice $\mathbb{Z}^2$ is isomorphic to its dual; the triangular lattice $\mathcal{T}$ is its own star graph. It follows that

$$p_c^{\text{bond}}(\mathbb{Z}^2) = p_c^{\text{site}}(\mathcal{T}) = \tfrac{1}{2}$$

The only other critical parameters that are known exactly are $p_c^{\text{bond}}(\mathcal{T}) = 2\sin(\pi/18)$ (and hence also $p_c^{\text{bond}}$ for $\mathcal{T}'$, i.e., the hexagonal lattice) and $p_c^{\text{bond}}$ for the bow-tie lattice which is a root of the equation $p^5 - 6p^3 + 6p^2 + p - 1 = 0$. The value of the critical parameter for site percolation on $\mathbb{Z}^2$ might, on the other hand, never be known; it is even possible that it is "just a number" without any other signification.

Still using duality, one can prove that the probability, for bond percolation on the square lattice with parameter $p = 1/2$, that there is a connected component crossing an $(n+1) \times n$ rectangle in the longer direction is exactly equal to 1/2. This and clever arguments involving the symmetry of the lattice lead to the following result, proved independently by Russo and by Seymour and Welsh and known as the RSW theorem:

**Theorem 3** (Russo 1978, Seymour and Welsh 1978). *For every $a, b > 0$ there exist $\eta > 0$ and $n_0 > 0$ such that for every $n > n_0$, the probability that there is a cluster crossing an $\lfloor na \rfloor \times \lfloor nb \rfloor$ rectangle in the first direction is greater than $\eta$.*

The most direct consequence of this estimate is that the probability that there is a cluster going around an annulus of a given modulus is bounded below independently of the size of the annulus; in particular, almost surely there is some annulus around 0 in which this happens, and that is what allows to prove that $\theta(p_c) = 0$ for bond percolation on $\mathbb{Z}^2$ (**Figure 2**).

### The Scaling Limit

RSW-type estimates give positive evidence that a scaling limit of the model should exist; it is indeed essentially sufficient to show convergence of the crossing probabilities to a nontrivial limit as $n$ goes to infinity. The limit, which should depend only on the ratio $a/b$, was predicted by Cardy using conformal field theory methods. A celebrated result of Smirnov is the proof of Cardy's formula in the case of site percolation on the triangular lattice $\mathcal{T}$:

**Theorem 4** (Smirnov (2001)). *Let $\Omega$ be a simply connected domain of the plane with four points $a$, $b$, $c$, $d$ (in that order) marked on its boundary. For every $\delta > 0$, consider a critical site-percolation*

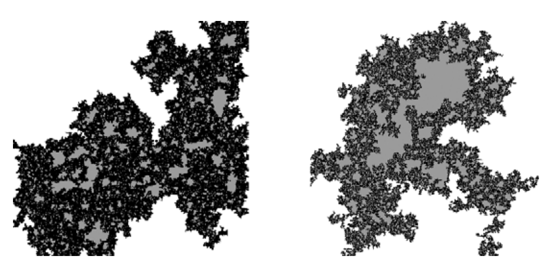

**Figure 2** Two large critical percolation clusters in a box of the square lattice (first: bond percolation, second: site percolation).

*model on the intersection of* $\Omega$ *with* $\delta\mathcal{T}$ *and let* $f_\delta(ab, cd; \Omega)$ *be the probability that it contains a cluster connecting the arcs ab and cd. Then*:

(i) $f_\delta(ab, cd; \Omega)$ *has a limit* $f_0(ab, cd; \Omega)$ *as* $\delta \to 0$;

(ii) *the limit is conformally invariant, in the following sense: if* $\Phi$ *is a conformal map from* $\Omega$ *to some other domain* $\Omega' = \Phi(\Omega)$, *and maps* $a$ *to* $a', b$ *to* $b', c$ *to* $c'$ *and* $d$ *to* $d'$, *then* $f_0(ab, cd; \Omega) = f_0(a'b', c'd'; \Omega')$; *and*

(iii) *in the particular case when* $\Omega$ *is an equilateral triangle of side length* 1 *with vertices a, b and c, and if d is on (ca) at distance* $x \in (0, 1)$ *from c, then* $f_0(ab, cd; \Omega) = x$.

Point (iii) in particular is essential since it allows us to compute the limiting crossing probabilities in any conformal rectangle. In the original work of Cardy, he made his prediction in the case of a rectangle, for which the limit involves hypergeometric functions; the remark that the equilateral triangle gives rise to nicer formulae is originally due to Carleson.

To precisely state the convergence of percolation to its scaling limit, define the random curve known as the percolation exploration path (see Figure 3) as follows: In the upper half-plane, consider a site-percolation model on a portion of the triangular lattice and impose the boundary conditions that on the negative real half-line all the sites are open, while on the other half-line the sites are closed. The exploration curve is then the common boundary of the open cluster spanning from the negative half-line, and the closed cluster spanning from the positive half-line; it is an infinite, self-avoiding random curve in the upper half-plane.

As the mesh of the lattice goes to 0, the exploration curve then converges in distribution to the trace of an SLE process, as introduced by Schramm, with parameter $\kappa = 6$ – see Figure 4. The limiting curve is not simple anymore (which corresponds to the existence of pivotal sites on large critical percolation clusters), and it has Hausdorff dimension 7/4. For more details on SLE processes, see, for example, the related entry in the present volume.

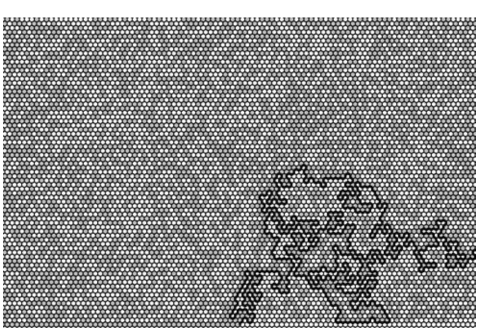

Figure 3 A percolation exploration path. Figure courtesy Schramm O (2000) Scaling limits of loop-erased random walks and uniform spanning trees. *Israel Journal of Mathematics* 118: 221–228.

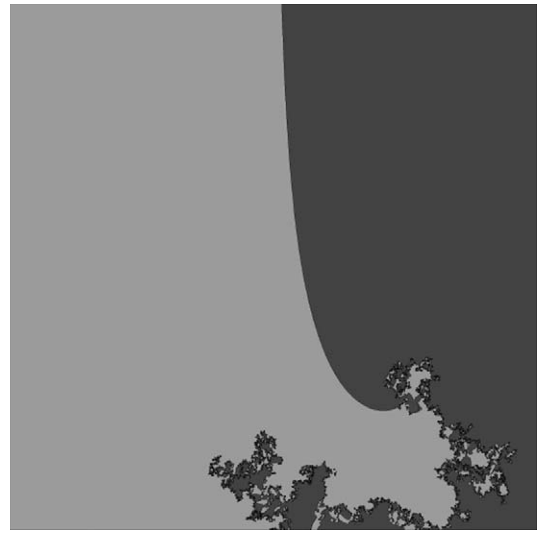

Figure 4 An SLE process with parameter $\kappa = 6$ (infinite time, with the driving process stopped at time 1).

As an application of this convergence result, one can prove that the critical exponents described in the previous section do exist (still in the case of the triangular lattice), and compute their exact values, except for $\alpha$, which is still listed here for completeness:

$$\left[\alpha = -\frac{2}{3}\right], \beta = \frac{5}{36}, \gamma = \frac{43}{18}, \delta = \frac{91}{5}$$
$$\eta = \frac{5}{24}, \nu = \frac{4}{3}, \rho = \frac{48}{5}, \Delta = \frac{91}{36}$$

These exponents are expected to be universal, in the sense that they should be the same for percolation on any two-dimensional lattice; but at the time of this writing, this phenomenon is far from being understood on a mathematical level.

The rigorous derivation of the critical exponents for percolation is due to Smirnov and Werner (2001); the dimension of the limiting curve was obtained by Beffara (2004).

## Other Lattices and Percolative Systems

Some modifications or generalizations of standard Bernoulli percolation on $\mathbb{Z}^d$ exhibit an interesting behavior and as such provide some insight into the original process as well; there are too many mathematical objects which can be argued to be percolative in some sense to give a full account of all

of them, so the following list is somewhat arbitrary and by no means complete.

### Percolation on Nonamenable Graphs

The first modification of the model one can think of is to modify the underlying graph and move away from the cubic lattice; phase transition still occurs, and the main difference is the possibility for infinitely many infinite clusters to coexist. On a regular tree, such is the case whenever $p \in (p_c, 1)$, the first nontrivial example was produced by Grimmett and Newman as the product of $\mathbb{Z}$ by a tree: there, for some values of $p$ the infinite cluster is unique, while for others there is coexistence of infinitely many of them. The corresponding definition, due to Benjamini and Schramm, is then the following: if $N$ is as above the number of infinite open clusters,

$$p_u := \inf\{p : P_p(N = 1) = 1\} \geq p_c$$

The main question is then to characterize graphs on which $0 < p_c < p_u < 1$.

A wide class of interesting graphs is that of Cayley graphs of infinite, finitely generated groups. There, by a simultaneous result by Häggström and Peres and by Schonmann, for every $p \in (p_c, p_u)$ there are $P_p$-a.s. infinitely many infinite cluster, while for every $p \in (p_u, 1]$ there is only one – note that this does not follow from the definition since new infinite components could appear when $p$ is increased. It is conjectured that $p_c < p_u$ for any Cayley graph of a nonamenable group (and more generally for any quasitransitive graph with positive Cheeger constant), and a result by Pak and Smirnova is that every infinite, finitely generated, nonamenable group has a Cayley graph on which $p_c < p_u$; this is then expected not to depend on the choice of generators. In the general case, it was recently proved by Gaboriau that if the graph $\mathcal{G}$ is unimodular, transitive, locally finite, and supports nonconstant harmonic Dirichlet functions (i.e., harmonic functions whose gradient is in $\ell^2$), then indeed $p_c(\mathcal{G}) < p_u(\mathcal{G})$.

For reference and further reading on the topic, the reader is advised to refer to the review paper by Benjamini and Schramm (1996), the lecture notes of Peres (1999), and the more recent article of Gaboriau (2005).

### Gradient Percolation

Another possible modification of the original model is to allow the parameter $p$ to depend on the location; the porous medium may for instance have been created by some kind of erosion, so that there will be more open edges on one side of a given domain than on the other. If $p$ still varies smoothly, then one expects some regions to look subcritical and others to look supercritical, with interesting behavior in the vicinity of the critical level set $\{p = p_c\}$. This particular model was introduced by Sapoval *et al.* (1978) under the name of gradient percolation (see Figure 5).

**Figure 5** Gradient percolation in a square. In black is the cluster spanning from the bottom side of the square.

The control of the model away from the critical zone is essentially the same as for usual Bernoulli percolation, the main question being how to estimate the width of the phase transition. The main idea is then the same as in scaling theory: if the distance between a point $v$ and the critical level set is less than the correlation length for parameter $p(v)$, then $v$ is in the phase transition domain. This of course makes sense only asymptotically, say in a large $n \times n$ square with $p(x, y) = 1 - y/n$ as is the case in the figure: the transition then is expected to have width of order $n^a$ for some exponent $a > 0$.

### First-Passage Percolation

First-passage percolation (also known as Eden or Richardson model) was introduced by Hammersley and Welsh (1965) as a time-dependent model for the passage of fluid through a porous medium. To define the model, with each edge $e \in \mathcal{E}(\mathbb{Z}^d)$ is associated a random variable $T(e)$, which can be interpreted as being the time required for fluid to flow along $e$. The $T(e)$ are assumed to be independent non-negative random variables having common distribution $F$. For any path $\pi$ we define the passage time $T(\pi)$ of $\pi$ as

$$T(\pi) := \sum_{e \in \pi} T(e)$$

The first passage time $a(x, y)$ between vertices $x$ and $y$ is given by

$$a(x,y) = \inf\{T(\pi) : \pi \text{ a path from } x \text{ to } y\}$$

and we can define

$$W(t) := \{x \in \mathbb{Z}^d : a(0,x) \le t\}$$

the set of vertices reached by the liquid by time $t$. It turns out that $W(t)$ grows approximately linearly as time passes, and that there exists a nonrandom limit set $B$ such that either $B$ is compact and

$$(1-\varepsilon)B \subseteq \frac{1}{t}\widetilde{W}(t) \subseteq (1+\varepsilon)B, \text{ eventually a.s.}$$

for all $\epsilon > 0$, or $B = \mathbb{R}^d$, and

$$\{x \in \mathbb{R}^d : |x| \le K\} \subseteq \frac{1}{t}\widetilde{W}(t), \text{ eventually a.s.}$$

for all $K > 0$. Here $\widetilde{W}(t) = \{z + [-1/2, 1/2]^d : z \in W(t)\}$.

Studies of first-passage percolation brought many fascinating discoveries, including Kingman's celebrated subadditive ergodic theorem. In recent years interest has been focused on study of fluctuations of the set $\widetilde{W}(t)$ for large $t$. In spite of huge effort and some partial results achieved, it still remains a major task to establish rigorously conjectures predicted by Kardar–Parisi–Zhang theory about shape fluctuations in first passage percolation.

### Contact Processes

Introduced by Harris and conceived with biological interpretation, the contact process on $\mathbb{Z}^d$ is a continuous-time process taking values in the space of subsets of $\mathbb{Z}^d$. It is informally described as follows: particles are distributed in $\mathbb{Z}^d$ in such a way that each site is either empty or occupied by one particle. The evolution is Markovian: each particle disappears after an exponential time of parameter 1, independently from the others; at any time, each particle has a possibility to create a new particle at any of its empty neighboring sites, and does so with rate $\lambda > 0$, independently of everything else.

The question is then whether, starting from a finite population, the process will die out in finite time or whether it will survive forever with positive probability. The outcome will depend on the value of $\lambda$, and there is a critical value $\lambda_c$, such that for $\lambda \le \lambda_c$ process dies out, while for $\lambda > \lambda_c$ indeed there is survival, and in this case the shape of the population obeys a shape theorem similar to that of first-passage percolation.

The analogy with percolation is strong, the corresponding percolative picture being the following: in $\mathbb{Z}_+^{d+1}$, each edge is open with probability $p \in (0,1)$, and the question is whether there exists an infinite oriented path $\pi$ (i.e., a path along which the sum of the coordinates is increasing), composed of open edges. Once again, there is a critical parameter customarily denoted by $\boldsymbol{p}_c$, at which no such path exists (compare this to the open question of the continuity of the function $\theta$ at $p_c$ in dimensions $3 \le d \le 18$). This variation of percolation lies in a different universality class than the usual Bernoulli model.

### Invasion Percolation

Let $X(e) : e \in \mathcal{E}$ be independent random variables indexed by the edge set $\mathcal{E}$ of $\mathbb{Z}^d$, $d \ge 2$, each having uniform distribution in $[0,1]$. One constructs a sequence $C = \{C_i, i \ge 1\}$ of random connected subgraphs of the lattice in the following iterative way: the graph $C_0$ contains only the origin. Having defined $C_i$, one obtains $C_{i+1}$ by adding to $C_i$ an edge $e_{i+1}$ (with its outer lying end-vertex), chosen from the outer edge boundary of $C_i$ so as to minimize $X(e_{i+1})$. Still very little is known about the behavior of this process.

An interesting observation, relating $\theta(p_c)$ of usual percolation with the invasion dynamics, comes from CM Newman:

$$\theta(p_c) = 0 \Leftrightarrow P\{x \in C\} \to 0 \text{ as } |x| \to \infty$$

## Further Remarks

For a much more in-depth review of percolation on lattices and the mathematical methods involved in its study, and for the proofs of most of the results we could only point at, we refer the reader to the standard book of Grimmett (1999); another excellent general reference, and the only place to find some of the technical graph-theoretical details involved, is the book of Kesten (1982). More information in the case of graphs that are not lattices can be found in the lecture notes of Peres (1999).

For curiosity, the reader can refer to the first mention of a problem close to percolation, in the problem section of the first volume of the *American Mathematical Monthly* (problem 5, June 1894, submitted by D V Wood).

# Perturbation Theory and Its Techniques

**R J Szabo**, Heriot-Watt University, Edinburgh, UK

## Introduction

There are several equivalent formulations of the problem of quantizing an interacting field theory. The list includes canonical quantization, path-integral (or functional) techniques, stochastic quantization, "unified" methods such as the Batalin–Vilkovisky formalism, and techniques based on the realizations of field theories as low-energy limits of string theory. The problem of obtaining an exact nonperturbative description of a given quantum field theory is most often a very difficult one. Perturbative techniques, on the other hand, are abundant, and common to all of the quantization methods mentioned above is that they admit particle interpretations in this formalism.

The basic physical quantities that one wishes to calculate in a relativistic $(d+1)$-dimensional quantum field theory are the $S$-matrix elements

$$S_{ba} = {}_{\text{out}}\langle \psi_b(t)|\psi_a(t)\rangle_{\text{in}} \qquad [1]$$

between in and out states at large positive time $t$. The scattering operator $\mathsf{S}$ is then defined by writing [1] in terms of initial free-particle (descriptor) states as

$$S_{ba} =: \langle \psi_b(0)|\mathsf{S}|\psi_a(0)\rangle \qquad [2]$$

Suppose that the Hamiltonian of the given field theory can be written as $H = H_0 + H'$, where $H_0$ is the free part and $H'$ the interaction Hamiltonian. The time evolutions of the in and out states are governed by the total Hamiltonian $H$. They can be expressed in terms of descriptor states which evolve in time with $H_0$ in the interaction picture and correspond to free-particle states. This leads to the Dyson formula

$$\mathsf{S} = \mathrm{T}\exp\left(-\mathrm{i}\int_{-\infty}^{\infty} \mathrm{d}t\, H_I(t)\right) \qquad [3]$$

where T denotes time ordering and $H_I(t) = \int \mathrm{d}^d x \mathcal{H}_{\text{int}}(x,t)$ is the interaction Hamiltonian in the interaction picture, with $\mathcal{H}_{\text{int}}(x,t)$ the interaction Hamiltonian density, which deals with essentially free fields. This formula expresses $\mathsf{S}$ in terms of interaction-picture operators acting on free-particle states in [2] and is the first step towards Feynman perturbation theory.

For many analytic investigations, such as those which arise in renormalization theory, one is interested instead in the Green's functions of the quantum field theory, which measure the response of the system to an external perturbation. For definiteness, let us consider a free real scalar field theory in $d+1$ dimensions with Lagrangian density

$$\mathcal{L} = \frac{1}{2}\partial_\mu\phi\partial^\mu\phi - \frac{1}{2}m^2\phi^2 + \mathcal{L}_{\rm int} \qquad [4]$$

where $\mathcal{L}_{\rm int}$ is the interaction Lagrangian density which we assume has no derivative terms. The interaction Hamiltonian density is then given by $\mathcal{H}_{\rm int} = -\mathcal{L}_{\rm int}$. Introducing a real scalar source $J(x)$, we define the normalized "partition function" through the vacuum expectation values,

$$Z[J] = \frac{\langle 0|\mathsf{S}[J]|0\rangle}{\langle 0|\mathsf{S}[0]|0\rangle} \qquad [5]$$

where $|0\rangle$ is the normalized perturbative vacuum state of the quantum field theory given by (4) (defined to be destroyed by all field annihilation operators), and

$$\mathsf{S}[J] = \mathrm{T}\exp\left(\mathrm{i}\int \mathrm{d}^{d+1}x(\mathcal{L}_{\rm int} + J(x)\phi(x))\right) \qquad [6]$$

from the Dyson formula. This partition function is the generating functional for all Green's functions of the quantum field theory, which are obtained from [5] by taking functional derivatives with respect to the source and then setting $J(x)=0$. Explicitly, in a formal Taylor series expansion in $J$ one has

$$Z[J] = \sum_{n=0}^{\infty}\frac{\mathrm{i}^n}{n!}\prod_{i=1}^{n}\int \mathrm{d}^{d+1}x_i\, J(x_i)\, G^{(n)}(x_1,\ldots,x_n) \qquad [7]$$

whose coefficients are the Green's functions

$$G^{(n)}(x_1,\ldots,x_n) := \frac{\langle 0|\mathrm{T}[\exp\left(\mathrm{i}\int \mathrm{d}^{d+1}x\mathcal{L}_{\rm int}\right)\phi(x_1)\cdots\phi(x_n)]|0\rangle}{\langle 0|\mathrm{T}\exp\left(\mathrm{i}\int \mathrm{d}^{d+1}x\mathcal{L}_{\rm int}\right)|0\rangle} \qquad [8]$$

It is customary to work in momentum space by introducing the Fourier transforms

$$\tilde{J}(k) = \int \mathrm{d}^{d+1}x\, \mathrm{e}^{\mathrm{i}k\cdot x}J(x)$$
$$\tilde{G}^{(n)}(k_1,\ldots,k_n) = \prod_{i=1}^{n}\int \mathrm{d}^{d+1}x_i\, \mathrm{e}^{\mathrm{i}k_i\cdot x_i}G^{(n)}(x_1,\ldots,x_n) \qquad [9]$$

in terms of which the expansion [7] reads

$$Z[J] = \sum_{n=0}^{\infty}\frac{\mathrm{i}^n}{n!}\prod_{i=1}^{n}\int \frac{\mathrm{d}^{d+1}k_i}{(2\pi)^{d+1}}\tilde{J}(-k_i) \times \tilde{G}^{(n)}(k_1,\ldots,k_n) \qquad [10]$$

The generating functional [10] can be written as a sum of Feynman diagrams with source insertions. Diagrammatically, the Green's function is an infinite series of graphs which can be represented symbolically as

$\tilde{G}^{(n)}(k_1,\ldots,k_n) =$  [11]

where the $n$ external lines denote the source insertions of momenta $k_i$ and the bubble denotes the sum over all Feynman diagrams constructed from the interaction vertices of $\mathcal{L}_{\rm int}$.

This procedure is, however, rather formal in the way that we have presented it, for a variety of reasons. First of all, by Haag's theorem, it follows that the interaction representation of a quantum field theory does not exist unless a cutoff regularization is introduced into the interaction term in the Lagrangian density (this regularization is described explicitly below). The addition of this term breaks translation covariance. This problem can be remedied via a different definition of the regularized Green's functions, as we discuss below. Furthermore, the perturbation series of a quantum field theory is typically divergent. The expansion into graphs is, at best, an asymptotic series which is Borel summable. These shortcomings will not be emphasized any further in this article. Some mathematically rigorous approaches to perturbative quantum field theory can be found in the bibliography.

The Green's functions can also be used to describe scattering amplitudes, but there are two important differences between the graphs [11] and those which appear in scattering theory. In the present case, external lines carry propagators, that is, the free-field Green's functions

$$\Delta(x-y) = \langle 0|\,\mathrm{T}[\phi(x)\,\phi(y)]\,|0\rangle = \left\langle x\middle|\left(\Box + m^2\right)^{-1}\middle|y\right\rangle = \int \frac{\mathrm{d}^{d+1}p}{(2\pi)^{d+1}}\frac{\mathrm{i}}{p^2 - m^2 + \mathrm{i}\epsilon}\mathrm{e}^{-\mathrm{i}p\cdot(x-y)} \qquad [12]$$

where $\epsilon \to 0^+$ regulates the mass shell contributions, and their momenta $k_i$ are off-shell in general ($k_i^2 \neq m^2$). By the LSZ theorem, the S-matrix element

is then given by the multiple on-shell residue of the Green's function in momentum space as

$$\langle k'_1,\ldots,k'_n|\,\mathsf{S}-\mathbb{1}|k_1,\ldots,k_l\rangle = \lim_{\substack{k'_1,\ldots,k'_n\to m^2\\ k_1,\ldots,k_l\to m^2}} \prod_{i=1}^{n}\frac{1}{\mathrm{i}\sqrt{c'_i}}\left(k_i'^2-m^2\right)\prod_{j=1}^{l}\frac{1}{\mathrm{i}\sqrt{c_j}}\left(k_j^2-m^2\right) \times \tilde{G}^{(n+m)}\left(-k'_1,\ldots,-k'_n,k_1,\ldots,k_l\right) \quad [13]$$

where $\mathrm{i}c'_i, \mathrm{i}c_j$ are the residues of the corresponding particle poles in the exact two-point Green's function.

This article deals with the formal development and computation of perturbative scattering amplitudes in relativistic quantum field theory, along the lines outlined above. Initially we deal only with real scalar field theories of the sort [4] in order to illustrate the concepts and technical tools in as simple and concise a fashion as possible. These techniques are common to most quantum field theories. Fermions and gauge theories are then separately treated afterwards, focusing on the methods which are particular to them.

## Diagrammatics

The pinnacle of perturbation theory is the technique of Feynman diagrams. Here we develop the basic machinery in a quite general setting and use it to analyze some generic features of the terms comprising the perturbation series.

### Wick's Theorem

The Green's functions [8] are defined in terms of vacuum expectation values of time-ordered products of the scalar field $\phi(x)$ at different spacetime points. Wick's theorem expresses such products in terms of normal-ordered products, defined by placing each field creation operator to the right of each field annihilation operator, and in terms of two-point Green's functions [12] of the free-field theory (propagators). The consequence of this theorem is the Haffnian formula

$$\langle 0|\,\mathrm{T}[\phi(x_1)\cdots\phi(x_n)]|0\rangle = \begin{cases} 0 & n=2k-1 \\ \displaystyle\sum_{\pi\in S_{2k}}\prod_{i=1}^{k}\langle 0|\,\mathrm{T}\left[\phi(x_{\pi(2i-1)})\,\phi(x_{\pi(2i)})\right]|0\rangle & n=2k \end{cases} \quad [14]$$

The formal Taylor series expansion of the scattering operator $\mathsf{S}$ may now be succinctly summarized into a diagrammatic notation by using Wick's theorem. For each spacetime integration $\int \mathrm{d}^{d+1}x_i$ we introduce a vertex with label $i$, and from each vertex there emanate some lines corresponding to field insertions at the point $x_i$. If the operators represented by two lines appear in a two-point function according to [14], that is, they are contracted, then these two lines are connected together. The $\mathsf{S}$ operator is then represented as a sum over all such Wick diagrams, bearing in mind that topologically equivalent diagrams correspond to the same term in $\mathsf{S}$. Two diagrams are said to have the same pattern if they differ only by a permutation of their vertices. For any diagram $\mathfrak{D}$ with $n(\mathfrak{D})$ vertices, the number of ways of interchanging vertices is $n(\mathfrak{D})!$. The number of diagrams per pattern is always less than this number. The symmetry number $S(\mathfrak{D})$ of $\mathfrak{D}$ is the number of permutations of vertices that give the same diagram. The number of diagrams with the pattern of $\mathfrak{D}$ is then $n(\mathfrak{D})!/S(\mathfrak{D})$.

In a given pattern, we write the contribution to $\mathsf{S}$ of a single diagram $\mathfrak{D}$ as

$$\frac{1}{n(\mathfrak{D})!}\,{:}\theta(\mathfrak{D}){:}$$

where the combinatorial factor comes from the Taylor expansion of $\mathsf{S}$, the large colons denote normal ordering of quantum operators, and ${:}\theta(\mathfrak{D}){:}$ contains spacetime integrals over normal-ordered products of the fields. Then all diagrams with the pattern of $\mathfrak{D}$ contribute ${:}\theta(\mathfrak{D}){:}/S(\mathfrak{D})$ to $\mathsf{S}$. Only the connected diagrams $\mathfrak{D}_r, r\in\mathbb{N}$ (those in which every vertex is connected to every other vertex) contribute and we can write the scattering operator in a simple form which eliminates contributions from all disconnected diagrams as

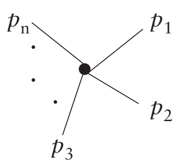
$$\mathsf{S} = {:}\exp\left(\sum_{r=1}^{\infty}\frac{\theta(\mathfrak{D}_r)}{S(\mathfrak{D}_r)}\right){:} \quad [15]$$

### Feynman Rules

Feynman diagrams in momentum space are defined from the Wick diagrams above by dropping the labels on vertices (and also the symmetry factors $S(\mathfrak{D})^{-1}$), and by labeling the external lines by the momenta of the initial and final particles that the corresponding field operators annihilate. In a spacetime interpretation, external lines

represent on-shell physical particles while internal lines of the graph represent off-shell virtual particles ($k^2 \neq m^2$). Physical particles interact via the exchange of virtual particles. An arbitrary diagram is then calculated via the Feynman rules:

$$= \int \frac{d^{d+1}p}{(2\pi)^{d+1}} \frac{i}{p^2 - m^2 + i\epsilon}$$

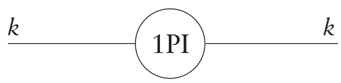


$$= ig\,(2\pi)^{d+1}\,\delta^{(d+1)}(p_1 + \cdots + p_n) \qquad [16]$$

for a monomial interaction $\mathcal{L}_{\text{int}} = (g/n!)\phi^n$.

## Irreducible Green's Functions

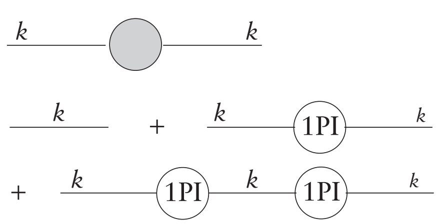
A one-particle irreducible (1PI) or proper Green's function is given by a sum of diagrams in which each diagram cannot be separated by cutting one internal line. In momentum space, it is defined without the overall momentum conservation delta-function factors and without propagators on external lines. For example, the two particle 1PI Green's function



$$=: \Sigma(k) \qquad [17]$$

is called the self-energy. If $G(k)$ is the complete two-point function in momentum space, then one has

$G(k) :=$



$$= \frac{i}{k^2 - m^2 - \Sigma(k)} \qquad [18]$$

and thus it suffices to calculate only 1PI diagrams.

The 1PI effective action, defined by the Legendre transformation $\Gamma[\phi] := -i \ln Z[J] - \int d^{d+1}x J(x)\phi(x)$ of [5], is the generating functional for proper vertex functions and it can be represented as a functional of only the vacuum expectation value of the field $\phi$, that is, its classical value. In the semiclassical (WKB) approximation, the one-loop effective action is given by

$$\begin{aligned}
\Gamma[\phi] &= S[\phi] + \frac{i\hbar}{2} \mathrm{Tr} \ln(1 + \Delta V''[\phi]) + O(\hbar^2) \\
&= S[\phi] + i\hbar \sum_{n=1}^{\infty} \frac{(-1)^n}{2n} \\
&\quad \times \prod_{i=1}^{n} \int d^{d+1}x_i \Delta(x_i - x_{i+1}) V''[\phi(x_{i+1})] \\
&\quad + O(\hbar^2)
\end{aligned} \qquad [19]$$

where we have denoted $S[\phi] = \int d^{d+1}x\mathcal{L}$ and $V[\phi] = -\mathcal{L}_{\text{int}}$, and for each term in the infinite series we define $x_{n+1} := x_1$. The first term in [19] is the classical contribution and it can be represented in terms of connected tree diagrams. The second term is the sum of contributions of one-loop diagrams constructed from $n$ propagators $-i\Delta(x-y)$ and $n$ vertices $-iV''[\phi]$. The expansion may be carried out to all orders in terms of connected Feynman diagrams, and the result of the above Legendre transformation is to select only the one-particle irreducible diagrams and to replace the classical value of $\phi$ by an arbitrary argument. All information about the quantum field theory is encoded in this effective action.

## Parametric Representation

Consider an arbitrary proper Feynman diagram $\mathfrak{D}$ with $n$ internal lines and $v$ vertices. The number, $\ell$, of independent loops in the diagram is the number of independent internal momenta in $\mathfrak{D}$ when conservation laws at each vertex have been taken into account, and it is given by $\ell = n + 1 - v$. There is an independent momentum integration variable $k_i$ for each loop, and a propagator for each internal line as in [16]. The contribution of $\mathfrak{D}$ to a proper Green's function with $r$ incoming external momenta $p_i$, with $\sum_{i=1}^{r} p_i = 0$, is given by

$$\begin{aligned}
\tilde{I}_{\mathfrak{D}}(p) &= \frac{V(\mathfrak{D})}{S(\mathfrak{D})} \prod_{i=1}^{n} \int \frac{d^{d+1}k_i}{(2\pi)^{d+1}} \frac{i}{k_i^2 - m^2 + i\epsilon} \\
&\quad \times \prod_{j=1}^{v} (2\pi)^{d+1} \delta^{(d+1)}\left(P_j - K_j\right)
\end{aligned} \qquad [20]$$

where $V(\mathfrak{D})$ contains all contributions from the interaction vertices of $\mathcal{L}_{\text{int}}$, and $P_j$ (resp. $K_j$) is the sum of incoming external momenta $p_{l_j}$ (resp. internal momenta $k_{l_j}$) at vertex $j$ with respect to a fixed chosen orientation of the lines of the graph. After resolving the delta-functions in terms of independent internal loop momenta $k_1, \ldots, k_\ell$ and dropping the overall momentum conservation

delta-function along with the symmetry and vertex factors in [20], one is left with a set of momentum space integrals

$$I_{\mathfrak{D}}(p) = \prod_{i=1}^{\ell} \int \frac{\mathrm{d}^{d+1} k_i}{(2\pi)^{d+1}} \prod_{j=1}^{n} \frac{\mathrm{i}}{a_j(k,p) + \mathrm{i}\epsilon} \qquad [21]$$

where $a_j(k,p)$ are functions of both the internal and external momenta.

It is convenient to exponentiate propagators using the Schwinger parametrization

$$\frac{\mathrm{i}}{a_j + \mathrm{i}\epsilon} = \int_0^{\infty} \mathrm{d}\alpha_j \, \mathrm{e}^{\mathrm{i}\alpha_j(a_j + \mathrm{i}\epsilon)} \qquad [22]$$

and after some straightforward manipulations one may write the Feynman parametric formula

$$\prod_{j=1}^{n} \frac{\mathrm{i}}{a_j(k,p) + \mathrm{i}\epsilon} = (n-1)! \prod_{j=1}^{n} \int_0^1 \mathrm{d}\alpha_j \frac{\delta\left(1 - \sum_j \alpha_j\right)}{D_{\mathfrak{D}}(k;\alpha,p)^n} \qquad [23]$$

where $D_{\mathfrak{D}}(k;\alpha,p) := \sum_j \alpha_j [a_j(k,p) + \mathrm{i}\epsilon]$ is generically a quadratic form

$$D_{\mathfrak{D}}(k;\alpha,p) = \frac{1}{2} \sum_{i,j=1}^{\ell} k_i \cdot Q_{ij}(\alpha) k_j + \sum_{i=1}^{\ell} L_i(p) \cdot k_i + \lambda(p^2) \qquad [24]$$

The positive symmetric matrix $Q_{ij}$ is independent of the external momenta $p_l$, invertible, and has nonzero eigenvalues $Q_1, \ldots, Q_\ell$. The vectors $L_i^\mu$ are linear combinations of the $p_j^\mu$, while $\lambda(p^2)$ is a function of only the Lorentz invariants $p_i^2$. After some further elementary manipulations, the loop diagram contribution [21] may be written as

$$I_{\mathfrak{D}}(p) = (n-1)! \prod_{j=1}^{n} \int_0^1 \mathrm{d}\alpha_j \prod_{i=1}^{\ell} \frac{1}{Q_i(\alpha)^2} \int \frac{\mathrm{d}^{d+1} k_i}{(2\pi)^{d+1}} \delta\left(1 - \sum_j \alpha_j\right) \times \left(\frac{1}{2} \sum_i k_i^2 + \lambda(p^2) - \frac{1}{2} \sum_{i,j} L_i(p) \cdot Q^{-1}(\alpha)_{ij} L_j(p)\right)^{-n} \qquad [25]$$

Finally, the integrals over the loop momenta $k_i$ may be performed by Wick-rotating them to Euclidean space and using the fact that the combination of $\ell$ integrations in $\mathbb{R}^{d+1}$ has $O((d+1)\ell)$ rotational invariance. The contribution from the entire Feynman diagram $\mathfrak{D}$ thereby reduces to the calculation of the parametric integrals:

$$I_{\mathfrak{D}}(p) = \frac{\Gamma\left(n - \frac{(d+1)\ell}{2}\right)}{(2\pi)^{\frac{(d+1)\ell}{2}} \mathrm{i}^{d\ell}} \prod_{j=1}^{n} \int_0^1 \mathrm{d}\alpha_j \prod_{i=1}^{\ell} \frac{1}{Q_i(\alpha)^2} \times \frac{\delta\left(1 - \sum_j \alpha_j\right)}{\left(\lambda(p^2) - \frac{1}{2} \sum_{i,j} L_i(p) \cdot Q^{-1}(\alpha)_{ij} L_j(p)\right)^{\frac{n-(d+1)\ell}{2}}} \qquad [26]$$

where $\Gamma(s)$ is the Euler gamma-function.

## Regularization

The parametric representation [26] is generically convergent when $2n - (d+1)\ell > 0$. When divergent, the infinities arise from the lower limits of integration $\alpha_j \to 0$. This is just the parametric representation of the large-$k$ divergence of the original Feynman amplitude [20]. Such ultraviolet divergences plague the very meaning of a quantum field theory and must be dealt with in some way. We will now quickly tour the standard methods of ultraviolet regularization for such loop integrals, which is a prelude to the renormalization program that removes the divergences (in a renormalizable field theory). Here we consider regularization simply as a means of justification for the various formal manipulations that are used in arriving at expressions such as [26].

### Momentum Cutoff

Cutoff regularization introduces a mass scale $\Lambda$ into the quantum field theory and throws away the Fourier modes of the fields for spatial momenta $\boldsymbol{k}$ with $|\boldsymbol{k}| > \Lambda$. This regularization spoils Lorentz invariance. It is also nonlocal. For example, if we restrict to a hypercube in momentum space, so that $|k_i| < \Lambda$ for $i = 1, \ldots, d$, then

$$\int_{|\boldsymbol{k}| > \Lambda} \frac{\mathrm{d}^d \boldsymbol{k}}{(2\pi)^d} \mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{x}} = \prod_{i=1}^{d} \frac{\sin(\Lambda x^i)}{\pi x^i}$$

which is a delta-function in the limit $\Lambda \to \infty$ but is nonlocal for $\Lambda < \infty$. The regularized field theory is finite order by order in perturbation theory and depends on the cutoff $\Lambda$.

#### Lattice Regularization

We can replace the spatial continuum by a lattice $\mathfrak{L}$ of rank $d$ and define a Lagrangian on $\mathfrak{L}$ by

$$L_{\mathfrak{L}} = \frac{1}{2}\sum_{i\in \mathrm{S}(\mathfrak{L})} \dot{\phi}_i^2 + J\sum_{\langle i,j\rangle\in \mathrm{L}(\mathfrak{L})} \phi_i\phi_j + \sum_{i\in \mathrm{S}(\mathfrak{L})} V(\phi_i) \quad [27]$$

where $\mathrm{S}(\mathfrak{L})$ is the set of sites $i$ of the lattice on each of which is situated a time-dependent function $\phi_i$, and $L_{\mathfrak{L}}$ is the collection of links connecting pairs $\langle i,j\rangle$ of nearest-neighbor sites $i,j$ on $\mathfrak{L}$. The regularized field theory is now local, but still has broken Lorentz invariance. In particular, it suffers from broken rotational symmetry. If $\mathfrak{L}$ is hypercubic with lattice spacing $a$, that is, $\mathfrak{L} = (\mathbb{Z}a)^d$, then the momentum cutoff is at $\Lambda = a^{-1}$.

#### Pauli–Villars Regularization

We can replace the propagator $\mathrm{i}(k^2 - m^2 + \mathrm{i}\epsilon)^{-1}$ by $\mathrm{i}(k^2 - m^2 + \mathrm{i}\epsilon)^{-1} + \mathrm{i}\sum_{j=1}^{N} c_j(k^2 - M_j^2 + \mathrm{i}\epsilon)^{-1}$, where the masses $M_j \gg m$ are identified with the momentum cutoff as $\min\{M_j\} = \Lambda \to \infty$. The mass-dependent coefficients $c_j$ are chosen to make the modified propagator decay rapidly as $(k^2)^{-N-1}$ at $k \to \infty$, which gives the $N$ equations $(m^2)^i + \sum_j c_j(M_j^2)^i = 0, i = 0, 1, \ldots, N-1$. This regularization preserves Lorentz invariance (and other symmetries that the field theory may possess) and is local in the following sense. The modified propagator can be thought of as arising through the alteration of the Lagrangian density [4] by $N$ additional scalar fields $\varphi_j$ of masses $M_j$ with

$$\mathcal{L}_{\mathrm{PV}} = \tfrac{1}{2}\partial_\mu\phi\partial^\mu\phi - \tfrac{1}{2}m^2\phi^2 + \sum_{j=1}^{N}\left(\tfrac{1}{2}\partial_\mu\varphi_j\partial^\mu\varphi_j - \tfrac{1}{2}M_j^2\varphi_j^2\right) + \mathcal{L}_{\mathrm{int}}[\Phi] \quad [28]$$

where $\Phi := \phi + \sum_j \sqrt{c_j}\varphi_j$. The contraction of the $\Phi$ field thus produces the required propagator. However, the $c_j$'s as computed above are generically negative numbers and so the Lagrangian density [28] is not Hermitian (as $\Phi \neq \Phi^\dagger$). It is possible to make [28] formally Hermitian by redefining the inner product on the Hilbert space of physical states, but this produces negative-norm states. This is no problem at energy scales $E \ll M_j$ on which the extra particles decouple and the negative probability states are invisible.

#### Dimensional Regularization

Consider a Euclidean space integral $\int \mathrm{d}^4k(k^2 + a^2)^{-r}$ arising after Wick rotation from some loop diagram in $(3+1)$-dimensional scalar field theory. We replace this integral by its $D$-dimensional version

$$\int \frac{\mathrm{d}^D k}{(k^2 + a^2)^r} = \frac{\pi^{D/2}(a^2)^{D/2-r}}{(r-1)!}\Gamma\left(r - \frac{D}{2}\right) \quad [29]$$

This integral is absolutely convergent for $D < 2r$. We can analytically continue the result of this integration to the complex plane $D \in \mathbb{C}$. As an analytic function, the only singularities of the Euler function $\Gamma(z)$ are poles at $z = 0, -1, -2, \ldots$. In particular, $\Gamma(z)$ has a simple pole at $z = 0$ of residue 1. If we write $D = 4 + \epsilon$ with $|\epsilon| \to 0$, then the integral [29] is proportional to $\Gamma(r - 2 - \epsilon/2)$ and $\epsilon$ plays the role of the regulator here. This regularization is Lorentz invariant (in $D$ dimensions) and is distinguished as having a dimensionless regularization parameter $\epsilon$. This parameter is related to the momentum cutoff $\Lambda$ by $\epsilon^{-1} = \ln(\Lambda/m)$, so that the limit $\epsilon \to 0$ corresponds to $\Lambda \to \infty$.

#### Infrared Divergences

Thus far we have only considered the ultraviolet behavior of loop amplitudes in quantum field theory. When dealing with massless particles ($m = 0$ in [4]) one has to further worry about divergences arising from the $k \to 0$ regions of Feynman integrals. After Wick rotation to Euclidean momenta, one can show that no singularities arise in a given Feynman diagram as some of its internal masses vanish provided that all vertices have superficial degree of divergence $d + 1$, the external momenta are not exceptional (i.e., no partial sum of the incoming momenta $p_i$ vanishes), and there is at most one soft external momentum. This result assumes that renormalization has been carried out at some fixed Euclidean point. The extension of this property when the external momenta are continued to physical on-shell values is difficult. The Kinoshita–Lee–Nauenberg theorem states that, as a consequence of unitarity, transition probabilities in a theory involving massless particles are finite when the sum over all degenerate states (initial and final) is taken. This is true order by order in perturbation theory in bare quantities or if minimal subtraction renormalization is used (to avoid infrared or mass singularities in the renormalization constants).

### Fermion Fields

We will now leave the generalities of our pure scalar field theory and start considering the extensions of our previous considerations to other types of particles. Henceforth we will primarily deal with the case of $(3+1)$-dimensional spacetime. We begin by indicating how the rudiments of perturbation

theory above apply to the case of Dirac fermion fields. The Lagrangian density is

$$\mathcal{L}_F = \overline{\psi}(\mathrm{i}\partial\!\!\!/ - m)\psi + \mathcal{L}' \quad [30]$$

where $\psi$ are four-component Dirac fermion fields in $3+1$ dimensions, $\overline{\psi} := \psi^\dagger\gamma^0$ and $\partial\!\!\!/ = \gamma^\mu\partial_\mu$ with $\gamma^\mu$ the generators of the Clifford algebra $\{\gamma^\mu, \gamma^\nu\} = 2\eta^{\mu\nu}$. The Lagrangian density $\mathcal{L}'$ contains couplings of the Dirac fields to other field theories, such as the scalar field theories considered previously.

Wick's theorem for anticommuting Fermi fields leads to the Pfaffian formula

$$\langle 0|\mathrm{T}[\psi(1)\cdots\psi(n)]|0\rangle = \begin{cases} 0, \; n = 2k-1 \\ \dfrac{1}{2^k k!}\sum_{\pi\in S_{2k}} \mathrm{sgn}(\pi) \\ \times \prod_{i=1}^{k} \langle 0|\mathrm{T}[\psi(\pi(2i-1))\psi(\pi(2i))]|0\rangle \\ n = 2k \end{cases} \quad [31]$$

where for compactness we have written in the argument of $\psi(i)$ the spacetime coordinate, the Dirac index, and a discrete index which distinguishes $\psi$ from $\overline{\psi}$. The nonvanishing contractions in [31] are determined by the free-fermion propagator

$$\begin{aligned}\Delta_F(x-y) &= \langle 0|\mathrm{T}[\psi(x)\overline{\psi}(y)]|0\rangle \\ &= \left\langle x\middle|(\mathrm{i}\partial\!\!\!/ - m)^{-1}\middle|y\right\rangle \\ &= \mathrm{i}\int \frac{\mathrm{d}^4p}{(2\pi)^4}\frac{p\!\!\!/ + m}{p^2 - m^2 + \mathrm{i}\epsilon}\mathrm{e}^{-\mathrm{i}p\cdot(x-y)}\end{aligned} \quad [32]$$

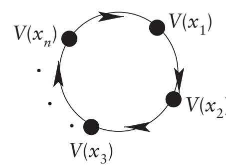
Perturbation theory now proceeds exactly as before. Suppose that the coupling Lagrangian density in [30] is of the form $\mathcal{L}' = \overline{\psi}(x)V(x)\psi(x)$. Both the Dyson formula [3] and the diagrammatic formula [15] are formally the same in this instance. For example, in the formal expansion in powers of $\int \mathrm{d}^4x\mathcal{L}'$, the vacuum-to-vacuum amplitude (the denominator in [5]) will contain field products of the form

$$\prod_{i=1}^{n}\int \mathrm{d}^4x_i\langle 0|\mathrm{T}[\overline{\psi}(x_i)V(x_i)\psi(x_i)]|0\rangle$$

which correspond to fermion loops. Before applying Wick's theorem, the fields must be rearranged as

$$\mathrm{tr}\prod_{i=1}^{n} V(x_i)\psi(x_i)\overline{\psi}(x_{i+1})$$

(with $x_{n+1} := x_1$), where tr is the $4\times 4$ trace over spinor indices. This reordering introduces the familiar minus sign for a closed fermion loop, and one has



$$\begin{aligned}= (-)\prod_{i=1}^{n}\int \mathrm{d}^4x_i \\ \times\, \mathrm{tr}\prod_{j=1}^{n-1}\Delta_F(x_j - x_{j+1}) \\ \times\, V(x_{j+1})\,\Delta_F(x_{j+1} - x_{j+2})\end{aligned} \quad [33]$$

Feynman rules are now described as follows. Fermion lines are oriented to distinguish a particle from its corresponding antiparticle, and carry both a four-momentum label $p$ as well as a spin polarization index $r = 1, 2$. Incoming fermions (resp. antifermions) are described by the wave functions $u_p^{(r)}$ (resp. $\overline{v}_p^{(r)}$), while outgoing fermions (resp. antifermions) are described by the wave functions $\overline{u}_p^{(r)}$ (resp. $v_p^{(r)}$). Here $u_p^{(r)}$ and $v_p^{(r)}$ are the classical spinors, that is, the positive and negative-energy solutions of the Dirac equation $(p\!\!\!/ - m)u_p^{(r)} = (p\!\!\!/ + m)v_p^{(r)} = 0$. Matrices are multiplied along a Fermi line, with the head of the arrow on the left. Closed fermion loops produce an overall minus sign as in [33], and the multiplication rule gives the trace of Dirac matrices along the lines of the loop. Unpolarized scattering amplitudes are summed over the spins of final particles and averaged over the spins of initial particles using the completeness relations for spinors

$$\sum_{r=1,2} u_p^{(r)}\overline{u}_p^{(r)} = p\!\!\!/ + m, \quad \sum_{r=1,2} v_p^{(r)}\overline{v}_p^{(r)} = p\!\!\!/ - m \quad [34]$$

leading to basis-independent results. Polarized amplitudes are computed using the spinor bilinears $\overline{u}_p^{(r)}\gamma^\mu u_p^{(s)} = \overline{v}_p^{(r)}\gamma^\mu v_p^{(s)} = 2p^\mu\delta^{rs}, \overline{u}_p^{(r)}u_p^{(s)} = -\overline{v}_p^{(r)}v_p^{(s)} = 2m\,\delta^{rs}$, and $\overline{u}_p^{(r)}v_p^{(s)} = 0$.

When calculating fermion loop integrals using dimensional regularization, one utilizes the Dirac algebra in $D$ dimensions

$$\begin{aligned}\gamma^\mu\gamma_\mu &= \eta^\mu_\mu = D \\ \gamma_\mu p\!\!\!/\gamma^\mu &= (2-D)p\!\!\!/ \\ \gamma^\mu p\!\!\!/ k\!\!\!/\gamma_\mu &= 4p\cdot k + (D-4)p\!\!\!/ k\!\!\!/ \\ \gamma^\mu p\!\!\!/ k\!\!\!/ q\!\!\!/\gamma_\mu &= -2q\!\!\!/ k\!\!\!/ p\!\!\!/ - (D-4)p\!\!\!/ k\!\!\!/ q\!\!\!/\end{aligned} \quad [35]$$

$$\mathrm{tr}\mathbb{1} = 4, \mathrm{tr}\gamma^{\mu_1}\cdots\gamma^{\mu_{2k-1}} = 0, \mathrm{tr}\gamma^\mu\gamma^\nu = 4\eta^{\mu\nu}$$

$$\mathrm{tr}\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma = 4(\eta^{\mu\nu}\eta^{\rho\sigma} - \eta^{\mu\rho}\eta^{\nu\sigma} + \eta^{\mu\sigma}\eta^{\nu\rho})$$

Specific to $D=4$ dimensions are the trace identities

$$\begin{aligned} \mathrm{tr}\gamma^5 &= \mathrm{tr}\gamma^\mu\gamma^\nu\gamma^5 = 0, \\ \mathrm{tr}\gamma^\mu\gamma^\nu\gamma^\rho\gamma^\sigma\gamma^5 &= -4\mathrm{i}\epsilon^{\mu\nu\rho\sigma} \end{aligned} \qquad [36]$$

where $\gamma^5 := \mathrm{i}\gamma^0\gamma^1\gamma^2\gamma^3$. Finally, loop diagrams evaluated with the fermion propagator [32] require a generalization of the momentum space integral [29] given by

$$\begin{aligned} &\int \frac{\mathrm{d}^D k}{(2\pi)^D} \frac{1}{(k^2 + 2k\cdot p + a^2 + \mathrm{i}\epsilon)^r} \\ &= \frac{\mathrm{i}(-\pi)^{D/2}\Gamma\left(r - \frac{D}{2}\right)}{(2\pi)^D (r-1)!} \frac{1}{(a^2 - p^2 + \mathrm{i}\epsilon)^{r-D/2}} \end{aligned} \qquad [37]$$

From this formula we can extract expressions for more complicated Feynman integrals which are tensorial, that is, which contain products of momentum components $k^\mu$ in the numerators of their integrands, by differentiating [37] with respect to the external momentum $p^\mu$.

## Gauge Fields

The issues we have dealt with thus far have interesting difficulties when dealing with gauge fields. We will now discuss some general aspects of the perturbation expansion of gauge theories using as prototypical examples quantum electrodynamics (QED) and quantum chromodynamics (QCD) in four spacetime dimensions.

### Quantum Electrodynamics

Consider the QED Lagrangian density

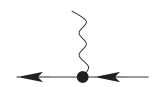
$$\begin{aligned} \mathcal{L}_{\mathrm{QED}} &= -\tfrac{1}{4}F_{\mu\nu}F^{\mu\nu} \\ &\quad + \tfrac{1}{2}\mu^2 A_\mu A^\mu + \overline{\psi}(\mathrm{i}\partial\!\!\!/ - eA\!\!\!/ - m)\psi \end{aligned} \qquad [38]$$

where $A_\mu$ is a U(1) gauge field in $3+1$ dimensions and $F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu$ is its field strength tensor. We have added a small mass term $\mu \to 0$ for the gauge field, which at the end of calculations should be taken to vanish in order to describe real photons (as opposed to the soft photons described by [38]). This is done in order to cure the infrared divergences generated in scattering amplitudes due to the masslessness of the photon, that is, the long-range nature of the electromagnetic interaction. The Bloch–Nordsieck theorem in QED states that infrared divergences cancel for physical processes, that is, for processes with an arbitrary number of undetectable soft photons.

Perturbation theory proceeds in the usual way via the Dyson formula, Wick's theorem, and Feynman diagrams. The gauge field propagator is given by

$$\begin{aligned} &\langle 0|\mathrm{T}\left[A_\mu(x)A_\nu(y)\right]|0\rangle \\ &= \langle x|\left[\eta_{\mu\nu}\left(\Box + \mu^2\right) - \partial_\mu\partial_\nu\right]^{-1}|y\rangle \\ &= \mathrm{i}\int \frac{\mathrm{d}^4 p}{(2\pi)^4} \frac{-\eta_{\mu\nu} + \frac{p_\mu p_\nu}{\mu^2}}{p^2 - \mu^2 + \mathrm{i}\epsilon} \mathrm{e}^{-\mathrm{i}p\cdot(x-y)} \end{aligned} \qquad [39]$$

and is represented by a wavy line. The fermion–fermion–photon vertex is



$\mu$ $= -\mathrm{i}e\gamma_\mu$ [40]

An incoming (resp. outgoing) soft photon of momentum $k$ and polarization $r$ is described by the wave function $e_\mu^{(r)}(k)$ (resp. $e_\mu^{(r)}(k)^*$), where the polarization vectors $e_\mu^{(r)}(k), r = 1, 2, 3$ solve the vector field wave equation $(\Box + \mu^2)A_\mu = \partial_\mu A^\mu = 0$ and obey the orthonormality and completeness conditions

$$\begin{aligned} e^{(r)}(k)^* \cdot e^{(s)}(k) &= -\delta^{rs} \\ \sum_{r=1}^{3} e_\mu^{(r)}(k) e_\nu^{(r)}(k)^* &= -\eta_{\mu\nu} + \frac{k_\mu k_\nu}{\mu^2} \end{aligned} \qquad [41]$$

along with $k \cdot e^{(r)}(k) = 0$. All vector indices are contracted along the lines of the Feynman graph. All other Feynman rules are as previously.

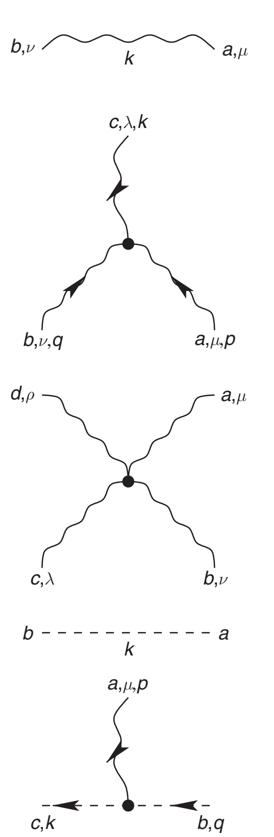
### Quantum Chromodynamics

Consider nonabelian gauge theory in $3+1$ dimensions minimally coupled to a set of fermion fields $\psi^A, A = 1, \ldots, N_f$, each transforming in the fundamental representation of the gauge group $G$ whose generators $T^a$ satisfy the commutation relations $[T^a, T^b] = f^{abc}T^c$. The Lagrangian density is given by

$$\begin{aligned} \mathcal{L}_{\mathrm{QCD}} &= -\frac{1}{4}F^a_{\mu\nu}F^{a\,\mu\nu} + \frac{1}{2\alpha}\left(\partial_\mu A^{a\,\mu}\right)^2 + \partial_\mu\overline{\eta}\,D^\mu\eta \\ &\quad + \sum_{A=1}^{N_f} \overline{\psi}^A(\mathrm{i}D\!\!\!/ - m_A)\psi^A \end{aligned} \qquad [42]$$

where $F^a_{\mu\nu} = \partial_\mu A^a_\nu - \partial_\nu A^a_\mu + f^{abc}A^b_\mu A^c_\nu$ and $D_\mu = \partial_\mu + \mathrm{i}eR(T^a)A^a_\mu$, with $R$ the pertinent representation of $G$ ($R(T^a)_{bc} = f^a_{bc}$ for the adjoint representation and $R(T^a) = T^a$ for the fundamental representation). The first term is the Yang–Mills Lagrangian density, the second term is the covariant gauge-fixing term, and the third term contains the Faddeev–Popov ghost fields $\eta$ which transform in the adjoint representation of the gauge group.

Feynman rules are straightforward to write down and are given in **Figure 1** where wavy lines



$$-\mathrm{i}\,\delta^{ab}\,\frac{\eta_{\mu\nu}+(\alpha-1)\,\dfrac{k_\mu k_\nu}{k^2}}{k^2+\mathrm{i}\epsilon}$$

$$e\,f^{abc}\left[\eta_{\lambda\mu}(p_\nu-k_\nu)+\eta_{\mu\nu}\,(q_\lambda-p_\lambda)+\eta_{\nu\lambda}(k_\mu-q_\mu)\right]$$

$$-\mathrm{i}\,e^2\left[f^{eab}\,f^{ecd}\,(\eta_{\mu\lambda}\,\eta_{\nu\rho}-\eta_{\mu\rho}\,\eta_{\nu\lambda}) + f^{eac}\,f^{ebd}\,(\eta_{\mu\nu}\,\eta_{\lambda\rho}-\eta_{\mu\rho}\,\eta_{\nu\lambda})+f^{ead}\,f^{ebc}\,(\eta_{\mu\nu}\,\eta_{\lambda\rho}-\eta_{\nu\rho}\,\eta_{\mu\lambda})\right]$$

$$\frac{\mathrm{i}\,\delta^{ab}}{k^2+\mathrm{i}\epsilon}$$

$$e k_\mu\, f^{abc}$$

**Figure 1** Feynman rules.

represent gluons and dashed lines represent ghosts. Feynman rules for the fermions are exactly as before, except that now the vertex [40] is multiplied by the color matrix $T^a$. All color indices are contracted along the lines of the Feynman graph. Color factors may be simplified by using the identities

$$\begin{aligned}&\operatorname{Tr} R^a\, R^b = \frac{\dim R}{\dim G}\, C_2(R)\delta^{ab}, \quad R^a\, R^a = C_2(R)\\ &R^a\, R^b\, R^a = \left(C_2(R) - \frac{1}{2}\, C_2(G)\right) R^b\end{aligned} \qquad [43]$$

where $R^a := R(T^a)$ and $C_2(R)$ is the quadratic Casimir invariant of the representation $R$ (with value $C_2(G)$ in the adjoint representation). For $G = \mathrm{SU}(N)$, one has $C_2(G) = N$ and $C_2(N) = (N^2 - 1)/2N$ for the fundamental representation.

The cancellation of infrared divergences in loop amplitudes of QCD is far more delicate than in QED, as there is no analog of the Bloch–Nordsieck theorem in this case. The Kinoshita–Lee–Nauenberg theorem guarantees that, at the end of any perturbative calculation, these divergences must cancel for any appropriately defined physical quantity. However, at a given order of perturbation theory, a physical quantity typically involves both virtual and real emission contributions that are separately infrared divergent. Already at two-loop level these divergences have a highly intricate structure. Their precise form is specified by the Catani color-space factorization formula, which also provides an efficient way of organizing amplitudes into divergent parts, which ultimately drop out of physical quantities, and finite contributions.

The computation of multigluon amplitudes in nonabelian gauge theory is rather complicated when one uses polarization states of vector bosons. A much more efficient representation of amplitudes is provided by adopting a helicity (or circular polarization) basis for external gluons. In the spinor–helicity formalism, one expresses positive and negative-helicity polarization vectors in terms of massless Weyl spinors $|k^\pm\rangle := \frac{1}{2}(\mathbb{1} \pm \gamma_5)u_k = \frac{1}{2}(\mathbb{1} \pm \gamma_5)v_k$ through

$$e^\pm_\mu(k;q) = \pm\frac{\langle q^\mp|\gamma_\mu|k^\mp\rangle}{\sqrt{2}\langle q^\mp|k^\pm\rangle} \qquad [44]$$

where $q$ is an arbitrary null reference momentum which drops out of the final gauge-invariant amplitudes. The spinor products are crossing symmetric, antisymmetric in their arguments, and satisfy the identities

$$\left\langle k_i^-|k_j^+\right\rangle\left\langle k_j^+|k_i^-\right\rangle = 2k_i\cdot k_j$$
$$\left\langle k_i^-\middle|k_j^+\right\rangle\langle k_l^-|k_r^+\rangle = \langle k_i^-|k_r^+\rangle\left\langle k_l^-|k_j^+\right\rangle + \langle k_i^-|k_l^+\rangle\left\langle k_j^-|k_r^+\right\rangle \quad [45]$$

Any amplitude with massless external fermions and vector bosons can be expressed in terms of spinor products. Conversely, the spinor products offer the most compact representation of helicity amplitudes which can be related to more conventional amplitudes described in terms of Lorentz invariants. For loop amplitudes, one uses a dimensional regularization scheme in which all helicity states are kept four dimensional and only internal loop momenta are continued to $D = 4 + \epsilon$ dimensions.

## Computing Loop Integrals

At the very heart of perturbative quantum field theory is the problem of computing Feynman integrals for multiloop scattering amplitudes. The integrations typically involve serious technical challenges and for the most part are intractable by straightforward analytical means. We will now survey some of the computational techniques that have been developed for calculating quantum loop amplitudes which arise in the field theories considered previously.

### Asymptotic Expansion

In many physical instances one is interested in scattering amplitudes in certain kinematical limits. In this case one may perform an asymptotic expansion of multiloop diagrams whose coefficients are typically nonanalytic functions of the perturbative expansion parameter $\hbar$. The main simplification which arises comes from the fact that the expansions are done before any momentum integrals are evaluated. In the limits of interest, Taylor series expansions in different selected regions of each loop momentum can be interpreted in terms of subgraphs and co-subgraphs of the original Feynman diagram.

Consider a Feynman diagram $\mathfrak{D}$ which depends on a collection $\{Q_i\}$ of large momenta (or masses), and a collection $\{m_i, q_i\}$ of small masses and momenta. The prescription for the large-momentum asymptotic expansion of $\mathfrak{D}$ may be summarized in the diagrammatic formula

$$\lim_{Q\to\infty}\mathfrak{D}(Q;m,q) = \sum_{\mathfrak{d}\subset\mathfrak{D}}(\mathfrak{D}/\mathfrak{d})(m,q)\star\left(\mathcal{T}_{\{m_\mathfrak{d},q_\mathfrak{d}\}}\mathfrak{d}\right)(Q;m_\mathfrak{d},q_\mathfrak{d}) \quad [46]$$

where the sum runs through all subgraphs $\mathfrak{d}$ of $\mathfrak{D}$ which contain all vertices where a large momentum enters or leaves the graph and is one-particle irreducible after identifying these vertices. The operator $\mathcal{T}_{\{m_\mathfrak{d},q_\mathfrak{d}\}}$ performs a Taylor series expansion before any integration is carried out, and the notation $(\mathfrak{D}/\mathfrak{d})\star(\mathcal{T}_{\{m_\mathfrak{d},q_\mathfrak{d}\}}\mathfrak{d})$ indicates that the subgraph $\mathfrak{d}\subset\mathfrak{D}$ is replaced by its Taylor expansion in all masses and external momenta of $\mathfrak{d}$ that do not belong to the set $\{Q_i\}$. The external momenta of $\mathfrak{d}$ which become loop momenta in $\mathfrak{D}$ are also considered to be small. The loop integrations are then performed only after all these expansions have been carried out. The diagrams $\mathfrak{D}/\mathfrak{d}$ are called co-subgraphs.

The subgraphs become massless integrals in which the scales are set by the large momenta. For instance, in the simplest case of a single large momentum $Q$ one is left with integrals over propagators. The co-subgraphs may contain small external momenta and masses, but the resulting integrals are typically much simpler than the original one. A similar formula is true for large-mass expansions, with the vertex conditions on subdiagrams replace by propagator conditions. For example, consider the asymptotic expansion of the two-loop double bubble diagram (Figure 2) in the region $q^2 \ll m^2$, where $m$ is the mass of the inner loop. The subgraphs (to the right of the stars) are expanded in all external momenta including $q$ and reinserted into the fat vertices of the co-subgraphs (to the left of the stars). Once such asymptotic expansions are carried out, one may attempt to reconstruct as much information as possible about the given scattering amplitude

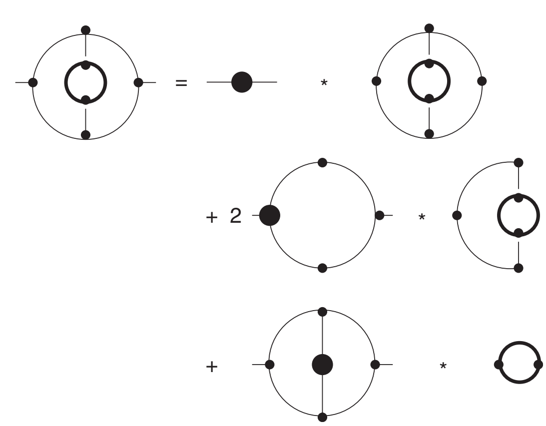


**Figure 2** Asymptotic expansion of the two-loop double bubble diagram.

by using the method of Padé approximation which requires knowledge of only part of the expansion of the diagram. By construction, the Padé approximation has the same analytic properties as the exact amplitude.

### Brown–Feynman Reduction

When considering loop diagrams which involve fermions or gauge bosons, one encounters tensorial Feynman integrals. When these involve more than three distinct denominator factors (propagators), they require more than two Feynman parameters for their evaluation and become increasingly complicated. The Brown–Feynman method simplifies such higher-rank integrals and effectively reduces them to scalar integrals which typically require fewer Feynman parameters for their evaluation.

To illustrate the idea behind this method, consider the one-loop rank-3 tensor Feynman integral

$$J^{\mu\nu\lambda} = \int \frac{\mathrm{d}^D k}{(2\pi)^D} \times \frac{k^\mu k^\nu k^\lambda}{k^2(k^2-\mu^2)(q-k)^2((k-q)^2+\mu^2)(k^2+2k\cdot p)} \quad [47]$$

where $p$ and $q$ are external momenta with the mass-shell conditions $p^2=(p-q)^2=m^2$. By Lorentz invariance, the general structure of the integral [47] will be of the form

$$J^{\mu\nu\lambda} = a^{\mu\nu}p^\lambda + b^{\mu\nu}q^\lambda + c^\mu s^{\nu\lambda} + c^\nu s^{\mu\lambda} \quad [48]$$

where $a^{\mu\nu}, b^{\mu\nu}$ are tensor-valued functions and $c^\mu$ a vector-valued function of $p$ and $q$. The symmetric tensor $s^{\mu\nu}$ is chosen to project out components of vectors transverse to both $p$ and $q$, i.e., $p_\mu s^{\mu\nu} = q_\mu s^{\mu\nu} = 0$, with the normalization $s_\mu{}^\mu = D-2$. Solving these constraints leads to the explicit form

$$s^{\mu\nu} = \eta^{\mu\nu} - \frac{m^2 q^\mu q^\nu + q^2 p^\mu p^\nu - (p\cdot q)(q^\mu p^\nu + p^\mu q^\nu)}{m^2 q^2 - (p\cdot q)^2} \quad [49]$$

To determine the as yet unknown functions $a^{\mu\nu}, b^{\mu\nu}$ and $c^\mu$ above, we first contract both sides of the decomposition [48] with $p^\mu$ and $q^\mu$ to get

$$\begin{aligned} 2p_\lambda J^{\mu\nu\lambda} &= 2m^2 a^{\mu\nu} + 2(p\cdot q)b^{\mu\nu} \\ 2q_\lambda J^{\mu\nu\lambda} &= 2(p\cdot q)a^{\mu\nu} + 2q^2 b^{\mu\nu} \end{aligned} \quad [50]$$

Inside the integrand of [47], we then use the trivial identities

$$\begin{aligned} 2k\cdot p &= \left(k^2 + 2k\cdot p\right) - k^2 \\ 2q\cdot k &= k^2 + q^2 - (k-q)^2 \end{aligned} \quad [51]$$

to write the left-hand sides of [50] as the sum of rank-2 Feynman integrals which, with the exception of the one multiplied by $q^2$ from [51], have one less denominator factor. This formally determines the coefficients $a^{\mu\nu}$ and $b^{\mu\nu}$ in terms of a set of rank-2 integrations. The vector function $c^\mu$ is then found from the contraction

$$J^{\mu\nu}{}_\nu = p_\nu a^{\mu\nu} + q_\nu b^{\mu\nu} + (D-2)c^\mu \quad [52]$$

This contraction eliminates the $k^2$ denominator factor in the integrand of [47] and produces a vector-valued integral. Solving the system of algebraic equations [50] and [52] then formally determines the rank-3 Feynman integral [47] in terms of rank-1 and rank-2 Feynman integrals. The rank-2 Feynman integrals thus generated can then be evaluated in the same way by writing a decomposition for them analogous to [48] and solving for them in terms of vector-valued and scalar-valued Feynman integrals. Finally, the rank-1 integrations can be solved for in terms of a set of scalar-valued integrals, most of which have fewer denominator factors in their integrands.

Generally, any one-loop amplitude can be reduced to a set of basic integrals by using the Passarino–Veltman reduction technique. For example, in supersymmetric amplitudes of gluons any tensor Feynman integral can be reduced to a set of scalar integrals, that is, Feynman integrals in a scalar field theory with a massless particle circulating in the loop, with rational coefficients. In the case of $\mathcal{N}=4$ supersymmetric Yang–Mills theory, only scalar box integrals appear.

### Reduction to Master Integrals

While the Brown–Feynman and Passarino–Veltman reductions are well suited for dealing with one-loop diagrams, they become rather cumbersome for higher-loop computations. There are other more powerful methods for reducing general tensor integrals into a basis of known integrals called master integrals. Let us illustrate this technique on a scalar example. Any scalar massless two-loop Feynman integral can be brought into the form

$$I(p) = \int \frac{\mathrm{d}^D k}{(2\pi)^D} \int \frac{\mathrm{d}^D k'}{(2\pi)^D} \prod_{j=1}^{t} \Delta_j^{-l_j} \prod_{i=1}^{q} \Sigma_i^{n_i} \quad [53]$$

where $\Delta_j$ are massless scalar propagators depending on the loop momenta $k, k'$ and the external momenta $p_1, \ldots, p_n$, and $\Sigma_i$ are scalar products of a loop momentum with an external momentum or of the two loop momenta. The topology of the corresponding Feynman diagram is uniquely determined by specifying the set $\Delta_1, \ldots, \Delta_t$ of $t$ distinct

propagators in the graph, while the integral itself is specified by the powers $l_j \geq 1$ of all propagators, by the selection $\Sigma_1, \ldots, \Sigma_q$ of $q$ scalar products and by their powers $n_i \geq 0$.

The integrals in a class of diagrams of the same topology with the same denominator dimension $r = \sum_j l_j$ and same total scalar product number $s = \sum_i n_i$ are related by various identities. One class follows from the fact that the integral over a total derivative with respect to any loop momentum vanishes in dimensional regularization as

$$\int \frac{\mathrm{d}^D k}{(2\pi)^D} \frac{\partial J(k)}{\partial k^\mu} = 0$$

where $J(k)$ is any tensorial combination of propagators, scalar products and loop momenta. The resulting relations are called integration-by-parts identities and for two-loop integrals can be cast into the form

$$\int \frac{\mathrm{d}^D k}{(2\pi)^D} \int \frac{\mathrm{d}^D k'}{(2\pi)^D} v^\mu \frac{\partial f(k,k',p)}{\partial k^\mu} = 0 = \int \frac{\mathrm{d}^D k}{(2\pi)^D} \int \frac{\mathrm{d}^D k'}{(2\pi)^D} v^\mu \frac{\partial f(k,k',p)}{\partial k'^\mu} \qquad [54]$$

where $f(k,k',p)$ is a scalar function containing propagators and scalar products, and $v^\mu$ is any internal or external momentum. For a graph with $\ell$ loops and $n$ independent external momenta, this results in a total of $\ell(n+\ell)$ relations.

In addition to these identities, one can also exploit the fact that all Feynman integrals [53] are Lorentz scalars. Under an infinitesimal Lorentz transformation $p^\mu \to p^\mu + \delta p^\mu$, with $\delta p^\mu = p^\nu \delta\epsilon^\mu_\nu$, $\delta\epsilon^\mu_\nu = -\delta\epsilon^\nu_\mu$, one has the invariance condition $I(p+\delta p) = I(p)$, which leads to the linear homogeneous differential equations

$$\sum_{i=1}^{n} \left( p_i^\nu \frac{\partial}{\partial p_{i\mu}} - p_i^\mu \frac{\partial}{\partial p_{i\nu}} \right) I(p) = 0 \qquad [55]$$

This equation can be contracted with all possible antisymmetric combinations of $p_{i\mu} p_{j\nu}$ to yield linearly independent Lorentz invariance identities for (53).

Using these two sets of identities, one can either obtain a reduction of integrals of the type (53) to those corresponding to a small number of simpler diagrams of the same topology and diagrams of simpler topology (fewer denominator factors), or a complete reduction to diagrams with simpler topology. The remaining integrals of the topology under consideration are called irreducible master integrals. These momentum integrals cannot be further reduced and have to be computed by different techniques. For instance, one can apply a Mellin–Barnes transformation of all propagators given by

$$\frac{1}{(k^2+a)^l} = \frac{1}{(l-1)!} \int_{-\mathrm{i}\infty}^{\mathrm{i}\infty} \frac{\mathrm{d}z}{2\pi \mathrm{i}} \frac{a^z}{(k^2)^{l+z}} \Gamma(l+z)\Gamma(-z) \qquad [56]$$

where the contour of integration is chosen to lie to the right of the poles of the Euler function $\Gamma(l+z)$ and to the left of the poles of $\Gamma(-z)$ in the complex $z$-plane. Alternatively, one may apply the negative-dimension method in which $D$ is regarded as a negative integer in intermediate calculations and the problem of loop integration is replaced with that of handling infinite series. When combined with the above methods, it may be used to derive powerful recursion relations among scattering amplitudes. Both of these techniques rely on an explicit integration over the loop momenta of the graph, their differences occurring mainly in the representations used for the propagators.

The procedure outlined above can also be used to reduce a tensor Feynman integral to scalar integrals, as in the Brown–Feynman and Passarino–Veltman reductions. The tensor integrals are expressed as linear combinations of scalar integrals of either higher dimension or with propagators raised to higher powers. The projection onto a tensor basis takes the form [53] and can thus be reduced to master integrals.

## String Theory Methods

The realizations of field theories as the low-energy limits of string theory provides a number of powerful tools for the calculation of multiloop amplitudes. They may be used to provide sets of diagrammatic computational rules, and they also work well for calculations in quantum gravity. In this final part we shall briefly sketch the insights into perturbative quantum field theory that are provided by techniques borrowed from string theory.

### String Theory Representation

String theory provides an efficient compact representation of scattering amplitudes. At each loop order there is only a single closed string diagram, which includes within it all Feynman graphs along with the contributions of the infinite tower of massive string excitations. Schematically, at one-loop order, the situation is as shown in Figure 3. The terms arising from the heavy string modes are removed by taking the low-energy limit in which all external momenta lie well below the energy scale set by the string tension. This limit picks out the regions of integration in the string diagram corresponding to particle-like graphs, but with different diagrammatic rules.

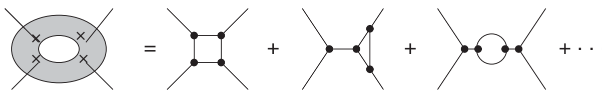

**Figure 3** String theory representation at one-loop order.

Given these rules, one may formulate a purely field-theoretic framework which reproduces them. In the case of QCD, a key ingredient is the use of a special gauge originally derived from the low-energy limit of tree-level string amplitudes. This is known as the Gervais–Neveu gauge and it is defined by the gauge-fixing Lagrangian density

$$\mathcal{L}_{\mathrm{GN}} = -\frac{1}{2}\mathrm{Tr}\left(\partial_\mu A^\mu - \frac{\mathrm{i}e}{\sqrt{2}}A_\mu A^\mu\right)^2 \qquad [57]$$

This gauge choice simplifies the color factors that arise in scattering amplitudes. The string theory origin of gauge theory amplitudes is then most closely mimicked by combining this gauge with the background field gauge, in which one decomposes the gauge field into a classical background field and a fluctuating quantum field as $A_\mu = A_\mu^{\mathrm{cl}} + A_\mu^{\mathrm{qu}}$, and imposes the gauge-fixing condition $D_\mu^{\mathrm{cl}} A^{\mathrm{qu}\mu} = 0$, where $D_\mu^{\mathrm{cl}}$ is the background field covariant derivative evaluated in the adjoint representation of the gauge group. This hybrid gauge is well suited for computing the effective action, with the quantum part describing gluons propagating around loops and the classical part describing gluons emerging from the loops. The leading loop momentum behavior of one-particle irreducible graphs with gluons in the loops is very similar to that of graphs with scalar fields in the loops.

### Supersymmetric Decomposition

String theory also suggests an intimate relationship with supersymmetry. For example, at tree level, QCD is effectively supersymmetric because a multi-gluon tree amplitude contains no fermion loops, and so the fermions may be taken to lie in the adjoint representation of the gauge group. Thus, pure gluon tree amplitudes in QCD are identical to those in supersymmetric Yang–Mills theory. They are connected by supersymmetric Ward identities to amplitudes with fermions (gluinos) which drastically simplify computations. In supersymmetric gauge theory, these identities hold to all orders of perturbation theory.

At one-loop order and beyond, QCD is not supersymmetric. However, one can still perform a supersymmetric decomposition of a QCD amplitude for which the supersymmetric components of the amplitude obey the supersymmetric Ward identities. Consider, for example, a one-loop multigluon scattering amplitude. The contribution from a fermion propagating in the loop can be decomposed into the contribution of a complex scalar field in the loop plus a contribution from an $\mathcal{N}=1$ chiral supermultiplet consisting of a complex scalar field and a Weyl fermion. The contribution from a gluon circulating in the loop can be decomposed into contributions of a complex scalar field, an $\mathcal{N}=1$ chiral supermultiplet, and an $\mathcal{N}=4$ vector supermultiplet comprising three complex scalar fields, four Weyl fermions and one gluon all in the adjoint representation of the gauge group. This decomposition assumes the use of a supersymmetry-preserving regularization.

The supersymmetric components have important cancellations in their leading loop momentum behavior. For instance, the leading large loop momentum power in an $n$-point 1PI graph is reduced from $|k|^n$ down to $|k|^{n-2}$ in the $\mathcal{N}=1$ amplitude. Such a reduction can be extended to any amplitude in supersymmetric gauge theory and is related to the improved ultraviolet behavior of supersymmetric amplitudes. For the $\mathcal{N}=4$ amplitude, further cancellations reduce the leading power behavior all the way down to $|k|^{n-4}$. In dimensional regularization, $\mathcal{N}=4$ supersymmetric loop amplitudes have a very simple analytic structure owing to their origins as the low-energy limits of superstring scattering amplitudes. The supersymmetric Ward identities in this way can be used to provide identities among the nonsupersymmetric contributions. For example, in $\mathcal{N}=1$ supersymmetric Yang–Mills theory one can deduce that fermion and gluon loop contributions are equal and opposite for multi-gluon amplitudes with maximal helicity violation.

### Scattering Amplitudes in Twistor Space

The scattering amplitude in QCD with $n$ incoming gluons of the same helicity vanishes, as does the amplitude with $n-1$ incoming gluons of one helicity and one gluon of the opposite helicity for $n \geq 3$. The first nonvanishing amplitudes are the maximal helicity violating (*MHV*) amplitudes involving $n-2$ gluons of one helicity and two gluons of the opposite helicity. Stripped of the momentum conservation delta-function and the group theory factor, the tree-level amplitude for a pair of gluons of negative helicity is given by

$$\mathcal{A}(k) = e^{n-2}\langle k_r^- | k_s^+ \rangle \prod_{i=1}^{n} \langle k_i^- | k_{i+1}^+ \rangle^{-1} \qquad [58]$$

This amplitude depends only on the holomorphic (negative chirality) Weyl spinors. The full MHV amplitude (with the momentum conservation delta-function) is invariant under the conformal group $\mathrm{SO}(4,2) \cong \mathrm{SU}(2,2)$ of four-dimensional

Minkowski space. After a Fourier transformation of the positive-chirality components, the complexification $SL(4, \mathbb{C})$ has an obvious four-dimensional representation acting on the positive- and negative-chirality spinor products. This representation space is isomorphic to $\mathbb{C}^4$ and is called twistor space. Its elements are called twistors.

Wave functions and amplitudes have a known behavior under the $\mathbb{C}^\times$-action which rescales twistors, giving the projective twistor space $\mathbb{CP}^3$ or $\mathbb{RP}^3$ according to whether the twistors are complex valued or real valued. The Fourier transformation to twistor space yields (due to momentum conservation) the localization of an MHV amplitude to a genus-0 holomorphic curve $\mathbb{CP}^1$ of degree 1 in $\mathbb{CP}^3$ (or to a real line $\mathbb{RP}^1 \subset \mathbb{RP}^3$). It is conjectured that, generally, an $\ell$-loop amplitude with $p$ gluons of positive helicity and $q$ gluons of negative helicity is supported on a holomorphic curve in twistor space of degree $q + \ell - 1$ and genus $\leq \ell$. The natural interpretation of this curve is as the world sheet of a string. The perturbative gauge theory may then be described in terms of amplitudes arising from the couplings of gluons to a string. This twistor string theory is a topological string theory which gives the appropriate framework for understanding the twistor properties of scattering amplitudes. This framework has been used to analyze MHV tree diagrams and one-loop $\mathcal{N} = 4$ supersymmetric amplitudes of gluons.

## Main Problems in the Perturbative Quantization of Gauge Theories

Gauge theories are field theories in which the basic fields are not directly observable. Field configurations yielding the same observables are connected by a gauge transformation. In the classical theory, the Cauchy problem is well posed for the observables, but in general not for the nonobservable gauge-variant basic fields, due to the existence of time-dependent gauge transformations.

Attempts to quantize the gauge-invariant objects directly have not yet been completely satisfactory. Instead, one modifies the classical action by adding a gauge-fixing term such that standard techniques of perturbative quantization can be applied and such that the dynamics of the gauge-invariant classical fields is not changed. In perturbation theory, this

problem shows up already in the quantization of the free gauge fields (see the section "Quantization of free gauge fields"). In the final (interacting) theory the physical quantities should be independent on how the gauge fixing is done ("gauge independence").

Traditionally, the quantization of gauge theories is mostly analyzed in terms of path integrals (e.g., by Faddeev and Popov), where some parts of the arguments are only heuristic. In the original treatment of Becchi, Rouet, and Stora (cf. also Tyutin) (which is called "BRST-quantization"), a restriction to purely massive theories was necessary; the generalization to the massless case by Lowenstein's method is cumbersome.

The BRST quantization is based on earlier work of Feynman, Faddeev, and Popov (introduction of "ghost fields"), and of Slavnov. The basic idea is that after adding a term to the Lagrangian which makes the Cauchy problem well posed but which is not gauge-invariant one enlarges the number of fields by infinitesimal gauge transformations ("ghosts") and their duals ("anti-ghosts"). One then adds a further term to the Lagrangian which contains a coupling of the anti-ghosts and ghosts. The BRST transformation acts as an infinitesimal gauge transformation on the original fields and on the gauge transformations themselves and maps the anti-ghosts to the gauge-fixing terms. This is done in such a way that the total Lagrangian is invariant and that the BRST transformation is nilpotent. The hard problem in the perturbative construction of gauge theories is to show that BRST symmetry can be maintained during renormalization (see the section on perturbative renormalization). By means of the "quantum action principle" of Lowenstein (1971) and Lam (1972, 1973) a cohomological classification of anomalies was worked out (an overview is given, e.g., in the book of Piguet and Sorella (1995)). For more details, *see* BRST Quantization.

The BRST quantization can be carried out in a transparent way in the framework of algebraic quantum field theory (AQFT, *see* Algebraic Approach to Quantum Field Theory). The advantage of this formulation is that it allows one to separate the three main problems of perturbative gauge theories:

1. the elimination of unphysical degrees of freedom,
2. positivity (or "unitarity"), and
3. the problem of infrared divergences.

In AQFT, the procedure is the following: starting from an algebra of all local fields, including the unphysical ones, one shows that after perturbative quantization the algebra admits the BRST transformation as a graded nilpotent derivation. The algebra of observables is then defined as the cohomology of the BRST transformation. To solve the problem of positivity, one has to show that the algebra of observables, in contrast to the algebra of all fields, has a nontrivial representation on a Hilbert space. Finally, one can attack the infrared problem by investigating the asymptotic behavior of states. The latter problem is nontrivial even in quantum electrodynamics (since an electron is accompanied by a "cloud of soft photons") and may be related to confinement in quantum chromodynamics.

The method of BRST quantization is by no means restricted to gauge theories, but applies to general constrained systems. In particular, massive vector fields, where the masses are usually generated by the Higgs mechanism, can alternatively be treated directly by the BRST formalism, in close analogy to the massless case (cf. the section on quantization of free gauge fields).

## Local Operator BRST Formalism

In AQFT, the principal object is the family of operator algebras $\mathcal{O} \to \mathcal{A}(\mathcal{O})$ (where $\mathcal{O}$ runs, e.g., through all double cones in Minkowski space), which fulfills the Haag–Kastler axioms (cf. Algebraic Approach to Quantum Field Theory). To construct these algebras, one considers the algebras $\mathcal{F}(\mathcal{O})$ generated by all local fields including ghosts $u$ and anti-ghosts $\tilde{u}$. Ghosts and anti-ghosts are scalar fermionic fields. The algebra gets a $\mathbb{Z}_2$ grading with respect to even and odd ghost numbers, where ghosts get ghost numbers +1 and anti-ghosts ghost number –1. The BRST transformation $s$ acts on these algebras as a $\mathbb{Z}_2$-graded derivation with $s^2 = 0$, $s(\mathcal{F}(\mathcal{O})) \subset \mathcal{F}(\mathcal{O})$, and $s(F^*) = -(-1)^{\delta_F} s(F)^*$, $\delta_F$ denoting the ghost number of $F$.

The observables should be $s$-invariant and may be identified if they differ by a field in the range of $s$. Since the range $\mathcal{A}_{00}$ of $s$ is an ideal in the kernel $\mathcal{A}_0$ of $s$, the algebra of observables is defined as the quotient

$$\mathcal{A} := \mathcal{A}_0 / \mathcal{A}_{00} \qquad [1]$$

and the local algebras $\mathcal{A}(\mathcal{O}) \subset \mathcal{A}$ are the images of $\mathcal{A}_0 \cap \mathcal{F}(\mathcal{O})$ under the quotient map $\mathcal{A}_0 \to \mathcal{A}$.

To prove that $\mathcal{A}$ admits a nontrivial representation by operators on a Hilbert space, one may use the BRST operator formalism (Kugo and Ojima 1979, Dütsch and Fredenhagen 1999): one starts from a representation of $\mathcal{F}$ on an inner-product space $(\mathcal{K}, \langle \cdot\,, \cdot \rangle)$ such that $\langle F^*\phi, \psi \rangle = \langle \phi, F\psi \rangle$

and that $s$ is implemented by an operator $Q$ on $\mathcal{K}$, that is,

$$s(F) = [Q, F] \qquad [2]$$

with $[\cdot,\cdot]$ denoting the graded commutator, such that $Q$ is symmetric and nilpotent. One may then construct the space of physical states as the cohomology of $Q$, $\mathcal{H} := \mathcal{K}_0/\mathcal{K}_{00}$, where $\mathcal{K}_0$ is the kernel and $\mathcal{K}_{00}$ the range of $Q$. The algebra of observables now has a natural representation $\pi$ on $\mathcal{H}$:

$$\pi([A])[\phi] := [A\phi] \qquad [3]$$

(where $A \in \mathcal{A}_0, \phi \in \mathcal{K}_0, [A] := A + \mathcal{A}_{00}, [\phi] := \phi + \mathcal{K}_{00}$). The crucial question is whether the scalar product on $\mathcal{H}$ inherited from $\mathcal{K}$ is positive definite.

In free quantum field theories $(\mathcal{K}, \langle\cdot,\cdot\rangle)$ can be chosen in such a way that the positivity can directly be checked by identifying the physical degrees of freedom (see next section). In interacting theories (see the section on perturbative construction of gauge theories), one may argue in terms of scattering states that the free BRST operator on the asymptotic fields coincides with the BRST operator of the interacting theory. This argument, however, is invalidated by infrared problems in massless gauge theories. Instead, one may use a stability property of the construction.

Namely, let $\tilde{\mathcal{F}}$ be the algebra of formal power series with values in $\mathcal{F}$, and let $\tilde{\mathcal{K}}$ be the vector space of formal power series with values in $\mathcal{K}$. $\tilde{\mathcal{K}}$ possesses a natural inner product with values in the ring of formal power series $\mathbb{C}[[\lambda]]$, as well as a representation of $\tilde{\mathcal{F}}$ by operators. One also assumes that the BRST transformation $\tilde{s}$ is a formal power series $\tilde{s} = \sum_n \lambda^n s_n$ of operators $s_n$ on $\mathcal{F}$ and that the BRST operator $\tilde{Q}$ is a formal power series $\tilde{Q} = \sum_n \lambda^n Q_n$ of operators on $\mathcal{K}$. The algebraic construction can then be done in the same way as before, yielding a representation $\tilde{\pi}$ of the algebra of observables $\tilde{\mathcal{A}}$ by endomorphisms of a $\mathbb{C}[[\lambda]]$ module $\tilde{\mathcal{H}}$, which has an inner product with values in $\mathbb{C}[[\lambda]]$.

One now assumes that at $\lambda = 0$ the inner product is positive, in the sense that

(Positivity)

$$\begin{aligned} &\text{(i) } \langle\phi,\phi\rangle \geq 0 \quad \forall \phi \in \mathcal{K} \text{ with } Q_0\phi = 0, \text{ and} \\ &\text{(ii) } Q_0\phi = 0 \wedge \langle\phi,\phi\rangle = 0 \Longrightarrow \phi \in Q_0\mathcal{K} \end{aligned} \qquad [4]$$

Then the inner product on $\tilde{\mathcal{H}}$ is positive in the sense that for all $\tilde{\phi} \in \tilde{\mathcal{H}}$ the inner product with itself, $\langle\tilde{\phi},\tilde{\phi}\rangle$, is of the form $\tilde{c}^*\tilde{c}$ with some power series $\tilde{c} \in \mathbb{C}[[\lambda]]$, and $\tilde{c} = 0$ iff $\tilde{\phi} = 0$.

This result guarantees that, within perturbation theory, the interacting theory satisfies positivity, provided the unperturbed theory was positive and BRST symmetry is preserved.

## Quantization of Free Gauge Fields

The action of a classical free gauge field $A$,

$$\begin{aligned} S_0(A) &= -\frac{1}{4}\int \mathrm{d}x\, F^{\mu\nu}(x)F_{\mu\nu}(x) \\ &= \frac{1}{2}\int \mathrm{d}k \hat{A}_\mu(k)^* M^{\mu\nu}(k)\hat{A}_\nu(k) \end{aligned} \qquad [5]$$

(where $F^{\mu\nu} := \partial^\mu A^\nu - \partial^\nu A^\mu$ and $M^{\mu\nu}(k) := k^2 g^{\mu\nu} - k^\mu k^\nu$) is unsuited for quantization because $M^{\mu\nu}$ is not invertible: due to $M^{\mu\nu}k_\mu = 0$, it has an eigenvalue 0. Therefore, the action is usually modified by adding a Lorentz-invariant gauge-fixing term: $M^{\mu\nu}$ is replaced by $M^{\mu\nu}(k) + \lambda k^\mu k^\nu$, where $\lambda \in \mathbb{R}\setminus\{0\}$ is an arbitrary constant. The corresponding Euler–Lagrange equation reads

$$\Box A^\mu - (1-\lambda)\partial^\mu\partial_\nu A^\nu = 0 \qquad [6]$$

For simplicity, let us choose $\lambda = 1$, which is referred to as Feynman gauge. Then the algebra of the free gauge field is the unital $\star$-algebra generated by elements $A^\mu(f), f \in \mathcal{D}(\mathbb{R}^4)$, which fulfill the relations:

$$f \mapsto A^\mu(f) \quad \text{is linear} \qquad [7]$$

$$A^\mu(\Box f) = 0 \qquad [8]$$

$$A^\mu(f)^* = A^\mu(\bar{f}) \qquad [9]$$

$$[A^\mu(f), A^\nu(g)] = \mathrm{i}g^{\mu\nu}\int \mathrm{d}x\,\mathrm{d}y\, f(x)D(x-y)g(y) \qquad [10]$$

where $D$ is the massless Pauli–Jordan distribution.

This algebra does not possess Hilbert space representations which satisfy the microlocal spectrum condition, a condition which in particular requires the singularity of the two-point function to be of the so-called Hadamard form. It possesses, instead, representations on vector spaces with a nondegenerate sequilinear form, for example, the Fock space over a one-particle space with scalar product

$$\langle\phi,\psi\rangle = (2\pi)^{-3}\int \frac{\mathrm{d}^3\boldsymbol{p}}{2|\boldsymbol{p}|}\overline{\phi^\mu(p)}\psi_\mu(p)|_{p^0=|\boldsymbol{p}|} \qquad [11]$$

Gupta and Bleuler characterized a subspace of the Fock space on which the scalar product is semidefinite; the space of physical states is then obtained

by dividing out the space of vectors with vanishing norm.

After adding a mass term

$$\frac{m^2}{2}\int \mathrm{d}x A_\mu(x)A^\mu(x)$$

to the action [5], it seems to be no longer necessary to add also a gauge-fixing term. The fields then satisfy the Proca equation

$$\partial_\mu F^{\mu\nu} + m^2 A^\nu = 0 \qquad [12]$$

which is equivalent to the equation $(\Box + m^2)A^\mu = 0$ together with the constraint $\partial_\mu A^\mu = 0$. The Cauchy problem is well posed, and the fields can be represented in a positive-norm Fock space with only physical states (corresponding to the three physical polarizations of $A$). The problem, however, is that the corresponding propagator admits no power-counting renormalizable perturbation series.

The latter problem can be circumvented in the following way: for the algebra of the free quantum field, one takes only the equation $(\Box + m^2)A^\mu = 0$ into account (or, equivalently, one adds the gauge-fixing term $(1/2)(\partial_\mu A^\mu)^2$ to the Lagrangian) and goes over from the physical field $A^\mu$ to

$$B^\mu := A^\mu + \frac{\partial^\mu \phi}{m} \qquad [13]$$

where $\phi$ is a real scalar field, to the same mass $m$ where the sign of the commutator is reversed ("bosonic ghost field" or "Stückelberg field"). The propagator of $B^\mu$ yields a power-counting renormalizable perturbation series; however, $B^\mu$ is an unphysical field. One obtains four independent components of $B$ which satisfy the Klein–Gordon equation. The constraint $0 = \partial_\mu A^\mu = \partial_\mu B^\mu + m\phi$ is required for the expectation values in physical states only. So, quantization in the case $m > 0$ can be treated in analogy with [8]–[10] by replacing $A^\mu$ by $B^\mu$, the wave operator by the Klein–Gordon operator $(\Box + m^2)$ in [8], and $D$ by the corresponding massive commutator distribution $\Delta_m$ in [10]. Again, the algebra can be nontrivially represented on a space with indefinite metric, but not on a Hilbert space.

One can now use the method of BRST quantization in the massless as well as in the massive case. One introduces a pair of fermionic scalar fields (ghost fields) $(u, \tilde{u})$. $u, \tilde{u}$, and (for $m > 0$) $\phi$ fulfill the Klein–Gordon equation to the same mass $m \geq 0$ as the vector field $B$. The free BRST transformation reads

$$\begin{aligned} s_0(B^\mu) &= \mathrm{i}\partial^\mu u, \qquad s_0(\phi) = \mathrm{i}mu \\ s_0(u) &= 0, \qquad s_0(\tilde{u}) = -\mathrm{i}(\partial_\nu B^\nu + m\phi) \end{aligned} \qquad [14]$$

(see, e.g., Scharf (2001)). It is implemented by the free BRST charge

$$Q_0 = \int_{x^0=\text{const.}} \mathrm{d}^3x j_0^{(0)}(x^0, \boldsymbol{x}) \qquad [15]$$

where

$$j_\mu^{(0)} := (\partial_\nu B^\nu + m\phi)\partial_\mu u - \partial_\mu(\partial_\nu B^\nu + m\phi)u \qquad [16]$$

is the free BRST current, which is conserved. (The interpretation of the integral in [15] requires some care.) $Q_0$ satisfies the assumptions of the (local) operator BRST formalism, in particular it is nilpotent and positive [4]. Distinguished representatives of the equivalence classes $[\phi] \in \mathrm{Ke}\, Q_0/\mathrm{Ra}\, Q_0$ are the states built up only from the three spatial (two transversal for $m = 0$, respectively) polarizations of $A$.

## Perturbative Renormalization

The starting point for a perturbative construction of an interacting quantum field theory is Dyson's formula for the evolution operator in the interaction picture. To avoid conflicts with Haag's theorem on the nonexistence of the interaction picture in quantum field theory, one multiplies the interaction Lagrangian $\mathcal{L}$ with a test function $g$ and studies the local $S$-matrix,

$$S(g\mathcal{L}) = 1 + \sum_{n=1}^{\infty} \frac{\mathrm{i}^n}{n!}\int \mathrm{d}x_1 \cdots \mathrm{d}x_n g(x_1)\cdots g(x_n) \times T(\mathcal{L}(x_1)\cdots\mathcal{L}(x_n)) \qquad [17]$$

where $T$ denotes a time-ordering prescription. In the limit $g \to 1$ (adiabatic limit), $S(g\mathcal{L})$ tends to the scattering matrix. This limit, however, is plagued by infrared divergences and does not always exist. Interacting fields $F_{g\mathcal{L}}$ are obtained by the Bogoliubov formula:

$$F_{g\mathcal{L}}(x) = \frac{\delta}{\delta h(x)}\Big|_{h=0} S(g\mathcal{L})^{-1} S(g\mathcal{L} + hF) \qquad [18]$$

The algebraic properties of the interacting fields within a region $\mathcal{O}$ depend only on the interaction within a slightly larger region (Brunetti and Fredenhagen 2000), hence the net of algebras in the sense of AQFT can be constructed in the adiabatic limit without the infrared problems (this is called the "algebraic adiabatic limit").

The construction of the interacting theory is thus reduced to a definition of time-ordered products of fields. This is the program of causal perturbation theory (CPT), which was developed by Epstein and Glaser (1973) on the basis of previous work by Stückelberg and Petermann (1953) and Bogoliubov

and Shirkov (1959). For simplicity, we describe CPT only for a real scalar field. Let $\varphi$ be a classical real scalar field which is not restricted by any field equation. Let $\mathcal{P}$ denote the algebra of polynomials in $\varphi$ and all its partial derivatives $\partial^a\varphi$ with multi-indices $a \in \mathbb{N}_0^4$. The time-ordered products $(T_n)_{n\in\mathbb{N}}$ are linear and symmetric maps $T_n : (\mathcal{P} \otimes \mathcal{D}(\mathbb{R}^4))^{\otimes n} \to L(\mathcal{D})$, where $L(\mathcal{D})$ is the space of operators on a dense invariant domain $\mathcal{D}$ in the Fock space of the scalar free field. One often uses the informal notation

$$T_n(g_1F_1 \otimes \cdots \otimes g_nF_n) = \int \mathrm{d}x_1 \cdots \mathrm{d}x_n T_n(F_1(x_1), \ldots, F_n(x_n)) \times g_1(x_1) \cdots g_n(x_n) \qquad [19]$$

where $F_j \in \mathcal{P}$, $g_j \in \mathcal{D}(\mathbb{R}^4)$.

The sequence $(T_n)$ is constructed by induction on $n$, starting with the initial condition

$$T_1\left(\prod_j \partial^{a_j}\varphi(x)\right) =: \prod_j \partial^{a_j}\phi(x) : \qquad [20]$$

where the right-hand side is a Wick polynomial of the free field $\phi$. In the inductive step the requirement of causality plays the main role, that is, the condition that

$$T_n(f_1 \otimes \cdots \otimes f_n) = T_k(f_1 \otimes \cdots \otimes f_k) \times T_{n-k}(f_{k+1} \otimes \cdots \otimes f_n) \qquad [21]$$

if

$$(\operatorname{supp} f_1 \cup \cdots \cup \operatorname{supp} f_k) \cap ((\operatorname{supp} f_{k+1} \cup \cdots \cup \operatorname{supp} f_n) + \bar{V}_-) = \emptyset$$

(where $\bar{V}_-$ is the closed backward light cone). This condition expresses the composition law for evolution operators in a relativistically invariant and local way. Causality determines $T_n$ as an operator-valued distribution on $\mathbb{R}^{4n}$ in terms of the inductively known $T_l$, $l < n$, outside of the total diagonal $\Delta_n := \{(x_1, \ldots, x_n) \mid x_1 = \cdots = x_n\}$, that is, on test functions from $\mathcal{D}(\mathbb{R}^{4n} \setminus \Delta_n)$.

Perturbative renormalization is now the extension of $T_n$ to the full test function space $\mathcal{D}(\mathbb{R}^{4n})$. Generally, this extension is nonunique. In contrast to other methods of renormalization, no divergences appear, but the ambiguities correspond to the finite renormalizations that persist after removal of divergences by infinite counter terms. The ambiguities can be reduced by (re-)normalization conditions, which means that one requires that certain properties which hold by induction on $\mathcal{D}(\mathbb{R}^{4n} \setminus \Delta_n)$ are maintained in the extension, namely:

- (N0) a bound on the degree of singularity near the total diagonal;
- (N1) Poincaré covariance;
- (N2) unitarity of the local $S$-matrix;
- (N3) a relation to the time-ordered products of subpolynomials;
- (N4) the field equation for the interacting field $\varphi_{g\mathcal{L}}$ [18];
- (AWI) the "action Ward identity" (Stora 2002, Dütsch and Fredenhagen 2003): $\partial^\mu T(\cdots F_l(x) \cdots) = T(\cdots \partial^\mu F_l(x) \cdots)$. This condition can be understood as the requirement that physics depends on the action only, so total derivatives in the interaction Lagrangian can be removed; and
- further symmetries, in particular in gauge theories, Ward identities expressing BRST invariance. A universal formulation of all symmetries which can be derived from the field equation in classical field theory is the "master Ward identity" (which presupposes (N3) and (N4)) (Boas and Dütsch 2002, Dütsch and Fredenhagen 2003); see next section.

The problem of perturbative renormalization is to construct a solution of all these normalization conditions. Epstein and Glaser have constructed the solutions of (N0)–(N3). Recently, the conditions (N4) and (AWI) have been included. The master Ward identity cannot always be fulfilled, the obstructions being the famous "anomalies" of perturbative quantum field theory.

## Perturbative Construction of Gauge Theories

In the case of a purely massive theory, the adiabatic limit $S = \lim_{g\to 1} S(g\mathcal{L})$ exists (Epstein and Glaser 1976), and one may adopt a formalism due to Kugo and Ojima (1979), who use the fact that in these theories the BRST charge $Q$ can be identified with the incoming (free) BRST charge $Q_0$ [15]. For the scattering matrix $S$ to be a well-defined operator on the physical Hilbert space of the free theory, $\mathcal{H} = \mathrm{Ke}\, Q_0 / \mathrm{Ra}\, Q_0$, one then has to require

$$\lim_{g\to 1} [Q_0, T((g\mathcal{L})^{\otimes n})]|_{\ker Q_0} = 0 \qquad [22]$$

This is the motivation for introducing the condition of "perturbative gauge invariance" (Dütsch *et al.* 1993, 1994); see Scharf (2001)): according to this condition, there should exist a Lorentz

vector $\mathcal{L}_1^\nu \in \mathcal{P}$ associated with the interaction $\mathcal{L}$, such that

$$[Q_0, T_n(\mathcal{L}(x_1)\cdots\mathcal{L}(x_n)] = \mathrm{i}\sum_{l=1}^{n} \partial_\nu^{x_l} T_n(\mathcal{L}(x_1)\cdots\mathcal{L}_1^\nu(x_l)\cdots\mathcal{L}(x_n)) \qquad [23]$$

This is a somewhat stronger condition than [22] but has the advantage that it can be formulated independently of the adiabatic limit. The condition [22] (or perturbative gauge invariance) can be satisfied for tree diagrams (i.e., the corresponding requirement in classical field theory can be fulfilled). In the massive case, this is impossible without a modification of the model; the inclusion of additional physical scalar fields (corresponding to Higgs fields) yields a solution. It is gratifying that, by making a polynomial ansatz for the interaction $\mathcal{L} \in \mathcal{P}$, perturbative gauge invariance [23] for tree diagrams, renormalizability (i.e., the mass dimension of $\mathcal{L}$ is $\leq 4$), and some obvious requirements (e.g., the Lorentz invariance) determine $\mathcal{L}$ to a far extent. In particular, the Lie-algebraic structure needs not to be put in, as it can be derived in this way (Stora 1997, unpublished). Including loop diagrams (i.e., quantum effects), it has been proved that (N0)–(N2) and perturbative gauge invariance can be fulfilled to all orders for massless SU($N$) Yang–Mills theories.

Unfortunately, in the massless case, it is unlikely that the adiabatic limit exists and, hence, an $S$-matrix formalism is problematic. One should better rely on the construction of local observables in terms of couplings with compact support. However, then the selection of the observables [1] has to be done in terms of the BRST transformation $\tilde{s}$ of the interacting fields.

For the corresponding BRST charge, one makes the ansatz

$$\tilde{Q} = \int \mathrm{d}^4x\, \tilde{j}^\mu_{g\mathcal{L}}(x) b_\mu(x), \quad \mathcal{L} = \sum_{n\geq 1} \mathcal{L}_n \lambda^n \qquad [24]$$

where $(b_\mu)$ is a smooth version of the $\delta$-function characterizing a Cauchy surface and $\tilde{j}^\mu_{g\mathcal{L}}$ is the interacting BRST-current [18] (where $\tilde{j}_\mu = \sum_n j_\mu^{(n)}\, \lambda^n$ ($j_\mu^{(n)} \in \mathcal{P}$) is a formal power series with $j_\mu^{(0)}$ given by [16]). (Note that there is a volume divergence in this integral, which can be avoided by a spatial compactification. This does not change the abstract algebra $\mathcal{F}_\mathcal{L}(\mathcal{O})$.) A crucial requirement is that $\tilde{j}^\mu_{g\mathcal{L}}$ is conserved in a suitable sense. This condition is essentially equivalent to perturbative gauge invariance and hence its application to classical field theory determines the interaction $\mathcal{L}$ in the same way, and in addition the deformation $j^{(0)} \to \tilde{j}_{g\mathcal{L}}$. The latter also gives the interacting BRST charge and transformation, $\tilde{Q}$ and $\tilde{s}$, by [24] and [2]. The so-obtained $\tilde{Q}$ is often nilpotent in classical field theory (and hence this holds also for $\tilde{s}$). However, in QFT conservation of $\tilde{j}_{g\mathcal{L}}$ and $\tilde{Q}^2 = 0$ requires the validity of additional Ward identities, beyond the condition of perturbative gauge invariance [23]. All the necessary identities can be derived from the master Ward identity

$$T_{n+1}(A, F_1, \ldots, F_n) = -\sum_{k=1}^{n} T_n(F_1, \ldots, \delta_A F_k, \ldots, F_n) \qquad [25]$$

where $A = \delta_A S_0$ with a derivation $\delta_A$. The master Ward identity is closely related to the quantum action principle which was formulated in the formalism of generating functionals of Green's functions. In the latter framework, the anomalies have been classified by cohomological methods. The vanishing of anomalies of the BRST symmetry is a selection criterion for physically acceptable models.

In the particular case of QED, the Ward identity

$$\partial_\mu^y T(j^\mu(y) F_1(x_1)\cdots F_n(x_n)) = \mathrm{i}\sum_{j=1}^{n} \delta(y - x_j) \times T\big(F_1(x_1)\cdots(\theta F_j)(x_j)\cdots F_n(x_n)\big) \qquad [26]$$

for the Dirac current $j^\mu := \bar{\psi}\gamma^\mu\psi$, is sufficient for the construction, where $(\theta F) := \mathrm{i}(r - s)F$ for $F = \psi^r \bar{\psi}^s B_1 \cdots B_l$ ($B_1, \ldots, B_l$ are nonspinorial fields) and $F_1, \ldots, F_n$ run through all subpolynomials of $\mathcal{L} = j^\mu A_\mu$, (N0)–(N4) and [26] can be fulfilled to all orders (Dütsch and Fredenhagen, 1999).

# Phase Transition Dynamics

**A Onuki**, Kyoto University, Kyoto, Japan

## Introduction

When an external parameter such as the temperature $T$ is changed, physical systems in a homogeneous state often become unstable and tend to an ordered phase with broken symmetry. The growth of new order takes place with coarsening of domains or defect structures on mesoscopic spatial scales much longer than the microscopic molecular scale. Such ordering processes are ubiquitously observed in many systems such as ferromagnetic (spin) systems, solid alloys, and fluids. Historically, structural ordering and phase separation in solid alloys have been one of the central problems in metallurgy (Cahn 1961). These are highly nonlinear and far-from-equilibrium processes and have been studied as challenging subjects in condensed matter physics, polymer science, and metallurgy (Gunton *et al.* 1983, Binder 1991, Bray 1994, Onuki 2002). Here a short review on phase ordering is given on the basis of prototype mathematical models, which can be a starting point to understand the real complex problems.

## Phase Ordering in Nonconserved Systems

Let us consider phase ordering in a system with a scalar spacetime-dependent variable $\psi(\boldsymbol{r}, t)$. If its space integral is not conserved in time, it is called the nonconserved order parameter, representing magnetization, electric polarization, etc. After appropriate scaling of time $t$, space $\boldsymbol{r}$, and $\psi$, the simplest dynamic equation reads

$$\frac{\partial}{\partial t}\psi = \nabla^2\psi - \tau\psi - \psi^3 + h + \theta \qquad [1]$$

The coefficient $\tau$ is related to the temperature by $\tau = A(T - T_c)$, where $A$ is a constant and $T_c$ is the critical temperature. The constant $h$ is also an externally controllable parameter, proportional to the applied magnetic field for the ferromagnetic case. The last term is the Markovian Gaussian random noise needed when eqn [1] is treated as a Langevin (stochastic differential) equation. In physics its stochastic property is usually expressed as

$$\langle\theta(\boldsymbol{r}, t)\theta(\boldsymbol{r}', t')\rangle = 2\varepsilon\delta(\boldsymbol{r} - \boldsymbol{r}')\delta(t - t') \qquad [2]$$

where $\varepsilon$ represents the strength of the noise (proportional to the temperature before the scaling). In the presence of $\theta$, the variable $\psi$ is a random variable, whose probability distribution $P(\{\psi\}, t)$

obeys the Fokker–Planck equation. The equilibrium (steady) distribution is given by

$$P_{\mathrm{eq}}\{\psi\} = \text{const. } \exp(-F\{\psi\}/\varepsilon) \qquad [3]$$

where

$$F = \int \mathrm{d}\boldsymbol{r}\left[\frac{\tau}{2}\psi^2 + \frac{1}{4}\psi^4 + \frac{1}{2}|\nabla\psi|^2 - h\psi\right] \qquad [4]$$

is the so-called Ginzburg–Landau free energy. Using $F$ we rewrite eqn [1] in a standard form of the Langevin equation,

$$\frac{\partial}{\partial t}\psi = -\frac{\delta F}{\delta \psi} + \theta \qquad [5]$$

In equilibrium $\psi$ consists of the average $\psi_e$ and the deviation $\delta\psi$, where the latter is a Gaussian fluctuation in the limit of small $\varepsilon$. If $\tau > 0$ and $h = 0$, we obtain $\psi_e = 0$. If $\tau < 0$ and $h = 0$, there are two minima $\psi_e = \pm|\tau|^{1/2}$. These two states can coexist in equilibrium with a planar interface separating them at $h = 0$. If its normal is along the $x$-axis, the interface solution is of the form

$$\psi(x) = |\tau|^{1/2}\tanh(|\tau|^{1/2}x/\sqrt{2}) \qquad [6]$$

which tends to $\pm|\tau|^{1/2}$ as $x \pm \infty$ and satisfies

$$\delta F/\delta\psi = (\tau + \psi^2)\psi - \mathrm{d}^2\psi/\mathrm{d}x^2 = 0 \qquad [7]$$

It is well known that the fluctuations of $\psi$ are increasingly enhanced near the critical point. The renormalization group theory shows how the equilibrium distribution $P_{\mathrm{eq}}\{\psi\}$ in eqn [3] depends on the upper cutoff wave number $\Lambda$ of $\psi$, where we suppose that $\psi$ consists of the Fourier components $\psi_{\boldsymbol{k}}$ with $k < \Lambda$ (Onuki 2002). In our phase-ordering problem the shortest relevant spatial scale is the interface width of the order of the thermal correlation length $\xi$ at the final temperature. Therefore, near criticality, we may assume that the thermal fluctuations with wave numbers larger than $\xi^{-1}$ have been eliminated in the model (or $\Lambda \sim \xi^{-1}$ at the starting point).

## Domain Growth

Thermodynamic instability occurs when $\tau$ is changed from a positive value $\tau_{\mathrm{i}}$ to a negative value $\tau_{\mathrm{f}}$ at $t = 0$. We here assume $h = 0$. We set $\tau_{\mathrm{f}} = -1$ using the scaling. At long wavelengths $k < 1$, small plane wave fluctuations with wave vector $\boldsymbol{k}$ grow exponentially as

$$\psi_{\boldsymbol{k}}(t) \sim \exp[(1 - k^2)t] \qquad [8]$$

with the growth rate largest at $k = 0$. This suggests that the nonlinear term in eqn [1] becomes crucial after a transient time. Numerically obtained snapshots of the subsequent $\psi(\boldsymbol{r}, t)$ are shown in Figure 1

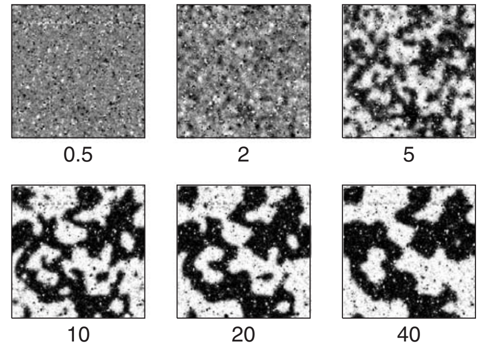

**Figure 1** Time evolution of $\psi$ in model [1] in 2D with system length = 128. The numbers are the times after quenching. Noise is added, but is not essential for large patterns or in the late stage. Reproduced with permission from Onuki A (2002) *Phase Transition Dynamics.* Cambridge, UK: Cambridge University Press.

in two dimensions (2D), where we can see the coarsening of the patterns. The characteristic domain size $\ell(t)$ grows algebraically as

$$\ell(t) \sim t^a \qquad [9]$$

where $a = 1/2$ is known for the model [1]. Scattering experiments detect the time-dependent correlation

$$g(r, t) = \langle \delta\psi(\boldsymbol{r} + \boldsymbol{r}_0, t)\delta\psi(\boldsymbol{r}_0, t)\rangle \qquad [10]$$

$$S(k, t) = \int \mathrm{d}\boldsymbol{r} g(r, t)\mathrm{e}^{\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{r}} \qquad [11]$$

where $S(k, t)$ is called the structure factor. We assume the translational invariance and the spatial isotropy after the thermal average $\langle\cdots\rangle$. If $\tau_i \gg 1$, the quartic term in $F$ is negligible, leading to the initial structure factor

$$S(k, 0) \cong \varepsilon/(\tau_{\mathrm{i}} + k^2) \qquad [12]$$

which is produced by the thermal fluctuations. However, when the domain size $\ell(t)$ much exceeds the microscopic length (lattice constant), the following scaling behavior emerges:

$$g(r, t) = G(r/\ell(t)) \qquad [13]$$

$$S(k, t) = \ell(t)^d Q(\ell(t)k) \qquad [14]$$

where $d$ is the space dimensionality and $G(x)$ and $Q(x)$ are the scaling functions of order unity for $x \sim 1$. The correlation on the scale of $\ell(t)$ in eqn [13] arises from large-scale domain structures, while eqn [14] is simply its Fourier transformation. The maximum of the structure factor grows as $\ell(t)^d$. When $\varepsilon \ll 1$, however, there can be a well-defined initial stage in which $S(k, t)$ grows exponentially at long wavelengths.

We may explain the roles of the terms on the right-hand side of eqn [1] in phase ordering in a simple manner.

1. The linear term $-\tau\psi$ triggers instability for $\tau < 0$.
2. The nonlinear term $-\psi^3$ gives rise to saturation of $\psi$ into $\pm 1$. To see this, we neglect $\nabla^2\psi$ and $\theta$ to have $\partial\psi/\partial t = (1-\psi^2)\psi$ for $\tau = -1$. This equation is solved to give

$$\psi(t) = \psi_0 \Big/ \sqrt{\psi_0^2 + (1-\psi_0^2)\mathrm{e}^{-2t}} \qquad [15]$$

where $\psi_0 = \psi(0)$ is the initial value. Thus, $\psi \to 1$ for $\psi_0 > 0$ and $\psi \to -1$ for $\psi_0 < 0$ as $t \to \infty$.
3. The gradient term limits the instability only in the long wavelength region $k < 1$ in the initial stage (see eqn [8]) and creates the interfaces in the late stage (see eqn [7]).
4. The noise term $\theta$ is relevant only in the early stage where $\psi$ is still on the order of the initial thermal fluctuations. The range of the early stage is of order 1 for $\varepsilon \gtrsim 1$, but weakly grows as $\ln(1/\varepsilon)$ for $\varepsilon \ll 1$. The noise term can be neglected once the fluctuations much exceed the thermal level.
5. If $h$ is a small positive number, it favors growth of regions with $\psi \cong 1$.

### Interface Dynamics

At long times $t \gg 1$ domains with typical size $\ell(t)$ are separated by sharp interfaces and the thermal noise is negligible. Allowing the presence of a small positive $h$, we may approximate the free energy $F$ as

$$F = \sigma S(t) - 2hV_+(t) + \text{const.} \qquad [16]$$

where $\sigma$ is a constant (surface tension), $S(t)$ is the surface area, and $V_+(t)$ is the volume of the regions with $\psi \cong 1$. In this stage the interface velocity $v_{\text{int}} = \boldsymbol{v}_{\text{int}} \cdot \boldsymbol{n}$ is given by the Allen–Cahn formula (Allen and Cahn 1979):

$$v_{\text{int}} = -\mathcal{K} + (2/\sigma)h \qquad [17]$$

The normal unit vector $\boldsymbol{n}$ is from a region with $\psi \cong 1$ to a region with $\psi \cong -1$. The $\mathcal{K}$ is the sum of the principal curvatures $1/R_1 + 1/R_2$ in 3D. This equation can be derived from eqn [1]. If the interface position $\boldsymbol{r}_a$ moves to $\boldsymbol{r}_a + \delta\zeta\boldsymbol{n}$ infinitesimally, the surface area changes by $\delta S = \int \mathrm{d}a\mathcal{K}\delta\zeta$, where $\int \mathrm{d}a \cdots$ denotes the surface integral. Therefore, $F$ in eqn [16] changes in time as

$$\frac{\mathrm{d}F}{\mathrm{d}t} = \int \mathrm{d}a(\sigma\mathcal{K} - 2h)v_{\text{int}} \le 0 \qquad [18]$$

which is non-negative-definite owing to eqn [17]. Furthermore, we may draw three results from eqn [17].

1. If we set $v_{\text{int}} \sim \ell(t)/t$ and $\mathcal{K} \sim 1/\ell(t)$, we obtain $a = 1/2$ in the growth law [9].
2. In phase ordering under very small positive $h$, the balance $1/\ell(t) \sim h/\sigma$ yields the crossover time $t_h \sim h^{-2}$. For $t < t_h$ the effect of $h$ is small, while for $t > t_h$ the region with $\psi \cong 1$ becomes predominant.
3. A spherical droplet with $\psi \cong 1$ evolves as

$$\frac{\partial R}{\partial t} = -\frac{2}{R} + \frac{2h}{\sigma} \qquad [19]$$

from which the critical radius is determined as

$$R_{\mathrm{c}} = \sigma/h \qquad [20]$$

A droplet with $R > R_{\mathrm{c}}(R < R_{\mathrm{c}})$ grows (shrinks).

We mention a statistical theory of interface dynamics at $h = 0$ by Ohta (1982). There, a smooth subsidiary field $u(\boldsymbol{r}, t)$ is introduced to represent surfaces by $u = \text{const}$. The differential geometry is much simplified in terms of such a field. The two-phase boundaries are represented by $u = 0$. If all the surfaces follow $v_{\text{int}} = -\mathcal{K}$ in eqn [17] in the whole space, $u$ obeys

$$\frac{\partial}{\partial t}u = \Big[\nabla^2 - \sum_{ij} n_i n_j \nabla_i \nabla_j\Big]u \qquad [21]$$

where $\nabla_i = \partial/\partial x_i$ and $n_i = \nabla_i u/|\nabla u|$. This equation becomes a linear diffusion equation if $n_i n_j \nabla_i \nabla_j$ is replaced by $d^{-1}\delta_{ij}\nabla^2$. Then $u$ can be expressed in terms of its initial value and the correlation function of $\psi(\boldsymbol{r}, t)(\cong u(\boldsymbol{r}, t)/|u(\boldsymbol{r}, t)|$ in the late stage) is calculated in the form of eqn [13] with

$$G(x) = \frac{2}{\pi}\sin^{-1}\left[\exp\left(-\frac{1}{8(1-1/d)}x^2\right)\right] \qquad [22]$$

which excellently agrees with simulations.

## Spinodal Decomposition in Conserved Systems

The order parameter $\psi$ can be a conserved variable such as the density or composition in fluids or alloys. With the same $F$ in eqn [4], a simple dynamic model in such cases reads

$$\frac{\partial}{\partial t}\psi = \nabla^2 \frac{\delta F}{\delta\psi} - \nabla \cdot \boldsymbol{j}^R \qquad [23]$$

Here $\boldsymbol{j}^R$ is the random current characterized by

$$\left\langle j_\alpha^R(\boldsymbol{r}, t) j_\beta^R(\boldsymbol{r}', t')\right\rangle = 2\varepsilon\delta_{\alpha\beta}\delta(\boldsymbol{r} - \boldsymbol{r}')\delta(t - t') \qquad [24]$$

which ensures the equilibrium distribution [3] of $\psi$. However, the noise $\boldsymbol{j}^R$ is negligible in late-stage phase separation as in the nonconserved case. Note that $h$ in the conserved case is the chemical potential

conjugate to $\psi$ and, if it is homogeneous, it vanishes in the dynamic equation [23]. In experiments the average order parameter

$$M = \langle \psi \rangle = \int d\boldsymbol{r} \psi(\boldsymbol{r})/V \qquad [25]$$

is used as a control parameter instead of $h$, where the integral is within the system with volume $V$. If there is no flux from outside, $M$ is constant in time. Here the instability occurs below the so-called spinodal $M^2 < 1/3(M^2 < |\tau|/3$ for general $\tau < 0)$. In fact, small fluctuations with wave vector $\boldsymbol{k}$ grow exponentially as

$$\psi_{\boldsymbol{k}}(t) \sim \exp[k^2(1 - 3M^2 - k^2)t] \qquad [26]$$

right after the quenching as in eqn [8]. The growth rate is largest at an intermediate wave number $k = k_m$ with

$$k_m = [(1 - 3M^2)/2]^{1/2} \qquad [27]$$

This behavior and the exponential growth of the structure factor have been observed in polymer mixtures where the parameter $\varepsilon$ in eqn [3] or [12] is expected to be small (Onuki 2002). In late-stage coarsening the peak position of $S(k, t)$ decreases in time as

$$k_m(t) \sim 2\pi/\ell(t) \qquad [28]$$

in terms of the domain size $\ell(t)$. The growth exponent in eqn [9] is given by 1/3 for the simple model [23] (see eqn [33] below).

Figure 2 shows the patterns after quenching in 2D. For $M = 0$ the two phases are symmetric and the patterns are bicontinuous, while for $M \neq 0$ the minority phase eventually appears as droplets in the percolating region of the majority phase.

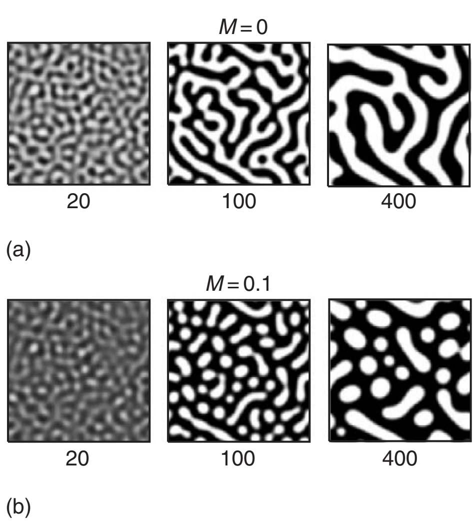

**Figure 2** Time evolution of $\psi$ in model [23] in 2D with system length = 128 without thermal noise: (a) $M = 0$ and (b) $M = 0.1$. The numbers are the times after quenching. Reproduced with permission from Onuki A (2002) *Phase Transition Dynamics.* Cambridge, UK: Cambridge University Press.

### Interface Dynamics

Interface dynamics in the conserved case is much more complicated than in the nonconserved case, because the coarsening can proceed only through diffusion. Long-distance correlations arise among the domains and the interface velocity cannot be written in terms of the local quantities like the curvature. As a simple example, we give the counterpart of eqn [19]. In 3D a spherical droplet with $\psi \cong 1$ appears in a nearly homogeneous matrix with $\psi = M$ far from the droplet. The droplet radius $R$ is then governed by (Lifshitz and Slyozov 1961)

$$\frac{\partial}{\partial t} R = D\left(\frac{\Delta}{R} - \frac{2d_0}{R^2}\right) \qquad [29]$$

where $\Delta = (M + 1)/2$ is called the supersaturation, while $D$ and $d_0$ are constants (equal to 2 and $\sigma/8$, respectively, after the scaling). The critical radius is written as

$$R_c = 2d_0/\Delta \qquad [30]$$

The general definition of the supersaturation is

$$\Delta = \left(M - \psi_{cx}^{(2)}\right) \Big/ \left(\psi_{cx}^{(1)} - \psi_{cx}^{(2)}\right) \qquad [31]$$

Here the equilibrium values of $\psi$ are written as $\psi_{cx}^{(1)}$ and $\psi_{cx}^{(2)}$ and $M$ is supposed to be slightly different from $\psi_{cx}^{(2)}$.

Lifshitz and Slyozov (1961) analyzed domain coarsening in binary AB alloys when the volume fraction $q$ of the A-rich domains is small. They noticed that the supersaturation $\Delta$ around each domain decreases in time with coarsening. That is, the A component atoms in the B-rich matrix are slowly absorbed onto the growing A-rich domains, while a certain fraction of the A-rich domains disappear. Thus, $q(t)$ and $\Delta(t)$ both depend on time, but satisfy the conservation law

$$q(t) + \Delta(t) = \Delta(0) = (M + 1)/2 \qquad [32]$$

With this overall constraint, they found the asymptotic late-stage behavior

$$\ell(t) \sim \Delta(t)^{-1} \sim t^{1/3} \qquad [33]$$

where $\ell(t)$ is the average droplet radius. Notice that this behavior is consistent with the droplet equation [29], where each term is of order $R/t \sim t^{-2/3}$.

## Nucleation

In metastable states the free energy is at a local minimum but not at the true minimum. Such states

are stable for infinitesimal fluctuations, but rare spatially localized fluctuations, called critical nuclei, can continue to grow, leading to macroscopic phase ordering (Onuki 2002, Debenedetti 1996). The birth of a critical droplet is governed by the Boltzmann factor $\exp(-F_c/k_BT)$ at finite temperatures, where $F_c$ is the free energy needed to create a critical droplet and $k_BT$ is the thermal energy with $k_B$ being the Boltzmann constant. In this section we explicitly write $k_BT$, but we may scale $\psi$ and space such that $\tau = -1$ at the final temperature.

### Droplet Free Energy and Experiments

In the nonconserved case we prepare a spin-down state with $\psi \cong -1$ in the time region $t < 0$ and then apply a small positive field $h$ at $t = 0$. For $t > 0$ a spin-up droplet with radius $R$ requires a free energy change

$$F(R) = 4\pi\sigma R^2 - \frac{8\pi}{3}hR^3 \qquad [34]$$

The first term is the surface free energy and the second term is the bulk decrease due to $h$. The critical radius $R_c$ in eqn [20] gives the maximum of $F(R)$ given by

$$F_c = \frac{4\pi}{3}\sigma R_c^2 \qquad [35]$$

In fact, $F'(R) = \partial F(R)/\partial R$ is written as

$$F'(R) = 8\pi\sigma(R - R^2/R_c) \qquad [36]$$

In conserved systems such as fluids or alloys, we lower the temperature slightly below the coexistence curve with the average order parameter $M$ held fixed. We again obtain the droplet free energy [34], but

$$h = (\sigma/2d_0)\Delta \qquad [37]$$

in terms of the (initial) supersaturation $\Delta = \Delta(0)$. Let the equilibrium values $\psi_{cx}^{(1)}$ and $\psi_{cx}^{(2)}$ in the two phases be written as $\pm A(T_c - T)^\beta$ with $A$ and $\beta$ being constants ($\beta \cong 1/3$ as $T \to T_c$). For each given $M$, we define the coexistence temperature $T_{cx}$ by $M = \psi_{cx}^{(2)} = -A(T_c - T_{cx})^\beta$. In nucleation experiments the final temperature $T$ is slightly below $T_{cx}$ and $\delta T \equiv T_{cx} - T$ is a positive temperature increment. For small $\delta T$ we find

$$\Delta \cong \frac{\beta}{2}\delta T/(T_c - T_{cx}) \qquad [38]$$

### Droplet Size Distribution and Nucleation Rate

In a homogeneous metastable matrix, droplets of the new phase appear as rare thermal fluctuations. We describe this process by adding a thermal noise term to the droplet equation [19] or [29]. The droplet size distribution $n(R,t)$ then obeys the Fokker–Planck equation

$$\frac{\partial}{\partial t}n = \frac{\partial}{\partial R}\mathcal{L}(R)\left[\frac{\partial}{\partial R} + \frac{F'(R)}{k_BT}\right]n \qquad [39]$$

Here $n(R,t)\mathrm{d}R$ denotes the droplet number density in the range $[R, R+\mathrm{d}R]$. We determine the kinetic coefficient $\mathcal{L}(R)$ such that

$$v(R) \equiv -\mathcal{L}(R)F'(R)/k_BT \qquad [40]$$

is the right-hand side of eqn [19] or [29]. It is equal to $\partial R/\partial t$ when the thermal noise is neglected. Thus, $\mathcal{L}(R) \propto R^{-2}$ or $R^{-3}$ for the nonconserved or conserved case. The second derivative $(\partial/\partial R)\mathcal{L}(R)(\partial/\partial R)$ in eqn [39] stems from the thermal noise and is negligible for $R - R_c \gtrsim 1$ in 3D (Onuki 2002). Hence, for $R - R_c \gtrsim 1$, the droplets follow the deterministic equation [19] or [29] and $n$ obeys

$$\frac{\partial}{\partial t}n = -\frac{\partial}{\partial R}[v(R)n] \qquad [41]$$

In **Figure 3**, we plot the solution of eqn [39] for the conserved case with $F_c/k_BT = 17.4$ (Onuki 2002). The time is measured in units of $1/\Gamma_c$, which is the timescale of a critical droplet defined by

$$\Gamma_c = (\partial v(R)/\partial R)_{R=R_c} \qquad [42]$$

We notice $\Gamma_c \propto R_c^{-3}$ from eqn [29] so $\Gamma_c$ is small. The initial distribution is given by

$$n(R,0) = n_0 \exp(-4\pi\sigma R^2/k_BT) \qquad [43]$$

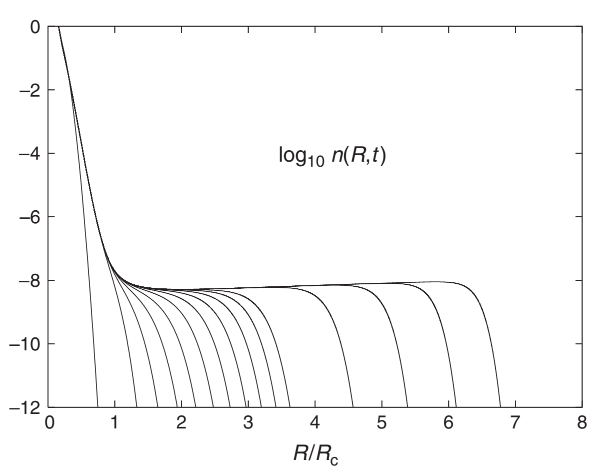

**Figure 3** Time evolution of the droplet size distribution $n(R,t)$ on a semilogarithmic scale as a solution of eqn [39] in the 3D conserved case. The first 11 curves correspond to the times at $\Gamma_c t = 0, 1, \ldots$ and 10. The last four curves are those at $\Gamma_c t = 15, 20, 25,$ and 30. Reproduced with permission from Onuki A (2002) *Phase Transition Dynamics.* Cambridge, UK: Cambridge University Press.

with $n_0$ being a constant number density. This form has been observed in computer simulations as the droplet size distribution on the coexistence curve ($h = 0$). Figure 3 indicates that $n(R, t)$ tends to a steady solution $n_s(R)$ which satisfies

$$\mathcal{L}(R)\left[\frac{\partial}{\partial R} + \frac{F'(R)}{k_B T}\right] n_s = -I \quad [44]$$

where $I$ is a constant. Imposing the condition $n_s(R) \to 0$ as $R \to \infty$, we integrate the above equation as

$$n_s(R) = I \int_R^\infty \mathrm{d}R_1 \frac{1}{\mathcal{L}(R_1)} \exp\left[\frac{F(R_1) - F(R)}{k_B T}\right] \quad [45]$$

For $R - R_c \gg 1$ we may replace $F(R_1) - F(R)$ by $F'(R)(R_1 - R)$ in the integrand of eqn [45] to obtain

$$n_s(R) \cong I/v(R) \quad [46]$$

which also follows from eqn [41]. Thus

$$n_s(R)\mathrm{d}R = I\,\mathrm{d}t \quad (\mathrm{d}R = v(R)\mathrm{d}t) \quad [47]$$

This means that $I$ is the nucleation rate of droplets with radii larger than $R_c$ emerging per unit volume and per unit time. Furthermore, as $R \to 0$, we require $n_s(R) \to n_0 = \text{const.}$ in eqn [43] so that

$$n_0 = I \int_0^\infty \mathrm{d}R_1 \frac{1}{\mathcal{L}(R_1)} \exp\left[\frac{F(R_1)}{k_B T}\right] \quad [48]$$

where the integrand becomes maximum around $R_c$. Using the expansion $F(R) = F_c + F''(R_c)\ (R - R_c)^2/2 + \cdots$, we obtain the famous formula for the nucleation rate

$$I = I_0\ \exp(-F_c/k_B T) \quad [49]$$

$$= I_0\ \exp(-C_0/\Delta^2) \quad [50]$$

where the coefficient $I_0$ is of order $n_0 \Gamma_c$. The second line holds in the 3D conserved case. Here, $C_0 \sim 10^{-3}$ typically and $I_0$ is a very large number in units of $\mathrm{cm}^{-3}\,\mathrm{s}^{-1}$, say, $10^{30}$. Then the exponential factor in $I$ changes abruptly from a very small to a very large number with only a slight increase of $\Delta$ at small $\Delta \ll 1$. For example, if $C_0/\Delta^2 = 50$, $I$ is increased by $\exp(100\delta\Delta/\Delta)$ with a small increase of $\Delta$ to $\Delta + \delta\Delta$. This factor can be of order $10^3$ even for $\delta\Delta/\Delta = 0.05$. Unless very close to criticality, simple metastable fluids become opaque suddenly with increasing $\Delta$ or $\delta T$ at a rather definite cloud point. In near-critical fluids, however, $I_0$ itself becomes small ($\propto \xi^{-6}$) such that the cloud point considerably depends on the experimental timescale (observation time).

## Remarks

The order parameter can be a scalar, a vector as in the Heisenberg spin system, a tensor as in liquid crystals, and a complex number as in superfluids and superconductors. In phase ordering a crucial role is played by topological singularities like interfaces in the scalar case and vortices in the complex number case. Furthermore, a rich variety of phase transition dynamics can be explained if the order parameter is coupled to other relevant variables in the free energy and/or in the dynamic equations. We mention couplings to velocity field in fluids, electrostatic field in charged systems, and elastic field in solids. Phase ordering can also be influenced profoundly by external fields such as electric field or shear flow.

# Phase Transitions in Continuous Systems

**E Presutti**, Università di Roma “Tor Vergata,” Rome, Italy

## Introduction

Many aspects of our everyday life, from weather to boiling water for a cup of coffee, involve heat exchanges and variations of pressure and, as a result, a phase transition. The general theory behind these phenomena is thermodynamics, which studies fluids and macroscopic bodies under these and more general transformations.

In the simple case of a one-component substance, the behavior under changes of temperature $T$ and pressure $P$ is described, according to the Gibbs phase rule, by a phase diagram such as the one in Figure 1. The curves in the $(T, P)$ plane, distinguish regions where the substance is in its solid, liquid, and gas phases. Thus, in an experiment where we vary the pressure and temperature moving along a line which crosses a transition curve, we observe an abrupt and dramatic change at the crossing, when the system changes phase. As already stated, everyday life is an active source of examples of such phenomena.

The picture is “far from innocent”, it states that air, liquid, and solid are not different elements of nature, as for long believed, but just different aspects of the same thing: substances are able to adapt to different external conditions in dramatically different ways. What properties of intermolecular forces are responsible for such astonishing behavior? The question has been extensively studied and it is the argument of the present article, where it will be discussed in the framework of statistical mechanics for continuous systems. Before entering into the matter, let us mention two basic motivations.

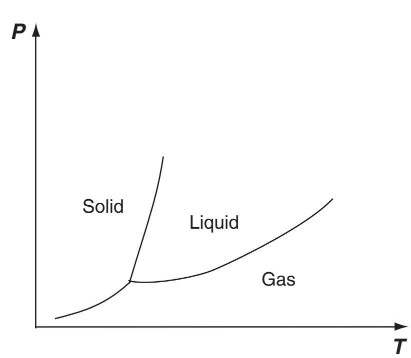

**Figure 1** Phase diagram of a one-component substance.

As always, there is a “fundamental theory” aspect; in the specific case it is the attempt for an atomistic theory able to describe also macroscopic phenomena, thus ranging from the angstrom to the kilometer scales. From an engineering point of view, the target is, for instance, to understand why and when a substance is an insulator, or a conductor or, maybe, a superconductor, and, more importantly, how should we change its microscopic interactions to produce such effects: this opens the way to technologies which are indeed enormously affecting our life.

## Phase Transitions and Statistical Mechanics

The modern theory of statistical mechanics is based upon the Gibbs hypothesis. In a classical (i.e., not quantum) framework, the macroscopic states are described by probability measures on a particle configuration phase space. The equilibrium states are then selected by the Gibbs prescription, which requires that the probability of observing a configuration which has energy $E$ should be proportional to $e^{-\beta E}$, where $\beta = 1/kT$, $k$ is the Boltzmann constant, and $T$ the absolute temperature. These are the “Gibbs measures” and the purpose of statistical mechanics is to study their properties. A prerequisite for the success of the theory is compatibility with the principles of thermodynamics, the theory should then be able to explain the origin of the various phase diagrams and in particular to determine the circumstances under which phase transitions appear.

The theory, commonly called DLR, after Dobrushin, Lanford, and Ruelle, who, in the 1960s, contributed greatly to its foundations, has solid mathematical basis. Its main success is a rigorous proof of consistency with thermodynamics, which is derived under the only assumption that surface effects are negligible, a condition which is mathematically achieved by studying the system in a “thermodynamic limit,” where the region containing the system invades the whole space.

In the thermodynamic limit, the equilibrium states can no longer be defined by the Gibbs prescription, because the energy of configurations in the whole space, being extensive, is typically infinite. The problem has been solved by first proving convergence of the finite-volume Gibbs measures in the thermodynamic limit. After defining the limit states, called “DLR states,” as the equilibrium states of the

infinite systems, it is proved that the DLR states can be directly characterized (i.e., without using limit procedures) as the solutions of a set of equations, the "DLR equations," which generalize the finite-volume Gibbs prescription.

In terms of DLR states, the mathematical meaning of phase transitions becomes very clear and sharp. The starting point is the proof that the physical property that intensive variables in a pure phase have negligible fluctuations is verified by all the DLR measures which are in a special class, thus selected by this property, and which are therefore interpreted as "pure phases." All the other DLR measures are proved to be mixtures, that is, general convex combinations, of the pure DLR states. Thus, in the DLR theory, the system is in a single phase when there is only one DLR state, at the given values of the thermodynamic parameters (e.g., temperature and chemical potential), while the system is at a phase transition if there are several distinct DLR states.

While the theory beautifully clarifies the meaning of phase transitions, it does not say whether the phenomenon really occurs! This is maybe the main open problem in equilibrium statistical mechanics. A general proof of existence of phase diagrams is needed, which should at least capture the basic property behind the Gibbs phase rule, namely that in most of the space (of thermodynamic parameters) there is a single phase, with rare exceptions where several phases coexist. A more refined result should then indicate that coexistence occurs only on regular surfaces of positive codimension.

There is, however, a general result of existence of the gaseous phase, with a proof of uniqueness of DLR measures when temperature is large and density low. Coexistence of phases is much less understood at a general level, but results for particular classes of models exist, for instance, in lattice systems at low temperatures. The prototype is the ferromagnetic Ising model in two or more dimensions, where indeed the full diagram has been determined, see Figure 2. The transition curve is the segment $\{0 \le T \le T_c, h = 0\}$, in the $(T, h)$ plane, $h$ being the magnetic field. In the upper-half plane, there is a single phase with positive magnetization, in the lower one with a negative value; at $h = 0$, positive and negative magnetization states can coexist, if the temperature is lower than the critical value $T_c$. Correspondingly, there are, simultaneously, a positive and a distinctly negative DLR state, which describe the two phases.

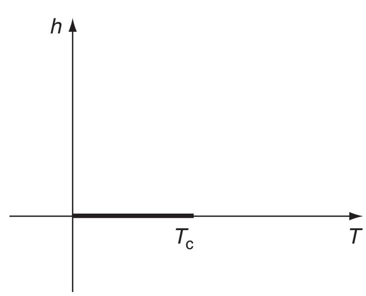

**Figure 2** Phase diagram of the Ising ferromagnet.

An analogous result is missing for systems of particles in the continuum, but there has been recent progress on the analysis of the liquid–vapor branch of the phase diagram, and the issue will be the main focus of this article.

## Sensitive Dependence on Boundary Conditions

Phase transitions describe exceptional regimes where the system is in a critical state; this is why they are so interesting and difficult to study. As in chaotic systems, criticality corresponds to a "butterfly effect," which, in a statistical-mechanics setting means changing far-away boundary conditions. Such changes affect the neighbors, which in turn influence their neighbors, and so on. In general, the effect decays with the distance but, at phase transition, it provokes an avalanche which propagates throughout the system reaching all its points. Its occurrence is not at all obvious, if we remember the stochastic nature of the theory. The domino effect described above can in fact, at each step, be subverted by stochastic fluctuations. The latter, in the end, may completely hide the effect of changing the boundary conditions. This is an instance of a competition between energy and entropy which is the ruling phenomenon behind phase transitions.

This intuitive picture also explains the relevance of space dimensionality. In a many-dimensional space, the influence of the boundary conditions has clearly many more ways to percolate, in contrast to the one-dimensional case, where in fact there is a general result on the uniqueness of DLR measures and therefore absence of phase transitions, for short-range interactions. For pair potentials, "short" means that the interaction energy between two molecules, respectively at $r$ and $r'$, decays as $|r - r'|^{-\alpha}$, $\alpha > 2$. There are results on the converse, namely on the presence of phase transitions when the above condition is not satisfied, mainly for lattice systems, but with partial extensions also to continuous systems. One-dimensional and long-range cases are not the main focus of this article, and the issue will not be discussed further here.

## Ising Model

In order to make the previous ideas quantitative, let us first describe the simple case of the Ising model. Ising spin configurations are collections $\{\sigma(x), x \in \mathbb{Z}^d\}$ of $\sigma(x) \in \{\pm 1\}$ magnetic moments called spins. In the nearest-neighbor case, the interaction between two spins is $-J\sigma(x)\sigma(y)$, $J > 0$, if $x$ and $y$ are nearest neighbors on $\mathbb{Z}^d$, or is vanishing otherwise. There are, therefore, two ground states, one with all spins equal to +1 and the other one with all spins equal to –1. Since the Gibbs probability of higher energies vanishes as the temperature goes to zero, these are interpreted as the equilibrium states at temperature $T = 0$.

If $T > 0$, configurations with larger energy will appear, even though depressed by the Gibbs factor, but their occurrence is limited if $T$ is small. In fact, in the ferromagnetic Ising model at zero magnetic field, dimensions $d \geq 2$, and low enough temperature, it has been proved that there are two distinct DLR measures, one called positive and the other negative. The typical configurations in the positive measure are mainly made by positive spins and, in such an "ocean of positive spins" there are rare and small islands of negative spins. The same situation, but with the positive and negative spins interchanged, occurs in the negative DLR state.

The selection of one of these two states can be made by choosing the positive or the negative boundary conditions, which shows how a surface effect, namely putting the boundary spins equal to 1 or –1, has a volume effect, as most of the spins in the system follow the value indicated by the boundary values. Again, this is more and more striking as we note that each spin is random, yet a strong, cooperative effect takes over and controls the system.

The original proof due to Peierls exploits the spin-flip symmetry of the Ising interaction, but it has subsequently been extended to a wider class of systems on the lattice, in the general framework of the "Pirogov–Sinai theory." This theory studies the low-temperature perturbations of ground states and it applies to many lattice systems, proving the existence of a phase transition and determining the structure of the phase diagram in the low-temperature region. The theory, however, does not cover continuous systems, where the low-temperature regime is essentially not understood, with the notable exception of the Widom and Rowlinson model.

## Two Competing Species in the Continuum

The simplest version of the Widom and Rowlinson model has two types of particles, red and black, which are otherwise identical. Particles are massive points and the only interaction is a hard-core interaction among different colors, namely a red and a black particle cannot be closer than $2R_0, R_0 > 0$ being the hard-core radius.

The order parameter for the phase transition is the particle color. For large values of the chemical potential, and thus large densities, there are two states, one essentially red, the other black, while, if the density is low, the colors "are not separated" and there is a unique state. The proof of the statement starts by dividing the particles of a configuration into clusters, each cluster made by a maximal connected component, where two particles are called connected when their mutual distance is $< 2R_0$. Then, in each cluster, all particles have the same color (because of the hard-core exclusion between black and red), and the color is either black or red, with equal probability.

The question of phase transition is then related to cluster percolation, namely the existence of clusters which extend to infinity. If this occurs, then the influence of fixing the color of a particle may propagate infinitely far away, hence the characteristic "sensitive dependence phenomenon" of phase transitions. Percolation and hence phase transitions have been proved to exist in the positive and negative states, if the density is large and, respectively, small. The above argument is a more recent version of the original proof by Ruelle, which goes back to the 1970s.

The key element for the appearance of the phase transition is the competition between two different components, so that the analysis is not useful in explaining the mechanisms for coexistence in the case of identical particles, which are considered in the following.

## Coarse Graining Transformations

The Peierls argument in Ising systems does not seem to extend to the continuum, certainly not in a trivial way. The ground states, in fact, will not be as simple as the constant configurations of a lattice system; they will instead be periodic or quasiperiodic configurations with a complicated dependence on the particle interactions. The typical fluctuations when we raise the temperature above zero have a much richer and complex structure and are correspondingly more difficult to control. Closeness to the ground states at nonzero temperature, as described in the Ising model, would prove the spontaneous breaking of the Euclidean symmetries and the existence of a crystalline phase. The question is, of course, of great interest, but it looks far beyond the reach of our present mathematical techniques.

The simpler Ising picture should instead reappear at the liquid–vapor coexistence line. Looking at the fluid on a proper spatial scale, we should in fact see a density that is essentially constant, except for small and rare fluctuations. Its value will differ in the liquid and in the gaseous states, $\rho_{\mathrm{gas}} < \rho_{\mathrm{liq}}$. Therefore, density is an order parameter for the transition and plays the role of the spin magnetization in the Ising picture.

There are general mathematical techniques developed to translate these ideas into proofs, they involve "coarse graining," "block spin transformations," and "renormalization group" procedures. The starting point is to ideally divide the space into cells. Their size should be chosen to be much larger than the typical microscopic distance between molecules, to depress fluctuations of the particle density in a cell. To study the probability distribution of the latter, we integrate out all the other degrees of freedom. After such a coarse graining, we are left with a system of spins on a lattice, the lattice sites labeling the cells (also called blocks) and each spin (also called block spin) giving the value of the density of particles in the corresponding cell. Translated into the language of block spins, the previous physical analysis of the state of the fluid suggests that most probably, in each block the density is approximately equal to either $\rho_{\mathrm{liq}}$ or $\rho_{\mathrm{gas}}$, and the same in different blocks, except in the case of small and rare fluctuations. If we represent the probability distribution of the block spins in terms of a Gibbs measure (as always possible if the system is in a bounded region), the previous picture is compatible with a new Hamiltonian with a single spin (one-body) potential which favors the two values $\rho_{\mathrm{liq}}$ and $\rho_{\mathrm{gas}}$ and an attractive interaction between spins which suppresses changes from one to the other. A new effective low temperature should finally dampen the fluctuations.

Thus, after coarse graining, the system should be in the same universality class as of the low-temperature Ising model, and we may hope, in this way, to extend to the liquid–vapor branch of the phase diagram the Pirogov–Sinai theory of low-temperature lattice systems. In particular, as in the Ising model, we will then be able to select the liquid or the vapor phases by the introduction of suitable boundary conditions.

The conditional tense arises because the computation of the coarse graining transformation is in general very difficult, if not impossible, to carry out, but there is a class of systems where it has been accomplished. These are systems of identical point particles in $\mathbb{R}^d$, $d \geq 2$, which interact with "special" two- and four-body potentials, having finite range and which can be chosen to be rotation and translation invariant; their specific form will be described later. For such systems, the above coarse graining picture works and it has been proved that in a "small" region of the temperature–chemical potential plane, there is a part of the curve where two distinct phases coexist, while elsewhere in the neighborhood, the phase is unique.

The ideas behind the choice of the Hamiltonian go back to van der Waals, and the Ginzburg–Landau theory, which are milestones in the theory of phase transitions, while the mathematics of variational problems also enters here in an important way. These are briefly discussed in the next sections.

## The van der Waals Liquid–Vapor Transition

Let us then do a step backwards and recall the van der Waals theory of the liquid–vapor transition. As typical intermolecular forces have a strong repulsive core and a rather long attractive tail, in a continuum, mesoscopic approximation of the system will be described by a free-energy functional of the type

$$F(\rho) = \int_\Lambda f^0_{\beta,\lambda}(\rho(r))\mathrm{d}r - \frac{1}{2}\int_{\Lambda\times\Lambda} J(r,r')\rho(r)\rho(r')\mathrm{d}r\,\mathrm{d}r' \qquad [1]$$

where $\rho = \{\rho(r), r \in \Lambda\}$ is the particles density and $\Lambda$ the region where the system is confined, which, for simplicity, is taken here as a torus in $\mathbb{R}^d$, consisting of a cube with periodic boundary conditions. The term $-J(r,r')\rho(r)\rho(r')$, $J(r,r') \geq 0$, is the energy due to the attractive tail of the interaction, which is periodic in $\Lambda$; $f^0_{\beta,\lambda}(\rho) = f^0_{\beta,0}(\rho) - \lambda\rho$ is the free-energy density due to the short, repulsive part of the interaction, $\lambda$ being the chemical potential.

As noted later, [1] can be rigorously derived by a coarse graining transformation; it will be used to build a bridge between the van der Waals theory and the previous block spin analysis of the liquid–vapor phase transition. Let us take for the moment [1] as a primitive notion. By invoking the second principle of thermodynamics, the equilibrium states can be found by minimizing the free-energy functional. Supposing $J$ to be translation invariant, that is, $J(r,r') = J(r+a, r'+a)$, $r$, $r'$, $a \in \mathbb{R}^d$, and calling $\alpha = \int J(r,r')\mathrm{d}r'$ the intensity of $J$, we can rewrite $F(\rho)$ as

$$F(\rho) = \int_\Lambda \left\{ f^0_{\beta,\lambda}(\rho(r)) - \frac{\alpha\rho(r)^2}{2} \right\} \mathrm{d}r + \frac{1}{4}\int_{\Lambda\times\Lambda} J(r,r')[\rho(r) - \rho(r')]^2 \mathrm{d}r\,\mathrm{d}r' \qquad [2]$$

This shows that the minimizer must have $\rho(r)$ constant (so that the second integral is minimized) and equal to any value which minimizes the function $\{f^0_{\beta,\lambda}(\rho) - \alpha\rho^2/2\}$. By thermodynamic principles, the free energy $f^0_{\beta,\lambda}(\rho)$ is convex in $\rho$, but, if $\alpha$ is large enough, the above expression is not convex and, by properly choosing the value of $\lambda$, the minimizers are no longer unique, hence the van der Waals phase transition.

## Kac Potentials

The analogy between the above analysis of [2] and the previous heuristic study of the fluid based on coarse graining is striking. As customary in continuum theory, each mesoscopic point $r$ should be regarded as representative of a cell containing many molecules. Then the functional $F(\rho)$ can be interpreted as the effective Hamiltonian after coarse graining. The role of the one-body term is played in [2] by the curly bracket, which selects two values of $\rho$ (its minimizers, to be identified with $\rho_{\text{liq}}$ and $\rho_{\text{gas}}$); the attractive two-body potential is then related to the last term in [2], as it suppresses the variations of $\rho$. The analogy clearly suggests a strategy for a rigorous proof of phase transitions in the continuum, an approach which has been and still is actively pursued. It will be discussed briefly in the sequel.

The first rigorous derivation of the van der Waals theory in a statistical-mechanics setting goes back to the 1960s and to Kac, who proposed a model where the particle pair interaction is

$$-\alpha\gamma^d\, e^{-\gamma|q_i-q_j|} + \text{hard core}, \quad \gamma, \alpha > 0 \qquad [3]$$

The phase diagram of such systems, after the thermodynamic limit, can be quite explicitly determined in the limit $\gamma \to 0$, where it has been proved to converge to the van der Waals phase diagram, under a proper choice of $f^0_{\beta,\lambda}(\cdot)$ in [1].

The characteristic features of the first term in [3] are: (1) very long range, which scales as $\gamma^{-1}$, and (2) very small intensity, which scales as $\gamma^d$, so that the total intensity of the potential, defined as the integral over the second position, is independent of $\gamma$. The additional hard-core term (which imposes that any two particles cannot get closer than $2R_0, R_0 > 0$ being the hard-core radius) is to ensure stability of matter, that is, to avoid collapse of the whole system on an infinitesimally small region, as it would happen if only the attractive part of the interaction were present.

Derivation of the van der Waals theory has been proved for a general class of Kac potentials, where the exponential term in [3] is replaced by functions whose dependence on $\gamma$ has the same scaling properties as mentioned above (in (1) and (2)), while the hard core can be replaced by suitably repulsive interactions.

The proof, in the version proposed by Lebowitz and Penrose, uses coarse graining and shows that the effective Hamiltonian is well approximated by the van der Waals functional [1], when $\gamma$ is small, while the effective temperature scales as $\gamma^d$. The approximation becomes exact in the limit $\gamma \to 0$, where it reduces the computation of the partition function to the analysis of the minima and the ground states of an effective Hamiltonian which, in the limit $\gamma \to 0$, is exactly the van der Waals functional.

A true proof of phase transitions requires instead to keep $\gamma > 0$ fixed (instead of letting $\gamma \to 0$) and thus to control the difference of the effective Hamiltonian after coarse graining and the van der Waals functional, which is the effective Hamiltonian, but only in the actual limit $\gamma \to 0$. In general, there is no symmetry between the two ground states, unlike in the Ising case where they are related by spin flip, and the Pirogov–Sinai theory thus enters into play. The framework in fact is exactly similar, with the lattice Hamiltonian replaced by the functional and low temperatures by small $\gamma$ (recall that the effective temperature scales as $\gamma^d$). The extension of the theory to such a setting, however, presents difficulties and success has so far been only partial.

## A Model for Phase Transitions in the Continuum

The problem is twofold: to have a good control of (1) the limit theory and (2) the perturbations induced by a nonzero value of the Kac parameter $\gamma$. The former falls in the category of variational problems for integral functionals, whose prototype is the Ginzburg–Landau free energy

$$F^{\text{gl}}(\rho) = \int \{w(\rho) + |\nabla\rho|^2\}\, dr \qquad [4]$$

which can be regarded as an approximation of [2] with $w$ equal to the curly bracket in [2] and $J$ replaced by a $\delta$-function. Minimization problems for this and similar functionals have been widely analyzed in the context of general variational problems theory and partial differential equations (PDEs), and the study of the limit theory can benefit from a vast literature on the subject. The analysis of the corrections due to small $\gamma$ is, however, so far quite limited. To implement the Pirogov–Sinai strategy, we need, in the case of the interaction [3],

a very detailed knowledge of the system without the Kac part of the interaction and with only hard cores. This, however, is so far not available when the particle density is near to close-packing (i.e., the maximal density allowed by the hard-core potential). Replacing hard cores by other short-range repulsive interactions does not help either, and this seems the biggest obstacle to the program.

The difficulty, however, can be avoided by replacing the hard-core potential by a repulsive many-body (more than two) Kac potential, which ensures stability as well. The class of systems covered by the approach is characterized by Hamiltonian of the form

$$H_{\gamma,\lambda}(q) = \int_{\mathbf{R}^d} e_\lambda(\phi_\gamma(r))\mathrm{d}r \qquad [5]$$

where $e_\lambda(\phi)$ is a polynomial of the scalar field variable $\phi$, a specific example being

$$e_\lambda(\phi) = \frac{\phi^4}{4!} - \frac{\phi^2}{2} - \lambda\phi \qquad [6]$$

This form of the Hamiltonian is familiar from Euclidean field theories. In these theories, the free distribution of the field is Gaussian; in our case, however, the field $\phi = \phi_\gamma(r)$ is a function of the particle configurations $q = (q_i, i = 1, \ldots, n)$:

$$\phi_\gamma(r) = j_\gamma * q(r) = \sum_{i=1}^{n} j_\gamma(r, q_i)$$
$$j_\gamma(r, r') = \gamma^d j(\gamma r, \gamma r') \qquad [7]$$

where $j(r, r')$ is a translation-invariant, symmetric transition probability kernel. Thus, $\phi_\gamma(r)$ is a nonnegative variable which has the meaning of a local density at $r$, weighted by the Kac kernel $j_\gamma(r, r')$.

## Contours and Phase Indicators

The dependence on $\gamma$ yields the scaling properties characteristic of the Kac potentials and [5] may be regarded as a generalized Kac Hamiltonian, which, in the polynomial case of [6], involves up to four-body Kac potentials. The phase diagram of the model, after taking first the thermodynamic limit and then the limit $\gamma \to 0$, is determined by the free-energy functional

$$F(\rho) = \int \left\{ e_\lambda(j * \rho(r)) - \frac{S(\rho(r))}{\beta} \right\} \mathrm{d}r \qquad [8]$$

$$S(\rho) = -\rho(\log\rho - 1) \qquad [9]$$

where [8] is taken to be defined on a torus (to avoid convergence problems of the integral), and $j = j_\gamma, \gamma = 1$.

Exploiting the concavity of the entropy $S(\rho)$, it is proved that the minimizers of $F(\cdot)$ are constant functions with the constants minimizing

$$f_{\lambda,\beta}(u) = e_\lambda(u) - \frac{S(u)}{\beta}, \quad u \geq 0 \qquad [10]$$

In the case of [6], to which we restrict in the sequel, for any $\beta > (3/2)^{3/2}$ there is $\lambda_\beta$ so that $f_{\lambda_\beta,\beta}(u)$ is double-well with two minimizers, $\rho_{\mathrm{gas}} < \rho_{\mathrm{liq}}$ (dependence on $\beta$ is omitted).

To "recognize" the densities $\rho_{\mathrm{gas}}$ and $\rho_{\mathrm{liq}}$ in a particle configuration, we use coarse graining and introduce two partitions of $\mathbb{R}^d$ into cubes $C^{(\ell_\mp,\gamma)}$. The cubes $C^{(\ell_-,\gamma)}$ of the first partition have side $\ell_{-,\gamma}$ proportional to $\gamma^{-1+\alpha}, \alpha > 0$ suitably small; those of the second one have length $\ell_{+,\gamma}$ proportional to $\gamma^{-1-\alpha}$; they are chosen so that each cube $C^{(\ell_+,\gamma)}$ is union of cubes $C^{(\ell_-,\gamma)}$. Notice that the small cubes have side much smaller than the interaction range (for small $\gamma$), while the opposite is true for the large cubes.

Given a particle configuration $q$, we say that a point $r$ is in the liquid phase and write $\Theta(r; q) = 1$, if

$$\left| \frac{|q \sqcap C^{(\ell_-,\gamma)}|}{\ell^d_{-\gamma}} - \rho_{\mathrm{liq}} \right| \leq \gamma^a, \quad a > 0 \text{ suitably small} \qquad [11]$$

for any small cube $C^{(\ell_-,\gamma)}$ contained either in $C_r^{(\ell_+,\gamma)}$ or in the cubes $C^{(\ell_+,\gamma)}$ contiguous to $C_r^{(\ell_+,\gamma)}$: $|q \sqcap C^{(\ell_-,\gamma)}|$ is referred to as the number of particles of $q$ in $C^{(\ell_-,\gamma)}$, and $C_r^{(\ell_+,\gamma)}$ as the large cube which contains $r$.

Thus, $\Theta(r; q) = 1$ if the local particle density is constantly close to $\rho_{\mathrm{liq}}$ in a large region around $r$. Defining $\Theta(r; q) = -1$ if the above holds with $\rho_{\mathrm{gas}}$ instead of $\rho_{\mathrm{liq}}$ and setting $\Theta(r; q) = 0$ in all the other cases, we then have a phase indicator $\Theta(r; q)$, which identifies, for all particle configurations, which spatial regions should be attributed to the liquid and gas phases. The connected components of the complementary region are called contours and the definition of $\Theta(r; q)$ has been structured in such a way that liquid and gas are always separated by a contour. The liquid phase will then be represented by a measure which gives large probability to configurations having mostly $\Theta = 1$, while the gas phase by configurations with mostly $\Theta = -1$.

This is quite similar to the Ising picture and, as in the Ising model, the existence of a phase transition follows from a Peierls estimate that contours have small probability. In fact, if there are few contours, the phase imposed on the boundaries of the region

where the system is observed percolates inside, invading most of the space. Thus, boundary conditions select the phase in the whole volume. The absence of the short-range potential, which was the hard-core interaction in [3], and hence the absence of all the difficulties which originate from it, allow one to carry through successfully the Pirogov–Sinai program and prove Peierls estimates on contours and, hence, the existence of a phase transition. In particular, the statistical weight of a contour is estimated by first relating the computation to one involving the functional [8] and then computing its value on density profiles compatible with the existence of the given contour. This part of the problem needs variational analysis for [8], with constraints and benefits of a vast literature on the subject.

The phase transition is very sharp, as shown by the following ideal experiment. Having fixed $\beta > (3/2)^{3/2}$, let $\lambda$ vary in a (suitably) small interval $[\lambda_\beta - \delta, \lambda_\beta + \delta], \delta > 0$, centered around the mean-field critical value $\lambda_\beta$. We consider the system in a large region with, for instance, boundary conditions $\Theta = -1$ (i.e., forcing the gas phase) and fix $\gamma$ small enough. At $\lambda = \lambda_\beta - \delta$, the system has $\Theta = -1$ in most of the domain, and this persists when we increase $\lambda$ till a critical value, $\lambda_{\beta,\gamma}$, close to, but not the same as $\lambda_\beta$. For $\lambda > \lambda_{\beta,\gamma}, \Theta = 1$ in most of the domain, except for a small layer around the boundaries. The analogous picture holds if we choose boundary conditions $\Theta = 1$, and $\lambda = \lambda_{\beta,\gamma}$ is the only value of the chemical potential where the system is sensitive to the boundary conditions and both phases can be produced by the right boundary conditions. The fact that the actual value $\lambda_{\beta,\gamma}$ differs from $\lambda_\beta$, is characteristic of the Pirogov–Sinai approach and enlightens the delicate nature of the proofs.

## Some Related Problems

In this concluding section, two important related problems, which have not been mentioned so far, are discussed.

A natural question, after proving a phase transition, is to describe how two phases coexist, once forced to be simultaneously present in the system. This can be achieved, for instance, by suitable boundary conditions (typically positive and negative on the top and bottom of the spatial domain) or by imposing a total density (or magnetization in the case of spins) intermediate between those of the pure phases. There will then be an interface separating the two phases with a corresponding surface tension and the geometry will be determined by the solution of a variational problem and given by the Wulff shape.

Can statistical mechanics explain and describe the phenomenon? Important progress has been made recently on the subject in the case of lattice systems at low temperatures. The question has also been widely studied at the mesoscopic level, in the context of variational problems for Ginzburg and Landau and many other functionals. Therefore, all the ingredients of further development of the theory in this direction are now present.

We have so far discussed only classical systems; a few words about extensions to the quantum case are now in order. In the range of values of temperatures and densities where the liquid–vapor transition occurs, the quantum effects are not expected to be relevant. Referring to the case of bosons, and away from the Bose condensation regime (and for system with Boltzmann statistics as well), the quantum delocalization of particles caused by the indeterminacy principle should essentially disappear after macroscopic coarse graining, and the block-spin variables should again behave classically, even though their underlying constituents are quantal. If this argument proves correct, then progress along these lines may be expected in near future.

# Pirogov–Sinai Theory

**R Kotecký**, Charles University, Prague, Czech Republic, and the University of Warwick, UK

## Introduction

Pirogov–Sinai theory is a method developed to study the phase diagrams of lattice models at low temperatures. The general claim is that, under appropriate conditions, the phase diagram of a lattice model is, at low temperatures, a small perturbation of the zero-temperature phase diagram designed by ground states. The treatment can be generalized to cover temperature driven transitions with coexistence of ordered and disordered phases.

## Formulation of the Main Result

### Setting

Refraining first from full generality, we formulate the result for a standard class of lattice models with finite spin state and finite-range interaction. We will mention different generalizations later.

We consider *classical lattice models* on the $d$-dimensional hypercubic lattice $\mathbb{Z}^d$ with $d \geq 2$. A *spin configuration* $\sigma = (\sigma_x)_{x \in \mathbb{Z}^d}$ is an assignment of a spin with values in a finite set $S$ to each lattice site $x \in \mathbb{Z}^d$; the configuration space is $\Omega = S^{\mathbb{Z}^d}$. For $\sigma \in \Omega$ and $\Lambda \subset \mathbb{Z}^d$, we use $\sigma_\Lambda \in \Omega_\Lambda = S^\Lambda$ to denote the restriction $\sigma_\Lambda = \{\sigma_x; x \in \Lambda\}$.

The Hamiltonian is given in terms of a collection of interaction potentials $(\Phi_A)$, where $\Phi_A$ are real functions on $\Omega$, depending only on $\sigma_x$ with $x \in A$, and $A$ runs over all finite subsets of $\mathbb{Z}^d$. We assume that the potential is *periodic* with *finite range of interactions*. Namely, $\Phi_{A'}(\sigma') = \Phi_A(\sigma)$ whenever $A$ and $\sigma$ are related to $A'$ and $\sigma'$ by a translation from $(a\mathbb{Z})^d$ for some fixed integer $a$ and there exists $R \geq 1$ such that $\Phi_A \equiv 0$ for all $A$ with diameter exceeding $R$.

Without loss of generality (possibly multiplying the number $a$ by an integer and increasing $R$), we may assume that $R = a$.

The Hamiltonian $H_\Lambda(\sigma|\eta)$ in $\Lambda$ with boundary conditions $\eta \in \Omega$ is then given by

$$H_\Lambda(\sigma|\eta) = \sum_{A \cap \Lambda \neq \emptyset} \Phi_A(\sigma_\Lambda \vee \eta_{\Lambda^c}) \qquad [1]$$

where $\sigma_\Lambda \vee \eta_{\Lambda^c} \in \Omega$ is the configuration $\sigma_\Lambda$ extended by $\eta_{\Lambda^c}$ on $\Lambda^c$. The *Gibbs state in* $\Lambda$ *under boundary conditions* $\eta \in \Omega$ (and with Hamiltonian $H$) is the probability $\mu_\Lambda(\cdot|\eta)$ on $\Omega_\Lambda$ defined by

$$\mu_\Lambda(\{\sigma_\Lambda\}|\eta) = \frac{\exp\{-\beta H_\Lambda(\sigma|\eta)\}}{Z(\Lambda|\eta)} \qquad [2]$$

with the *partition function*

$$Z(\Lambda|\eta) = \sum_{\sigma_\Lambda} \exp\{-\beta H_\Lambda(\sigma|\eta)\} \qquad [3]$$

We use $\mathcal{G}(H)$ to denote the set of all *periodic Gibbs states with Hamiltonian H* defined on $\Omega$ by means of the Dobrushin–Lanford–Ruelle (DLR) equations.

### Ground-State Phase Diagram and the Removal of Degeneracy

A periodic configuration $\sigma \in \Omega$ is called a (*periodic*) *ground state* of a Hamiltonian $H = (\Phi_A)$ if

$$H(\tilde{\sigma}; \sigma) = \sum_A (\Phi_A(\tilde{\sigma}) - \Phi_A(\sigma)) \geq 0 \qquad [4]$$

for every finite perturbation $\tilde{\sigma} \neq \sigma$ of $\sigma$ ($\tilde{\sigma}$ differs from $\sigma$ at a finite number of lattice sites). We use $g(H)$ to denote the set of all periodic ground states of $H$. For every configuration $\sigma \in g(H)$, we define the *specific energy* $e_\sigma(H)$ by

$$e_\sigma(H) = \lim_{n \to \infty} \frac{1}{|V_n|} \sum_{A \cap V_n \neq \emptyset} \Phi_A(\sigma) \qquad [5]$$

(with $V_n$ denoting a cube consisting of $n^d$ lattice sites).

To investigate the phase diagram, we will consider a parametric class of Hamiltonians around a fixed Hamiltonian $H^{(0)}$ with a finite set of periodic ground states $g(H^{(0)}) = \{\sigma_1, \ldots, \sigma_r\}$. Namely, let $H^{(0)}$, $H^{(1)}, \ldots,$ and $H^{(r-1)}$ be Hamiltonians determined by potentials $\Phi^{(0)}, \Phi^{(1)}, \ldots,$ and $\Phi^{(r-1)}$, respectively, and consider the $(r-1)$-parametric set of Hamiltonians $H_{\boldsymbol{t}} = H^{(0)} + \sum_{\ell=1}^{r-1} t_\ell H^{(\ell)}$ with $\boldsymbol{t} = (t_1, \ldots, t_{r-1}) \in \mathbb{R}^{r-1}$. Using a shorthand $e_m(H) = e_{\sigma_m}(H)$, and introducing the vectors $\boldsymbol{e}(H) = (e_1(H), \ldots, e_r(H))$ and $\boldsymbol{h}(\boldsymbol{t}) = \boldsymbol{e}(H_{\boldsymbol{t}}) - \min_m e_m(H_{\boldsymbol{t}})$, we notice that for each $\boldsymbol{t} \in \mathbb{R}^{r-1}$, the vector $\boldsymbol{h}(\boldsymbol{t}) \in \partial Q_r$, the boundary of the positive octant in $\mathbb{R}^r$. A crucial assumption for such a parametrization $H_{\boldsymbol{t}}$ to yield a meaningful phase diagram is the *condition of removal of degeneracy*: we assume that $g(H^{(0)} + H^{(\ell)}) \subsetneqq g(H^{(0)}), \ell = 1, \ldots, r-1$, and that the vectors $\boldsymbol{e}(H^{(\ell)}), \ell = 1, \ldots, r-1$, are linearly independent.

In particular, its immediate consequence is that the mapping $R^{r-1} \ni \boldsymbol{t} \mapsto \boldsymbol{h}(\boldsymbol{t}) \in \partial Q_r$ is a bijection. This fact has a straightforward interpretation in terms of *ground-state phase diagram*. Viewing the

phase diagram (at zero temperature) as a partition of the parameter space into regions $K_g$ with a given set $g \subset g(H^{(0)})$ of ground states – "coexistence of zero-temperature phases from $g$" – the above bijection means that the region $K_g$ is the preimage of the set

$$Q_g = \{\boldsymbol{h} \in \partial Q_r | h_m = 0 \text{ for } \sigma_m \in g \text{ and } h_m > 0 \text{ otherwise}\} \quad [6]$$

The partition of the set $\partial Q_r$ has a natural hierarchical structure implied by the fact that $\overline{Q_{g_1}} \cap \overline{Q_{g_2}} = \overline{Q_{g_1 \cup g_2}}$ ($\overline{Q_g}$ is the closure of $Q_g$). Namely, the origin $\{0\} = Q_{g(H^{(0)})}$ is the intersection of $r$ positive coordinate axes $\overline{Q_{\{\sigma_{\tilde{m}}, \tilde{m} \neq m\}}}, m = 1, \ldots, r$; each of those half-lines is an intersection of $r-1$ two-dimensional quarter-planes with boundaries on positive coordinate axes, etc., up to $(r-1)$-dimensional planes $\overline{Q_{\{\sigma_m\}}}, m = 1, \ldots, r$. This hierarchical structure is thus inherited by the partition of the parameter space $\mathbb{R}^{r-1}$ into the regions $K_g$. The phase diagrams with such regular structure are sometimes said to satisfy the Gibbs phase rule.

We can thus summarize in a rather trivial conclusion that the condition of removal of degeneracy implies that the ground-state phase diagram obeys the Gibbs phase rule. The task of the Pirogov–Sinai theory is to provide means for proving that this remains true, at least in a neighborhood of the origin of parameter space, also for small nonzero temperatures. To achieve this, we need an effective control of excitation energies.

### Peierls Condition

A crucial assumption for the validity of the Pirogov–Sinai theory is a lower bound on energy of excitations of ground states – the Peierls condition.

In spite of the fact that for a study of phase diagram we consider a parametric set of Hamiltonians whose set of ground states may differ, it is useful to introduce the Peierls condition with respect to a single fixed collection $G$ of *reference configurations* (eventually, it will be identified with the ground states of the Hamiltonian $H^{(0)}$). Let thus a fixed set $G$ of periodic configurations $\{\sigma_1, \ldots, \sigma_r\}$ be given. Again, without loss of generality, we may assume that the periodicity of all configurations $\sigma_m \in G$ is $R$.

Before formulating the Peierls condition, we have to introduce the notion of contours. Consider the set of all *sampling cubes* $C(x) = \{y \in \mathbb{Z}^d \| y_i - x_i| \leq R \text{ for } 1 \leq i \leq d\}, x \in \mathbb{Z}^d$. A *bad cube* of a configuration $\sigma \in \Omega$ is a sampling cube $C$ for which $\sigma_C$ differs from $\sigma_m$ restricted to $C$ for every $\sigma_m \in G$. The boundary $B(\sigma)$ of $\sigma$ is the union of all bad cubes of $\sigma$. If $\sigma_m \in G$ and $\sigma$ is its finite perturbation (differing from $\sigma_m$ on a finite set of lattice sites), then, necessarily, $B(\sigma)$ is finite. A *contour* of $\sigma$ is a pair $\gamma = (\Gamma, \sigma_\Gamma)$, where $\Gamma$ (the *support* of the contour $\gamma$) is a connected component of $B(\sigma)$ (and $\sigma_\Gamma$ is the restriction of $\sigma$ on $\Gamma$). Here, the connectedness of $\Gamma$ means that it cannot be split into two parts whose (Euclidean) distance is larger than 1. We use $\partial(\sigma)$ to denote the set of all contours of $\sigma$, $B(\sigma) = \bigcup_{\gamma \in \partial(\sigma)} \Gamma$.

Consider a configuration $\sigma^\gamma$ such that $\gamma$ is its unique contour. The set $\mathbb{Z}^d \backslash \Gamma$ has one infinite component to be denoted $\operatorname{Ext} \gamma$ and a finite number of finite components whose union will be denoted $\operatorname{Int} \gamma$. Observing that the configuration $\sigma^\gamma$ coincides with one of the states $\sigma_m \in G$ on every component of $\mathbb{Z}^d \backslash B(\sigma)$, each of those components can be labeled by the corresponding $m$. Let $q$ be the label of $\operatorname{Ext} \gamma$, we say that $\gamma$ is a $q$-contour, and let $\operatorname{Int}_m \gamma$ be the union of all components of $\operatorname{Int} \gamma$ labeled by $m, m = 1, \ldots, r$.

Defining the "energy" $\Psi(\gamma)$ of a $q$-contour $\gamma$ by the equation

$$\Psi(\gamma) = H(\sigma^\gamma; \sigma_q) + e_q(H)|\Gamma| - \sum_{m=1}^{r} (e_m(H) - e_q(H))|\operatorname{Int}_m \gamma| \quad [7]$$

the *Peierls condition* with respect to the set $G$ of reference configurations is an assumption of the existence of $\rho > 0$ such that

$$\Psi(\gamma) \geq (\rho + \min_m e_m(H))|\Gamma| \quad [8]$$

for any contour of any configuration $\sigma$ that is a finite perturbation of $\sigma_q \in G$.

Notice that if $G = g(H)$, the sum on the right-hand side of [7] vanishes.

### Phase Diagram

The main claim of the Pirogov–Sinai theory provides, for $\beta$ sufficiently large, a construction of regions $\mathcal{K}_g(\beta)$ of the parameter space characterized by the coexistence of phases labeled by configurations $\sigma_m \in g$. This is done similarly as for the ground-state phase diagram discussed earlier by constructing a homeomorphism $\boldsymbol{t} \mapsto \boldsymbol{a}(\boldsymbol{t})$ from a neighborhood of the origin of the parameter space to a neighborhood of the origin of $\partial Q_r$ that provides the phase diagram (actually, the function $\boldsymbol{a}(\boldsymbol{t})$ will turn out to be just a perturbation of $\boldsymbol{h}(\boldsymbol{t})$ with errors of order $e^{-\beta}$).

Before stating the result, however, we have to clarify what exactly is meant by existence of phase $m$ for a given Hamiltonian $H$. Roughly speaking, it is the existence of a periodic extremal Gibbs state $\mu_m \in \mathcal{G}(H)$, whose typical configurations do not differ too much from the ground-state configuration $\sigma_m$. In more technical terms, the existence of such a state is provided once we prove a

suitable bound, for the finite-volume Gibbs state $\mu_\Lambda(\{\sigma_\Lambda\}|\sigma_m)$ under the boundary conditions $\sigma_m$, on the probability that a fixed point in $\Lambda$ is encircled by a contour from $\partial\sigma$. If this is the case, we say that the *phase m is stable*. It turns out that such a bound is actually an integral part of the construction of metastable free energies $f_m(\boldsymbol{t})$ yielding the homeomorphism $\boldsymbol{t}\mapsto \boldsymbol{a}(\boldsymbol{t})$. In this way, we get the main claim formulated as follows:

**Theorem 1** *Consider a parametric set of Hamiltonians* $H_t = H^{(0)} + \sum_{\ell=1}^{r-1} t_\ell H^{(\ell)}$ *with periodic finite-range interactions satisfying the condition of removal of degeneracy as well as the Peierls condition with respect to the reference set* $G = g(H^{(0)})$. *Let* $d \geq 2$ *and let* $\beta$ *be sufficiently large. Then there exists a homeomorphism* $\boldsymbol{t}\mapsto \boldsymbol{a}(\boldsymbol{t})$ *of a neighborhood* $V_\beta$ *of the origin of the parameter space* $R^{r-1}$ *onto a neighborhood* $U_\beta$ *of the origin of* $\partial Q_r$ *such that, for any* $\boldsymbol{t} \in V_\beta$, *the set of all stable phases is* $\{m \in \{1,\ldots,r\} | a_m(\boldsymbol{t}) = 0\}$.

The Peierls condition can be actually assumed only for the Hamiltonian $H^{(0)}$ inferring its validity for $H_t$ on a sufficiently small neighborhood $V_\beta$.

Notice also that the result can be actually stated not as a claim about phase diagram in a space of parameters, but as a statement about stable phases of a fixed Hamiltonian $H$. Namely, for a Hamiltonian $H$ satisfying Peierls condition with respect to a reference set $G$, one can assure the existence of parameters $a_m$ labeled by elements from $G$ such that the set of extremal periodic Gibbs states of $H$ consists of all those $m$-phases for which $a_m = 0$.

### Construction of Metastable Free Energies

An important part of the Pirogov–Sinai theory is an actual construction of the *metastable free energies* – a set of functions $f_m(\boldsymbol{t}), m = 1,\ldots,r$, that provide the homeomorphism $\boldsymbol{a}(\boldsymbol{t})$ by taking $a_m(\boldsymbol{t}) = f_m(\boldsymbol{t}) - \min_{\bar m} f_{\bar m}(\boldsymbol{t})$.

We start with a *contour representation of partition function* $Z(\Lambda|\sigma_q)$. Considering, for each contributing configuration $\sigma$, the collection $\partial(\sigma)$ of its contours, we notice that, in addition to the fact that different contours $\gamma, \gamma' \in \partial(\sigma)$ have disjoint supports, $\Gamma \cap \Gamma' = \emptyset$, the contours from $\partial(\sigma)$ have to satisfy the *matching conditions*: if $C$ is a connected component of $\mathbb{Z}^d \setminus \bigcup_{\gamma\in\partial}\Gamma$, then the restrictions of the spin configurations $\sigma^\gamma$ to $C$ are the same for all contours $\gamma \in \partial(\sigma)$ with $\mathrm{dist}(\Gamma, C) = 1$. In other words, the contours touching $C$ induce the same label on $C$. Let us observe that there is actually one-to-one correspondence between configurations $\sigma$ that coincide with $\sigma_q$ on $\Lambda^c$ and collections $\mathcal{M}(\Lambda, q)$ of contours $\partial$ in $\Lambda$ satisfying the matching condition, and such that the external among them are $q$-contours. Here, a contour $\gamma \in \partial$ is called an *external contour* in $\partial$ if $\Gamma \subset \mathrm{Ext}\,\gamma'$ for all $\gamma' \in \partial$ different from $\gamma$.

With this observation and using $\Lambda_m(\partial)$ to denote the union of all components of $\Lambda \setminus \bigcup_{\gamma\in\partial}\Gamma$ with label $m$, we get

$$Z(\Lambda|\sigma_q) = \sum_{\partial\in\mathcal{M}(\Lambda,q)} \prod_m \mathrm{e}^{-\beta e_m(H)|\Lambda_m(\gamma)|} \prod_{\gamma\in\partial} \mathrm{e}^{-\beta\Psi(\gamma)} \qquad [9]$$

Usefulness of such contour representations stems from an expectation that, for a stable phase $q$, contours should constitute a suppressed excitation and one should be able to use cluster expansions to evaluate the behavior of the Gibbs state $\mu_q$. However, the direct use of the cluster expansion on [9] is trammeled by the presence of the energy terms $\mathrm{e}^{-\beta e_m(H)|\Lambda_m(\partial)|}$ and, more seriously, by the requirement that the contour labels match.

Nevertheless, one can rewrite the partition function in a form that does not involve any matching condition. Namely, considering first a sum over mutually external contours $\partial^{\mathrm{ext}}$ and resumming over collections of contours which are contained in their interiors without touching the boundary (being thus prevented to "glue" with external contours), we get

$$Z(\Lambda|\sigma_q) = \sum_{\partial^{\mathrm{ext}}} \mathrm{e}^{-\beta e_q(H)|\mathrm{Ext}|} \times \prod_{\gamma\in\partial^{\mathrm{ext}}} \left\{ \mathrm{e}^{-\beta\Psi(\gamma)} \prod_m Z^{\mathrm{dil}}(\mathrm{Int}_m\gamma|\sigma_m) \right\} \qquad [10]$$

Here the sum goes over all collections of compatible external $q$-contours in $\Lambda$, $\mathrm{Ext} = \mathrm{Ext}_\Lambda(\partial^{\mathrm{ext}}) = \bigcap_{\gamma\in\partial^{\mathrm{ext}}} (\mathrm{Ext}\,\gamma \cap \Lambda)$, and the partition function $Z^{\mathrm{dil}}(\Lambda|\sigma_q)$ is defined by [9] with $\mathcal{M}(\Lambda, q)$ replaced by $\mathcal{M}^{\mathrm{dil}}(\Lambda, q) \subset \mathcal{M}(\Lambda, q)$, the set of all those collections whose external countours $\gamma$ are such that $\mathrm{dist}\,(\Gamma, \Lambda^c) > 1$. Multiplying now each term by

$$1 = \prod_{\gamma\in\partial^{\mathrm{ext}}} \prod_m \frac{Z^{\mathrm{dil}}(\mathrm{Int}_m\,\gamma|\sigma_q)}{Z^{\mathrm{dil}}(\mathrm{Int}_m\,\gamma|\sigma_q)} \qquad [11]$$

we get

$$Z(\Lambda|\sigma_q) = \sum_{\partial^{\mathrm{ext}}} \mathrm{e}^{-\beta e_q(H)|\mathrm{Ext}|} \times \prod_{\gamma\in\partial^{\mathrm{ext}}} \left( \mathrm{e}^{-\beta e_q(H)|\Gamma|} w_q(\gamma) Z^{\mathrm{dil}}(\mathrm{Int}\,\gamma|\sigma_q) \right) \qquad [12]$$

where $w_q(\gamma)$ is given by

$$w_q(\gamma) = \mathrm{e}^{-\beta\Psi(\gamma)}\,\mathrm{e}^{\beta e_q(H)|\Gamma|} \prod_m \frac{Z^{\mathrm{dil}}(\mathrm{Int}_m\,\gamma|\sigma_m)}{Z^{\mathrm{dil}}(\mathrm{Int}_m\,\gamma|\sigma_q)} \qquad [13]$$

Observing that a similar expression is valid for $Z^{\mathrm{dil}}(\Lambda|\sigma_q)$ (with an appropriate restriction on the sum over external contours $\partial^{ext}$) and proceeding by induction, we eventually get the representation

$$Z(\Lambda|\sigma_q) = \mathrm{e}^{-\beta e_q(H)|\Lambda|} \sum_{\partial \in \mathcal{C}(\Lambda,q)} \prod_{\gamma \in \partial} w_q(\gamma) \qquad [14]$$

where $\mathcal{C}(\Lambda, q)$ denotes the set of all collections of nonoverlapping $q$-contours in $\Lambda$. Clearly, the sum on the right-hand side is exactly of the form needed to apply cluster expansion, provided the contour weights satisfy the necessary convergence assumptions.

Even though this is not necessarily the case, there is a way to use this representation. Namely, one can artificially change the weights to satisfy the needed bound, for example, by modifying them to the form

$$w'_q(\gamma) = \min\left(w_q(\gamma), \mathrm{e}^{-\tau|\Gamma|}\right) \qquad [15]$$

with a suitable constant $\tau$. The modified partition function

$$Z'(\Lambda|\sigma_q) = \mathrm{e}^{-\beta e_q(H)|\Lambda|} \sum_{\partial \in \mathcal{C}(\Lambda,q)} \prod_{\gamma \in \partial} w'_q(\gamma) \qquad [16]$$

can then be controlled by cluster expansion allowing to *define*

$$f_q(H) = -\frac{1}{\beta} \lim_{|\Lambda|\to\infty} \frac{1}{|\Lambda|} \log Z'(\Lambda|\sigma_q) \qquad [17]$$

This is the *metastable free energy* corresponding to the phase $q$. Applying the cluster expansion to the logarithm of the sum in [16], we get $|f_q(H) - e_q(H)| \leq \mathrm{e}^{-\tau/2}$. The metastable free energy corresponds to taking the ground state $\sigma_q$ and its excitations as long as they are sufficiently suppressed. Once $w_q(\gamma)$ exceeds the weight $\mathrm{e}^{-\tau|\Gamma|}$ (and the contour would have been actually preferred), we suppress it "by hand." The point is that if the phase $q$ is stable, this never happens and $w'_q(\gamma) = w_q(\gamma)$ for *all* $q$-contours $\gamma$. This is the idea behind the use of the function $f_q(H)$ as an indicator of the stability of the phase $q$ by taking

$$a_q(\boldsymbol{t}) = f_q(H_{\boldsymbol{t}}) - \min_m f_m(H_{\boldsymbol{t}}) \qquad [18]$$

Of course, the difficult point is to actually prove that the stability of phase $q$ (i.e., the fact that $a_q(\boldsymbol{t}) = 0$) indeed implies $w'_q(\gamma) = w_q(\gamma)$ for all $\gamma$. The crucial step is to prove, by induction on the diameter of $\Lambda$ and $\gamma$, the following three claims (with $\epsilon = 2\mathrm{e}^{-\tau/2}$):

1. *If $\gamma$ is a $q$-contour with $a_q(\boldsymbol{t})\,\mathrm{diam}\,\Gamma \leq \tau/4$, then* $w'_q(\gamma) = w_q(\gamma)$.
2. *If* $a_q(\boldsymbol{t})\,\mathrm{diam}\,\Lambda \leq \tau/4$, *then* $Z(\Lambda|\sigma_q) = Z'(\Lambda|\sigma_q) \neq 0$ *and*

$$\left|Z(\Lambda|\sigma_q)\right| \geq \mathrm{e}^{-f_q(H_t)|\Lambda| - \epsilon|\partial\Lambda|} \qquad [19]$$

3. *If $m \in G$, then*

$$|Z(\Lambda|\sigma_m)| \leq \mathrm{e}^{-\min_q f_q(H_t)|\Lambda|}\mathrm{e}^{\epsilon|\partial\Lambda|} \qquad [20]$$

A standard example illuminating the perturbative construction of the metastable free energies and showing the role of entropic contributions is the Blume–capel model. It is defined by the Hamiltonian

$$H_\Lambda(\sigma) = -J\sum_{\langle x,y\rangle}(\sigma_x - \sigma_y)^2 - \lambda\sum_{x\in\Lambda}\sigma_x^2 - h\sum_{x\in\Lambda}\sigma_x \qquad [21]$$

with spins $\sigma_x \in \{-1, 0, 1\}$. Taking into account only the lowest-order excitations, we get:

$$\tilde{f}_\pm(\lambda, h) = -\lambda \mp h - \frac{1}{\beta}\mathrm{e}^{-\beta(2d-\lambda\pm h)}$$

(sea of pluses or minuses with a single spin flip $\pm \to 0$) and

$$\tilde{f}_0(\lambda, h) = -\frac{1}{\beta}\mathrm{e}^{-\beta(2d+\lambda)}\left(\mathrm{e}^{\beta h} + \mathrm{e}^{-\beta h}\right)$$

(sea of zeros with a single spin flip either $0 \to +$ or $0 \to -$)
Since these functions differ from full metastable free energies $f_\pm(\lambda, h), f_0(\lambda, h)$ by terms of higher order ($\sim\mathrm{e}^{-(4d-2)\beta}$), the real phase diagram differs in this order from the one constructed by equating the functions $\tilde{f}_\pm(\lambda, h)$ and $\tilde{f}_0(\lambda, h)$. It is particularly interesting to inspect the origin, $\lambda = h = 0$. It is only the phase 0 that is stable there at all small temperatures since

$$f_0(0,0) \sim -\frac{2}{\beta}\mathrm{e}^{-\beta 2d} < f_\pm(0,0) \sim -\frac{1}{\beta}\mathrm{e}^{-\beta 2d} \qquad [22]$$

The only reason why the phase 0 is favored at this point with respect to phases + and − is that there are two excitations of order $\mathrm{e}^{-2d\beta}$ for the phase 0, while there is only *one* such excitation for + or −. The entropy of the lowest-order contribution to $f_0(0,0)$ is overweighting the entropy of the contribution to $f_\pm(0,0)$ of the same order.

## Applications

Several applications, stemming from the Pirogov–Sinai theory, are based on the fact that, due to the cluster expansion, we have quite accurate description of the model in finite volume.

One class of applications concerns various problems featuring interfaces between coexisting phases. To be able to transform the problem into a study of the random boundary line separating the two phases, one needs a precise cluster expansion formula for partition functions in volumes occupied by those phases. In the situation with no symmetry

between the phases, the use of the Pirogov–Sinai theory is indispensable.

Another interesting class of applications concerns the behavior of the system with periodic boundary conditions. It is based on the fact that the partition function $Z_{T_N}$ on a torus $T_N$ consisting of $N^d$ sites can be, again with the help of the cluster expansions, explicitly and very accurately evaluated in terms of metastable free energies,

$$\left| Z_{T_N} - \sum_{q=1}^{r} e^{-\beta f_q(H) N^d} \right| \leq \exp\{-\beta \min_m f_m(H) N^d - b\beta N\} \qquad [23]$$

with a fixed constant $b$. This formula (and its generalization to the case of complex parameters) allows us to obtain various results concerning the behavior of the model in finite volumes.

### Finite-Size Effects

Considering as an illustration a perturbation of the Ising model, so that it does not have the $\pm$ symmetry any more (and the value $h_t(\beta)$ of external field at which the phase transition between plus and minus phase occurs is not known), we can pose a natural question that has an importance for correct interpretation of simulation data. Namely, what is the asymptotic behavior of the magnetization $m_N^{\text{per}}(\beta, h) = \mu_{T_N}(1/\Lambda \sum_{x\in\Lambda} \sigma_x)$ on a torus? In the thermodynamic limit, the magnetization $m_\infty^{\text{per}}(\beta, h)$ displays, as a function of $h$, a discontinuity at $h = h_t(\beta)$. For finite $N$, we get a *rounding* of the discontinuity – the jump is smoothed. What is the shift of a naturally chosen finite-volume transition point $h_t(N)$ with respect to the limiting value $h_t$? The answer can be obtained with the help of [23] once sufficient care is taken to use the freedom in the definition of the metastable free energies $f_+(h)$ and $f_-(h)$ to replace them with a sufficiently smooth version allowing an approximation of the functions $f_\pm(h)$ around limiting point $h_t$ in terms of their Taylor expansion.

As a result, in spite of the asymmetry of the model, the finite-volume magnetization $m_N^{\text{per}}(\beta, h)$ has a universal behavior in the neighborhood of the transition point $h_t$. With suitable constants $m$ and $m_0$, we have

$$m_N^{\text{per}}(\beta, h) \sim m_0 + m \tanh\{N^d \beta m (h - h_t)\} \qquad [24]$$

Choosing the inflection point $h_{\max}(N)$ of $m_N^{\text{per}}(\beta, h)$ as a natural finite-volume indicator of the occurence of the transition, one can show that

$$h_{\max}(N) = h_t + \frac{3\chi}{2\beta^2 m^3} N^{-2d} + O(N^{-3d}) \qquad [25]$$

### Zeros of Partition Functions

The full strength of the formula [23] is revealed when studying the zeros of the partition function $Z_{T_N}(z)$ as a polynomial in a complex parameter $z$ entering the Hamiltonian of the model. To be able to use the theory in this case, one has to extend the definitions of the metastable free energies to complex values of $z$. Indeed, the construction still goes through, now yielding genuinely complex, contour models $w_\pm$ with the help of an inductive procedure. Notice that no analytic continuation is involved. An analog of [23] is still valid,

$$\left| Z_{T_N}(z) - \sum_{m=1}^{r} e^{-\beta f_m(z) N^d} \right| \leq \exp\{-\beta \min_m \Re f_m(z) N^d - b\beta N\} \qquad [26]$$

Using [26], it is not difficult to convince oneself that the loci of zeros can be traced down to the phase coexistence lines. Indeed, on the line of the coexistence of two phases $\Re f_m = \Re f_q$, the partition function $Z_{T_N}(z)$ is approximated by $e^{-\beta f N^d}(e^{-\beta \Im f_m N^d} + e^{-\beta \Im f_n N^d})$. The zeros of this approximation are thus given by the equations

$$\begin{aligned} &\Re f_m = \Re f_n < \Re f_\ell \quad \text{for all } \ell \neq m, n \\ &\beta N^d(\Im f_m - \Im f_n) = \pi \bmod 2\pi \end{aligned} \qquad [27]$$

The zeros of the full partition function $Z_{T_N}(z)$ can be proved to be exponentially close, up to a shift of order $\mathcal{O}(e^{-\beta b N})$, to those of the discussed approximation.

Briefly, the zeros of $Z_{T_N}(z)$ asymptotically concentrate on the phase coexistence curves with the density $(1/2\pi)\beta N^d |(d/dz)(f_m - f_n)|$.

## Bibliographical Remarks and Generalizations

The original works Pirogov and Sinai (1975, 1976) and Sinai (1982) introduced an analog of the weights $w'_q(\gamma)$ and parameters $a_q(H)$ as a fixed point of a suitable mapping on a Banach space. The inductive definition used here was introduced in Kotecký and Preiss (1983) and Zahradník (1984). The *completeness of phase diagram* – the fact that the stable phases exhaust the set of all periodic extremal Gibbs states was first proved in Zahradník (1984). Extension to complex parameters was first considered in Gawędzki *et al.* (1987) and Borgs and Imbrie (1989). For a review of the standard Pirogov–Sinai theory, see Sinai (1982) and Slawny (1987).

Application of Pirogov–Sinai theory for finite-size effects was studied in Borgs and Kotecký (1990) and

general theory of zeros of partition functions is presented in Biskup *et al.* (2004).

The basic statement of the Pirogov–Sinai theory yielding the construction of the full phase diagram has been extended to a large class of models. Let us mention just few of them (with rather incomplete references):

1. *Continuous spins.* The main difficulty in these models is that one has to deal with contours immersed in a sea of fluctuating spins (Dobrushin and Zahradník 1986, Borgs and Waxler 1989).
2. *Potts model.* An example of a system a transition in temperature with the coexistence of the low-temperature ordered and the high-temperature disordered phases. Contour reformulation is employing contours between ordered and disordered regions (Bricmont *et al.* 1985, Kotecký *et al.* 1990). The treatment is simplified with help of Fortuin–Kasteleyn representation (Laanait *et al.* 1991).
3. *Models with competing interactions.* ANNNI model, microemulsions. Systems with a rich phase structure (Dinaburg and Sinai 1985).
4. *Disordered systems.* An example is a proof of the existence of the phase transition for the three-dimensional random field Ising model (Bricmont and Kupiainen 1987, 1988) using a renormalization group version of the Pirogov–Sinai theory first formulated in Gawędzki *et al.* (1987).
5. *Quantum lattice models.* A class of quantum models that can be viewed as a quantum perturbation of a classical model. With the help of Feynman–Kac formula these are rewritten as a $(d+1)$-dimensional classical model that is, in its turn, treated by the standard Pirogov–Sinai theory (Datta *et al.* 1996, Borgs *et al.* 1996).
6. *Continuous systems.* Gas of particles in continuum interacting with a particular potential of Kac type. Pirogov–Sinai theory is used for a proof of the existence of the phase transitions after a suitable discretisation (Lebowitz *et al.* 1999).

# Point-Vortex Dynamics

**S Boatto**, IMPA, Rio de Janeiro, Brazil
**D Crowdy**, Imperial College, London, UK

## Introduction

Vortices have a long fascinating history. Descartes wrote in his *Le Monde*:

> ...que tous les mouvements qui se font au Monde sont en quelque façon circulaire: c'est à dire que, quand un corps quitte sa place, il entre toujours en celle d'un autre, et celui-ci en celle d'un autre, et ainsi de suite jusques au dernier, qui occupe au même instant le lieu délaissé par le premier.

In particular, Descartes thought of vortices to model the dynamics of the solar system, as reported by W W R Ball (1940):

> Descartes' physical theory of the universe, embodying most of the results contained in his earlier and unpublished *Le Monde*, is given in his *Principia*, 1644,... He assumes that the matter of the universe must be in motion, and that the motion must result in a number of vortices. He stated that the sun is the center of an immense whirlpool of this matter, in which the planets float and are swept round like straws in a whirlpool of water.

Descartes' theory was later on recused by Newton in his *Principia* in 1687. Few centuries later, W Thomson (1867) the later Lord Kelvin, made use of vortices to formulate his atomic theory: each atom was assumed to be made up of vortices in a sort of ideal fluid. In 1878–79 the American physicist A M Mayer conducted a few experiments with needle magnets placed on floating pieces of cork in an applied magnetic field, as toy models for studying atomic interactions and forms (Mayer 1878, Aref *et al.* 2003). In 1883 inspired by Mayer experiments, J J Thomson combined W Thomson's atomic theory with H von Helmholtz's point-vortex theory (Helmholtz 1858): he thought as the electrons were point vortices inside a positively charged shell (see Figure 1), the vortices being located at the vertices of regular parallelograms and investigated about the stability of such structures (see Thomson (1883, section 2.1)). The vortex-atomic theory survived for quite a few years up to Rutherford's experiments proved that atoms have quite a different structure! Before continuing this historical/modeling overview, let's address the following question:

> *what is a vortex and, more specifically, what is a point-vortex?*

Roughly speaking, following Descartes, a vortex is an entity which makes particles move along circular-like orbits. Examples are the cyclones and anticyclones in the atmosphere (see Figure 3). Mathematically speaking, let $\boldsymbol{u} = (u, v, w) \in \mathbb{R}^3$ be a velocity field, the associated vorticity field $\omega$ is defined to be

$$\omega = \nabla \wedge \boldsymbol{u} \qquad [1]$$

In this article we are considering exclusively inviscid flows which are also incompressible, that is,

$$\nabla \cdot \boldsymbol{u} = 0 \qquad [2]$$

and have constant density $\rho$, which we normalize to be equal to 1 ($\rho = 1$). In two dimensions, a point-vortex field is the simplest of all vorticity fields: it can be thought as an entity where the vorticity field is concentrated into a point. In other words, point vortices are singularities of the vorticity field! Then, in the plane the vorticity field associated to a system of $N$ point vortices is

$$\omega(\boldsymbol{r}) = \sum_{\alpha=1}^{N} \Gamma_\alpha \delta(\boldsymbol{r} - \boldsymbol{r}_\alpha) \qquad [3]$$

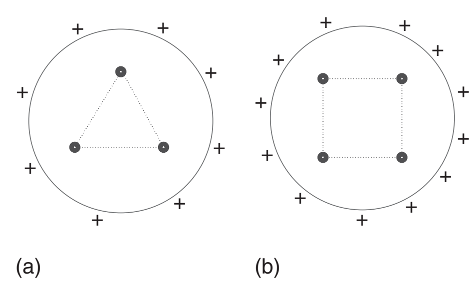

**Figure 1** Thomson atomic model: (a) atom with three electrons and (b) atom with four electrons. From Thomson JJ (1883) *A Treatise on the Motion of Vortex Rings*. New York: Macmillan and Thomson JJ (1904) *Electricity and Matter*. Westmister: Archibald Constable.

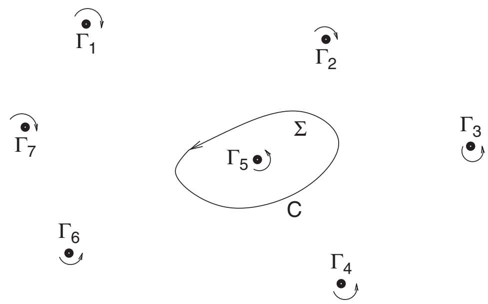

**Figure 3** Cyclones and anticyclones in the atmosphere. Reproduced from Boatto S and Cabrel HE, *SIAM Journal of Applied Mathematics* 64:216–230 (2003). With the permission of SIAM.

where $\Gamma_\alpha$, $\alpha = 1, \ldots, N$, is a constant and corresponds to the vorticity (or circulation) of the $\alpha$-vortex, situated at $\boldsymbol{r}_\alpha$. In fact by definition, the circulation around a curve $C$ delimiting a region $\Sigma$ with boundary $C$,

$$\Gamma_C = \oint_C \boldsymbol{u} \cdot \mathrm{d}\boldsymbol{s} = \iint_\Sigma (\nabla \wedge \boldsymbol{u}) \cdot \boldsymbol{n}\, \mathrm{d}A = \iint_\Sigma \omega \qquad [4]$$

where we have used Stokes' theorem to bring in the vorticity. Then if the region contains only the $\alpha$th point vortex, we obtain

$$\Gamma_C = \iint_\Sigma \omega \cdot \mathrm{d}\boldsymbol{A} = \Gamma_\alpha \qquad [5]$$

by eqn [3]. A positive (resp. negative) sign of $\Gamma_\alpha$ indicates that the corresponding point vortex induces an anticlockwise (resp. clockwise) particle motion, see **Figure 4a**)). Is there an analog of a point-vortex system for a three-dimensional flow?

Yes, and this brings in the analogy between vortex lines and magnetic field lines that Mayer used in his experiments with floating magnets. In fact, in three dimensions, the notion of a point vortex can be extended to that one of a straight vortex line (see **Figure 4b**), where, by definition, a vortex line is a curve that is tangent to the vorticity vector $\omega$ at each of its point. In this context we would like to mention the beautiful experiments of Yarmchuck–Gordon–Packard on vortices in superfluid helium. They observed the formation of stable polygonal configurations of identical vortices, quite similar to the ones observed by Mayer with his magnets (see **Figures 5 and 1**).

One would like to understand how such configurations form and to give a theoretical account about their stability. In order to answer these questions we have to first be able to describe the dynamics of a system of point vortices from a mathematical point of view.

## Evolution Equations

Can point vortices be viewed as "discrete" (or localized) solutions of Euler equation in two dimensions? Let us consider the Euler equation

$$\frac{\partial \boldsymbol{u}}{\partial t} + \boldsymbol{u} \cdot \nabla \boldsymbol{u} = -\nabla p + \boldsymbol{f} \qquad [6]$$

where $p$ is the pressure, $\boldsymbol{f} = -\nabla U$ is a conservative force, and restrict our attention to the two-dimensional setting, for example, vortex dynamics on the plane (or a sphere). Then it is immediate that by taking the curl of eqn [6] we obtain the evolution equation of the vorticity, that is,

$$\frac{\partial \omega}{\partial t} + \boldsymbol{u} \cdot \nabla \omega = 0, \quad \text{or} \quad \frac{D\omega}{Dt} = 0 \qquad [7]$$

where the operator $D/Dt = \partial/\partial t + \boldsymbol{u} \cdot \nabla$ is called the material derivative and describes the evolution along the flow lines. It follows from eqn [7] that in two dimensions the vorticity is conserved as it is transported along the flow lines. Then a natural question arises: supposing the vorticity field $\omega$ is known, is it possible to deduce the velocity field $\boldsymbol{u}$ generating $\omega$? Or in other words, is it possible to solve the system of eqns [1]–[2]? It is immediate to see that in general the solution is not unique, if some boundary conditions are not specified (see Marchioro and Pulvirenti (1993)). Furthermore, as already observed by Kirchhoff in 1876 (Boatto and Cabral 2003), in two dimensions we can recast the fluid equations [1]–[2] into a Hamiltonian formalism. In fact, notice that on the plane $\boldsymbol{u} = (\dot{x}, \dot{y})$ and eqn [2] is still satisfied if we represent the velocity components as

**Figure 4** (a) Advected by the velocity field of one point vortex, a test particle follows a circular orbit, with a speed proportional to the absolute value of the vortex circulation and inversely proportional to the square of its distance from the vortex. (b) Straight vortex lines.

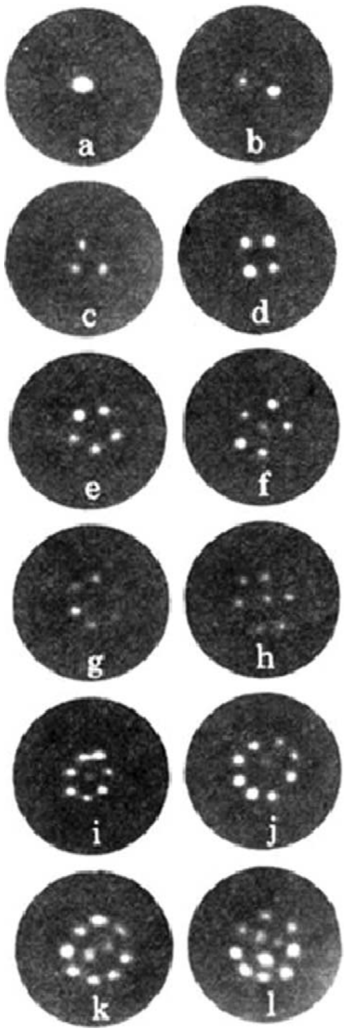

**Figure 5** Photographs of vortex configurations in a rotated sample of superfluid helium with 1,...,11 vortices. Reprinted figure with permission from Yarmchuk EJ, Gordon MJV, and Packard RE (1979) Observation of stationary vortices arrays in rotating superfluid Helium. *Physical Review Letters* 43(3): 214–217. Copyright (1979) by the American Physical Society.

$$\dot{x} = \frac{\partial \Psi}{\partial y}, \qquad \dot{y} = -\frac{\partial \Psi}{\partial x} \qquad [8]$$

that is, by means of $\Psi$, called the stream function. Formally, $\Psi$ plays the rôle of a Hamiltonian for the pair of conjugate variables $(x, y)$ and it is used to describe the dynamics of a test particle, located at $(x, y)$ and advected by the flow. By substituting [8] into [1], we obtain

$$\Delta\Psi(\boldsymbol{r}) = \omega(\boldsymbol{r}) \qquad [9]$$

that is, a Poisson equation with $\omega$ as a source term. Then, once we specify the vorticity field, by inverting [9] we obtain the stream function $\Psi$ to be

$$\Psi(\boldsymbol{r}) = \int G(\boldsymbol{r}, \boldsymbol{r}')\omega(\boldsymbol{r}')\,\mathrm{d}\boldsymbol{r}' \qquad [10]$$

where $G(\boldsymbol{r}, \boldsymbol{r}')$ is the Green's function, solution of the equation $\Delta G(x, y) = -\delta(x, y)$. The Green's function both for the plane and the sphere is (Marchioro and Pulvirenti 1993)

$$G(\boldsymbol{r}, \boldsymbol{r}') = -\frac{1}{4\pi}\log\|\boldsymbol{r} - \boldsymbol{r}'\|^2 \qquad [11]$$

where $\|\boldsymbol{r} - \boldsymbol{r}'\|^2 = (x - x')^2 + (y - y')^2$. By [10], once we specify the vorticity field $\omega(\boldsymbol{r})$ we can compute $\Psi$, and by replacing it into [8] the velocity field becomes

$$\boldsymbol{u}(\boldsymbol{r}) = \int K(\boldsymbol{r}, \boldsymbol{r}')\omega(\boldsymbol{r}')\,\mathrm{d}\boldsymbol{r}' \qquad [12]$$

where $K(\boldsymbol{r}, \boldsymbol{r}') = -(\boldsymbol{r} - \boldsymbol{r}')^{\perp}/[2\pi\|\boldsymbol{r} - \boldsymbol{r}'\|^2]$ and it represents the velocity field generated by a point vortex of intensity one, located at $\boldsymbol{r}'$. Then by considering the vorticity field generated by point vortices, eqn [3], together with eqn [11], eqn [10] becomes

$$\Psi(\boldsymbol{r}) = -\frac{1}{4\pi}\int \log\|\boldsymbol{r} - \boldsymbol{r}'\|^2 \left(\sum_{\alpha=1}^{N}\Gamma_\alpha \delta(\boldsymbol{r}' - \boldsymbol{r}_\alpha)\right)\mathrm{d}\boldsymbol{r}'$$
$$= -\frac{1}{4\pi}\sum_{\alpha=1}^{N}\Gamma_\alpha \log\|\boldsymbol{r} - \boldsymbol{r}_\alpha\|^2 \qquad [13]$$

Equation [13] describes together with [8], the dynamics of a test particle at a point $\boldsymbol{r} = (x, y)$ in the plane. Analogously, it can be shown that the dynamics of a systems of point vortices in the plane is given by the equations

$$\Gamma_\alpha \frac{\mathrm{d}x_\alpha}{\mathrm{d}t} = \frac{\partial H_v}{\partial y_\alpha}, \qquad \Gamma_\alpha \frac{\mathrm{d}y_\alpha}{\mathrm{d}t} = -\frac{\partial H_v}{\partial x_\alpha} \qquad [14]$$

where $(q_\alpha, p_\alpha) = (x_\alpha, \Gamma_\alpha y_\alpha)$, $\alpha = 1, \ldots, N$, is a pair of conjugate variables and $H_v$ is the generalization of the stream function $\Psi$ (eqn [13]):

$$H_v = -\frac{1}{4\pi}\sum_{\substack{\alpha,\beta=1\\ \alpha\neq\beta}}^{N}\Gamma_\alpha\Gamma_\beta \log\|\boldsymbol{r}_\alpha - \boldsymbol{r}_\beta\|^2 \qquad [15]$$

Notice that the vortex Hamiltonian $H_v$ (eqn [15]) is an autonomous Hamiltonian and, as we will discuss in the first subsection, it provides a good Lyapunov-like function to study stability properties of some vortex configurations. Moreover, $H_v$ is invariant with respect to rotations and translations, then by the Noether theorem there are other first integrals of motion, that is,

$$L = \sum_{k=1}^{N}\Gamma_k \parallel \boldsymbol{x}_k \parallel^2, \qquad M_x = \sum_{k=1}^{N}\Gamma_k x_k,$$
$$M_y = \sum_{k=1}^{N}\Gamma_k y_k$$

expressing, respectively, the conservation of angular momentum, $L$, and linear momentum, $\boldsymbol{M} = (M_x, M_y)$, on the plane. We shall denote with $M$ the magnitude of $\boldsymbol{M}$ (i.e., $M = \|\boldsymbol{M}\|$). Furthermore, by introducing the Poisson bracket

$$[f, g] = \sum_{\alpha=1}^{N} \left( \frac{\partial f}{\partial q_\alpha} \frac{\partial g}{\partial p_\alpha} - \frac{\partial f}{\partial p_\alpha} \frac{\partial g}{\partial q_\alpha} \right) = \sum_{\alpha=1}^{N} \frac{1}{\Gamma_\alpha} \left( \frac{\partial f}{\partial x_\alpha} \frac{\partial g}{\partial y_\alpha} - \frac{\partial f}{\partial y_\alpha} \frac{\partial g}{\partial x_\alpha} \right)$$

we can construct three integrals in involution out of the four conserved quantities $L$, $M_x, M_y$, and $H_v$. These are $L, M_x^2 + M_y^2$ and $H_v$: in fact,

$$[H_v, L] = 0, \qquad \left[H_v, M_x^2 + M_y^2\right] = 0, \qquad \left[L, M_x^2 + M_y^2\right] = 0$$

It is then possible to reduce the system of equations from $N$ to $N - 2$ degrees of freedom. A Hamiltonian system with $N$ degrees of freedom is integrable whenever there are $N$ independent integrals of motion in involution. It follows that a vortex system with $N \leq 3$ is integrable, whereas the system of equations of four identical vortices has been shown by Ziglin to be nonintegrable in the sense that there are no other first integrals analytically depending on the coordinates and circulations, and functionally independent of $L, H_v, M_x, M_y$ (see Ziglin (1982)). The following, however, has been shown:

1. Let $K = \sum_{\alpha=1}^{N} k_\alpha$ be the total vorticity, $\boldsymbol{M} = (M_x, M_y)$ the total momentum and $M = \|\boldsymbol{M}\|$. Then, as shown by Aref and Stremler (1999), if $K = 0$ and $M = 0$, $N$-vortex problem [16] is integrable.
2. A system of four identical vortices (i.e., $k_\alpha = k$ for $\alpha = 1, \ldots, 4$) can undergo periodic or quasiperiodic motion for special initial conditions (see Khanin (1981) *Russian Math. Surveys* 36: 231; Aref and Pomphrey (1982) *Proc. R. Soc. Lond. A* 380: 359–387). More specifically, the motion of a system of four identical vortices can be periodic, quasiperiodic, or chaotic depending on the symmetry of the initial configuration. In fact, every vortex configuration that belongs to the subspace of symmetric configurations – $x_\alpha = -x_{\alpha+2}$ and $y_\alpha = y_{\alpha+2}, \alpha = 1, 2$ – gives rise to an integrable vortex motion.

We have that up to two vortices, the motion is almost always periodic and the orbits are circles; the only exception being the case for which $k_2 = -k_1$, when the circles degenerate into straight lines. Thus, a configuration of two point vortices is always a relative equilibrium configuration, that is, there exists a specific reference frame in which the two vortices are at rest. If the vortices are identical ($\Gamma_1 = \Gamma_2 = \Gamma$), the motion is synchronous with frequency $\Omega = \Gamma/\pi$ and the vortices share the same circular orbit (see Figure 6a). If the vortices are not identical and have vorticities of different magnitudes (say $|\Gamma_1| > |\Gamma_2|$), their motion is still synchronous and periodic, with frequency $\Omega = (\Gamma_1 + \Gamma_2)/(2\pi)$, and the vortices move on different circular orbits (with $r_2 < r_1$) both centered at the center of vorticity. Note that for both cases, identical and nonidentical vortices, we can view the vortex dynamics in a co-rotating frame where the vortices are simply at rest.

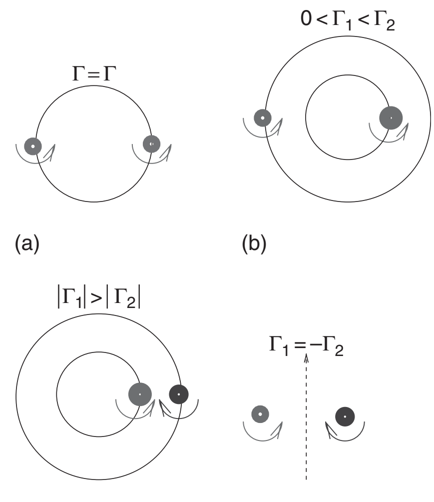

**Figure 6(a–d)** For $N = 2$ the vortex dipole exhibits a synchronous and the orbits are in general circular orbits, with the exception of the case (d) for which $\Gamma_1 = -\Gamma_2$ and the circular orbit degenerates into a line (or a circle of infinite radius).

For three vortices we can have periodic and quasiperiodic motion, depending on the initial conditions, and for four vortices we can have periodic, quasiperiodic, or weakly chaotic motion.

### Remarks

(i) The nonintegrability of the 4-vortex system was also proved for configurations of nonidentical vortices. Koiller and Carvalho (1989) gave an analytical proof for $\Gamma_1 = -\Gamma_2$ and $\Gamma_3 = \Gamma_4 = \epsilon, 0 \ll \epsilon \ll 1$. Moreover, Castilla *et al.* (1993) considered the case: $\Gamma_1 = \Gamma_2 = \Gamma_3 = 1$ and $\Gamma_4 = \epsilon$.

(ii) Due to the translational and rotational symmetries of $H_v$, there are some analogies between the $N$-vortex problem and the $N$-body problem, especially for what concerns configurations of relative equilibria (see Albouy (1996) and Glass (2000)). A relative equilibrium is a vortex (or mass) configuration that moves without change of shape or form, that is, a configuration which is steadily

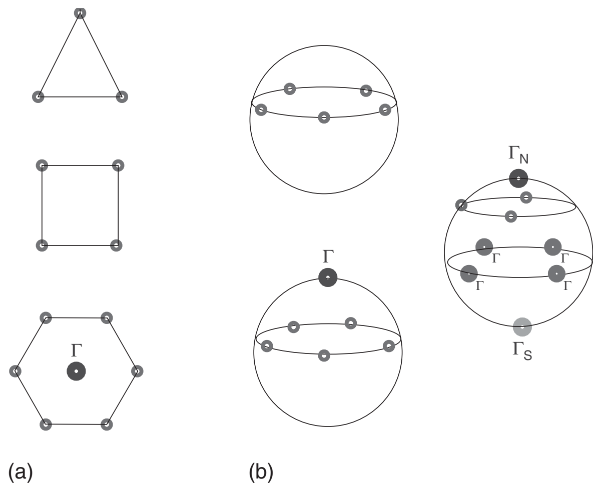

**Figure 7** Polygonal configuration of vortices: (a) planar configurations and (b) configurations of vortex rings on a sphere, with and without polar vortices.

rotating or translating. A few examples are vortex polygons (see **Figure 7**) like the ones studied by Thomson, Mayer, Yarmchuk–Gordon–Packard, Boatto–Cabral (2003), Cabral–Schmidt (1999/2000), Dritschel–Polvani (1993), Lim–Montaldi–Roberts (2001), Sakajo (2004). For an exhaustive review on relative equilibria of vortices, see the article by Aref *et al.* (2003). We shall discuss stability of polygonal vortex configuration in the following subsection.

(iii) As shown by Kimura (1999) in a beautiful geometrical formalism, on the unit sphere ($S^2$) and on the Hyperbolic plane ($H^2$), the vortex Hamiltonians [15] are

$$H_v = -\frac{1}{4\pi}\sum_{\alpha\neq\beta}^{N}\Gamma_\alpha\Gamma_\beta\log(1-\cos\rho_{\alpha\beta}) \quad \text{on } S^2$$

$$H_v = -\frac{1}{4\pi}\sum_{\alpha\neq\beta}^{N}\Gamma_\alpha\Gamma_\beta\log\frac{\cosh\rho_{\alpha\beta}-1}{\cosh\rho_{\alpha\beta}+1} \quad \text{on } H^2$$

where

$$\cos\rho_{\alpha\beta} = \cos\theta_\alpha\cos\theta_\beta + \sin\theta_\alpha\sin\theta_\beta\cos(\phi_\alpha-\phi_\beta) \quad \text{on } S^2$$

$$\cosh\rho_{\alpha\beta} = \cosh\theta_\alpha\cosh\theta_\beta + \sinh\theta_\alpha\sinh\theta_\beta\cos(\phi_\alpha-\phi_\beta) \quad \text{on } H^2$$

On $S^2, \theta_\alpha$ and $\phi_\alpha$ are, respectively, the co-latitude and the longitude of the $\alpha$-vortex, $\alpha = 1, \ldots, N$. We can define canonical variables $q_\alpha$ and $p_\alpha$ on $S^2$ and $H^2$, respectively, as

$$q_\alpha = \Gamma_\alpha\cos\theta_\alpha, \qquad p_\alpha = \phi_\alpha \quad \text{on } S^2$$
$$q_\alpha = \Gamma_\alpha\cosh\theta_\alpha, \qquad p_\alpha = \phi_\alpha \quad \text{on } H^2$$

Montaldi *et al.* (2002) studied vortex dynamics on a cylindrical surface, and Soulière and Tokieda (2002) considered vortex dynamics on surfaces with symmetries.

(iv) As we shall see in the section on point vortex motion, it is sometimes useful to employ the complex analysis formalism. Then the variables of interest are $z_\alpha = x_\alpha + \mathrm{i}y_\alpha, \alpha = 1, \ldots, N$, and its conjugate $\bar{z}_\alpha$, the Hamiltonian [15] takes the form

$$H_v = -\frac{1}{2\pi}\sum_{\alpha\neq\beta}\Gamma_\alpha\Gamma_\beta\log|z_\alpha - z_\beta|$$

and the equations of motions become

$$\dot{z}_\alpha = \frac{\mathrm{i}}{2\pi}\sum_{\beta\neq\alpha,\beta=1}^{N}\Gamma_\beta\frac{z_\alpha - z_\beta}{|z_\alpha - z_\beta|^2}, \quad \alpha = 1, \ldots, N \quad [16]$$

(v) Equation [14] can we rewritten in a more compact form as

$$\frac{\mathrm{d}X}{\mathrm{d}t} = J\nabla_X H_v \quad [17]$$

where

$$X = (q_1, \ldots, q_N, p_1, \ldots, p_N)$$
$$\nabla_X = \left(\frac{\partial}{\partial q_1}, \ldots, \frac{\partial}{\partial q_N}, \frac{\partial}{\partial p_1}, \ldots, \frac{\partial}{\partial p_N}\right)$$
$$J = \begin{pmatrix} O & \mathbb{I} \\ -\mathbb{I} & O \end{pmatrix}$$

$\mathbb{I}$ being the $N \times N$ identity matrix.

(vi) How close is the point-vortex model to the original Euler equation? Point-vortex systems represent discrete solutions of the Euler equation in a "weak" sense – see both the book and the article by Marchioro and Pulvirenti (1993, 1994). These authors proved that the Euler dynamics is "similar" to the vortex dynamics in which the vortices are localized in very small regions, and the vortex intensities are the total vorticities associated to such small regions. In particular, let us consider a vorticity field with compact support on a family of $\epsilon$-balls, that is,

$$\omega^\epsilon = \sum_{i=1}^{N}\omega_i^\epsilon$$

with support of $\omega_i^\epsilon$ contained in the ball of center $x_i$ (independent of $\epsilon$) and radius $\epsilon$. Furthermore let us assume that

$$\int_{|\boldsymbol{r}-\boldsymbol{r}_i|\leq\epsilon}\omega_i^\epsilon\,\mathrm{d}\boldsymbol{r} = \Gamma_i$$

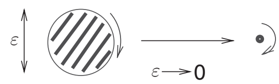

**Figure 8** In the limit $\epsilon \to 0$, the dynamics of the center of vorticity of a vortex $\epsilon$-ball is approximated by the dynamics of a point vortex.

with the $\gamma_i$ independent of $\epsilon$. Then in the limit $\epsilon \to 0$ the dynamics of the center of vorticity $B_\epsilon(t) = \int r\omega_\epsilon(r, t)\,\mathrm{d}r$, of a given $\epsilon$-ball, "converges" to the motion of a single point vortex (see Figure 8). This result is important to illustrate as vortex systems provide both a useful heuristic tool in the analysis of the general properties of the solutions of Euler's equations (Poupaud 2002, Schochet 1995), and a useful starting point for the construction of practical algorithms for solving equations in specific situations. In particular, it provides a theoretical justification to the vortex method previously introduced by Carnevale *et al.* (1992). These authors constructed a numerical algorithm to study turbulence decaying in two dimensions. Their vortex method greatly simplifies fluid simulations as basically it relies on a discretization of the fluid into circular patches. The dynamics of patches is given by the centers of vorticity, which interact as a point-vortex system, endowed with a rule dictating how patches merge (see Figure 9).

### Stability of a Vortex Ring

As mentioned in the Introduction section, the study of vortex relative equilibria has a long history. Kelvin showed that steadily rotating patterns of identical vortices arise as solutions of a variational problem in which the interaction energy (vortex Hamiltonian) is minimized subject to the constraint that the angular impulse be maintained (see Aref (2003). In 1883, while studying and modeling the atomic structure, J J Thomson investigated the linear stability of co-rotating point vortices in the plane. In particular, his interest was in configurations of identical vortices equally spaced along the circumference of a circle, that is, located at the vertices of a regular polygon (see Figure 7). He proved that for six or fewer vortices the polygonal configurations are stable, while for seven vortices – the Thomson heptagon – he erroneously concluded that the configuration is slightly unstable. It took more than a century to make some progresses on this problem. D G Dritschel (1985) succeeded in solving the heptagon mystery for what concerns its linear stability analysis, leaving open the nonlinear stability question: he proved that the Thomson heptagon is neutrally stable and that for eight or more vortices the corresponding polygonal configurations are linearly unstable. Later on in 1993, Polvani and Dritschel (1993) generalized the techniques used in Dritschel (1985) to study the linear stability of a "latitudinal" ring of point vortices on the sphere, as a function of the number $N$ of vortices in the ring, and of the ring's co-latitude $\theta$ (see Figure 10). They proved that polygonal configurations are more unstable on the sphere than in the plane. In particular, they showed that at the pole, for $N < 7$ the configuration is stable, for $N = 7$ it is neutrally stable and for $N > 7$ it is unstable. By means of the energy momentum method (Marsden–Meyer–Weistein reduction), J E Marsden and S Pekarsky (1998) studied the nonlinear stability analysis for the integrable case of polygonal configurations of three vortices of arbitrary vorticities ($\Gamma_1, \Gamma_2$ and $\Gamma_3$) on the sphere, leaving open the stability analysis for nonintegrable vortex systems ($N > 3$). In 1999 H E Cabral and D S Schmidt completed the linear and nonlinear stability analysis at once for polygonal configurations in the plane. In 2003 Boatto and Cabral studied the nonlinear stability of a ring of vortices on the sphere, as a function of the number of vortices $N$ and the ring colatitude $\theta$.

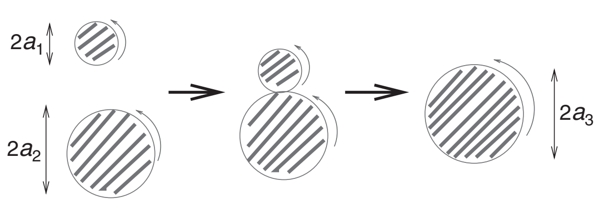

**Figure 9** In Carnevale *et al.* (1992) the fluid is modeled by a dilute vortex gas with density $\rho$ and typical radius $a$. The dynamics is governed by the point-vortex dynamics of the disk centers, each disk corresponding to a point vortex of intensity $\Gamma = \pi\xi_{ext}a^2$, where $\xi_{ext}$ plays the role of a vorticity density. Two vortices or radius $a_1$ and $a_2$ merge when their center-to-center distance is less or equal to the sum of their radii, $a_1 + a_1$. Then a new vortex is created and its radius $a_3$ is given by $a_3 = (a_1^4 + a_2^4)^{1/4}$.

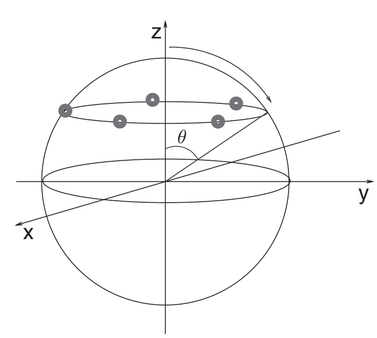

**Figure 10** Latitudinal ring of vortices. Reproduced with permission from Boatto S and Cabral HE *SIAM Journal of Applied Mathematics* 64: 216–230 (2003).

Boatto and Simó (2004) generalized the stability analysis to the case of a ring with polar vortices and of multiple rings, the key idea being, as we shall discuss in this section, the structure of the Hessian of the Hamiltonian.

*How to infer about linear and nonlinear stability of steadily rotating configurations?*

Let us restrict the discussion to a polygonal ring of identical vortices on a sphere as illustrated in **Figure 7** (Boatto and Cabral 2003, Boatto and Simó 2004). The reasoning is easily generalized for the planar case. The case of multiple rings is discussed in great detail in Boatto and Simó (2004). A polygonal ring is a relative equilibrium of coordinates $X(t) = (q_1(t), \ldots, q_N(t), p_1(t), \ldots, p_N(t))$, where

$$\begin{aligned} q_\alpha(t) &= \phi_\alpha(t) = \omega t + \phi_{o\alpha} \\ p_\alpha(t) &= p_o = \Gamma \cos\theta_o \quad \alpha = 1, \ldots, N \end{aligned} \qquad [18]$$

$\omega = (N-1)p_o/r_o^2$, $r_o = \sqrt{1 - p_o^2/\Gamma^2}$, $\phi_{o\alpha}$ and $\theta_{o\alpha} = \theta_o$ being the initial longitude and co-latitude of the $\alpha$th vortex.

**Theorem 1** (Spherical case) (Boatto and Simó 2004). *The relative equilibrium* [18] *is* (*linearly and nonlinearly*) *stable if*

$$\begin{aligned} &-4(N-1)(11-N) + 24(N-1)r_o^2 \\ &\quad + 2N^2 + 1 + 3(-1)^N < 0 \end{aligned} \qquad [19]$$

*and it is unstable if the inequality is reversed.*

**Remarks**

(i) By Theorem 1 a vortex polygon, of $N$ point vortices, is stable for $0° \le \theta_o \le \theta_o^*$ and $(180° - \theta_o^*) \le \theta_o \le 180°$, where $\theta_o^* = \arcsin(r_o^*)$ and

$$r_o^{*2} < \frac{7-N}{4} \qquad \text{for } N \text{ odd}$$

$$r_o^{*2} < -\frac{N^2 - 8N + 8}{4(N-1)} \qquad \text{for } N \text{ even}$$

where $r_o^* = \sin\theta_o^*$.

(ii) Theorem 1 includes at once the results of Thomson (1883), Dritschel (1985), and Polvani and Dritschel (1993) (and other authors who have been working in the area (Aref *et al.* 2003)). We recover the planar case by setting $r_o = 0$ in eqn [19], deducing that stability is guaranteed for $N < 7$.

To prove Theorem 1 it is useful to consider the Hamiltonian equations as in eqn [17]. The first step is to make a change of reference frame: view the dynamics in a frame co-rotating with the relative equilibrium configuration. In the co-rotating reference system, the Hamiltonian takes the form

$$\tilde{H} = H + \omega M$$

where $M$ is the momentum of the system, and $H$ and $\omega$ are, respectively, the Hamiltonian and the rotational frequency of the relative equilibrium in the original frame of reference. In the new reference frame, the relative equilibrium becomes an equilibrium, $X^*$, and the standard techniques can be used to study its stability.

To study linear stability, the relevant equation is

$$\frac{d\Delta X}{dt} = JS\Delta X \qquad [20]$$

where $X = X^* + \Delta X$, and $S$ is the Hessian of $\tilde{H}$ evaluated at the equilibrium $X^*$. Then linear (or spectral) stability is deduced by studying the eigenvalues of the matrix $JS$ (spectral stability). For nonlinear stability we make use of a sufficient stability criterion due to Dirichlet (1897) (see G Lejeune Dirichlet (1897). *Werke*, vol. 2, Berlin, pp. 5–8; Boatto and Cabral (2003) and references therein).

**Theorem 2** *Let $X^*$ be an equilibrium of an autonomous system of ordinary differential equations*

$$\frac{dX}{dt} = f(X), \qquad \Omega \subset \mathbb{R}^{2N} \qquad [21]$$

*that is, $f(X^*) = 0$. If there exists a positive* (*or negative*) *definite integral* **F** *of the system* [21] *in a neighborhood of the equilibrium $X^*$, then $X^*$ is stable.*

In our case the Hamiltonian itself is an integral of motion. Then by studying definiteness of its Hessian, $S$, evaluated at $X^*$, we infer minimal stability intervals in $\theta$ and $N$. Details are given in Boatto and Cabral (2003) and Boatto and Simó (2004). The proof is mainly based on the following considerations:

1. Since $S$ is a symmetric matrix it is diagonalizable, that is, there exists an orthogonal matrix $C$ such that $C^T S C = D$, where $D$ is a diagonal matrix, $D = \mathrm{diag}(\lambda_1, \ldots, \lambda_N)$. Furthermore, the matrix $C$ can be chosen to leave invariant the symplectic form (equivalently $J = C^T J C$). Then by the canonical change of variables $Y = C^T X$ eqn [20] becomes

$$\frac{d\Delta Y}{dt} = JD\Delta Y \qquad [22]$$

where $Y = (\tilde{q}_1, \ldots, \tilde{q}_N, \tilde{p}_1, \ldots, \tilde{p}_N)$ and $(\tilde{q}_j, \tilde{p}_j)$, $j = 1, \ldots, N$, are pairs of conjugate variables. Equation [22] can be rewritten as

$$\frac{d^2 \Delta\tilde{q}_j}{dt^2} = -\lambda_j \lambda_{j+N} \Delta\tilde{q}_j, \quad j = 1, \ldots, N$$

2. When evaluated at the equilibrium $X^*$, the Hessian $S$ takes the block structure

$$\tilde{S} = \left( \begin{array}{c|c} Q & \mathbf{O} \\ \hline \mathbf{O} & P \end{array} \right)$$

where the matrices $Q$ and $P$ are symmetric circulant matrices, that is, $(N \times N)$ matrices of the form

$$A = \begin{pmatrix} a_1 & a_2 & \ldots & a_N \\ a_N & a_1 & \ldots & a_{N-1} \\ \vdots & \vdots & \ddots & \vdots \\ a_2 & a_3 & \ldots & a_1 \end{pmatrix} \qquad [23]$$

Circulant matrices are of special interest to us because we can easily compute their eigenvalues and eigenvectors for all $N$. In fact, it is immediate to show that:

**Lemma 3** *All circulant matrices [23] have eigenvalues*

$$\lambda_j = \sum_{k=1}^{N} a_k r_j^{k-1}, \quad j = 1, \ldots, N$$

*and corresponding eigenvectors* $v_j = (1, r_j, \ldots, r_j^{N-1})^{\mathrm{T}}, j = 1, \ldots, N,$ *where* $r_j = \exp(2\pi(j-1)/N)$ *are solutions of* $r^N = 1$.

### Passive Tracers in the Velocity Fields of $N$ Point Vortices: The Restricted $(N+1)$-Vortex Problem

The terminology "restricted $(N+1)$-vortex problem" is used in analogy with celestial mechanics literature, when one of the vorticities is taken to be zero. The zero-vorticity vortex does not affect the dynamics of the remaining $N$-vortices. For this reason, it is said to be passively advected by the flow of the remaining $N$-vortices and in the fluid mechanics literature the terminology "passive tracer" is also employed. The tracer dynamics is given by the Hamiltonian equations [8]. Notice that in general the Hamiltonian $\Psi$ is time dependent, through the vortex variables $\boldsymbol{r}_j, j = 1, \ldots, N$, that is,

$$\Psi(\boldsymbol{r}, t) = \Psi(\boldsymbol{r}, \boldsymbol{r}_1(t), \ldots, \boldsymbol{r}_N(t))$$

and $(q, p) = (x, y)$ play the role of conjugate canonical variables. There is an extensive literature on the subject both from theoretical (see, e.g., Boatto and Simó (2004) and Newton (2001)) and an experimental (van Heijst 1993, Ottino 1990) point of view. As discussed in the previous section, there are some vortex configurations, such as the polygonal ones, for which vortices undergo a periodic circular motion. Then by viewing the dynamics in a reference frame co-rotating with the vortices the tracer Hamiltonian is manifestly time independent and, therefore, integrable – since it reduces to a Hamiltonian of one degree of freedom. In such an occurrence, tracer trajectories form a web of homoclinic and heteroclinic orbits. An interesting theoretical problem is to study how the tracer transport properties (i.e., existence of barriers to transport, diffusion etc.) are affected by perturbing the polygonal vortex configuration, that is, by introducing in $\Psi$ a "genuine" time dependence (periodic, quasi-periodic, or chaotic) (see, e.g., Boatto and Pierrehumbert (1999), Rom-Kedar, Leonard and Wiggins (1990), Kuznetsov and Zaslavsky (2000), and Newton (2001)). Furthermore, in the lab experiments, color dyes, which monitor the flow velocity field, are often used as the experimental equivalent of tracer particles. In this context we would like to stress the striking resemblance between theoretical particle trajectories, deduced from point vortex dynamics, and the actual dye visualizations observed by van Heijst and Flor for vortex dipoles in a stratified fluid (see **Figures 11 and 12**) (van Heijst 1993). Similarly, tripolar structures have been observed both in lab experiments (see **Figure 13**) and in nature (see **Figure 14**). Recently, the Danish group of Jansson–Haspang–Jensen–Hersen–Bohr has observed beautiful rotating polygons, such as squares and pentagons, on a fluid surface in the presence of a rotating cylinder (see **Figure 15**).

## Point Vortex Motion with Boundaries

In comparison with the extensive literature on point vortex motion in unbounded domains, the study of point vortex motion in the presence of walls is modest. There is, however, a general theory for such problems, and some recent new developments in this area have resulted in a versatile tool for analyzing point vortex motion with boundaries. Newton (Newton 2001) contains a chapter on point vortex motion with boundaries and also features a detailed bibliography. The reader is referred there for standard treatments; here, we focus on more recent developments of the mathematical theory.

### The Method of Images

When point vortices move around in bounded domains, it is clear that the motion is subject to the constraint that no fluid should penetrate any of

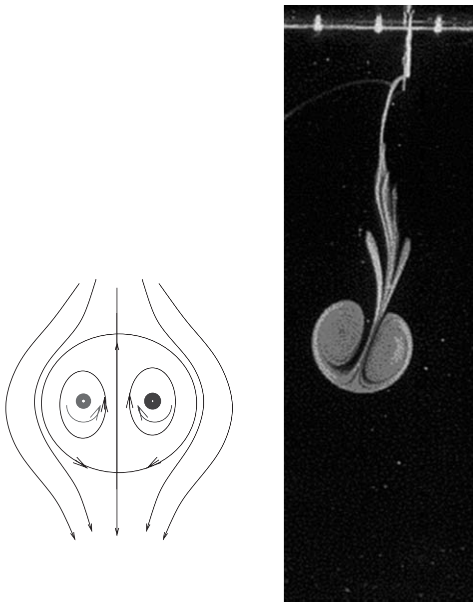

**Figure 11** Test-particle trajectories: on the left, theoretical trajectories, from the point-vortex model; on the right, a top view of a laboratory experiment in stratified flows. Reproduced from van Heijst GJF and Flor JB (1989) Dipole formation and collisions in a stratified fluid. *Nature* 340: 212–215, with permission from Nature Publishing Group.

the boundary walls of the domain. If $\boldsymbol{n}$ denotes the local normal to the boundary walls, the boundary condition on the velocity field $\boldsymbol{u}$ is therefore $\boldsymbol{u} \cdot \boldsymbol{n} = 0$ everywhere on the walls. Another way to say the same thing is that all the walls must be streamlines so that the streamfunction, $\psi$ say, must be constant on any boundary wall.

A classical approach to bounded vortex motion is the celebrated method of images – a rather special technique limited to cases where the domain of interest has certain geometrical symmetries so that an appropriate distribution of image vorticity can be ascertained, essentially by inspection. This image vorticity is placed in nonphysical regions of the plane in order to satisfy the boundary conditions that the walls act as impenetrable barriers for the flow.

The simplest example is the motion of a single vortex next to a straight plane wall of infinite extent. Suppose the wall is along $y = 0$ in an $(x, y)$-plane and that the fluid occupies the upper-half plane. If a circulation-$\Gamma$ vortex is at the complex position $z_0 = x_0 + \mathrm{i}y_0$, the solution for the streamfunction is

$$\psi(z, \bar{z}) = -\frac{\Gamma}{2\pi}\log\left|\frac{z - z_0}{z - \overline{z_0}}\right| \qquad [24]$$

where $z = x + \mathrm{i}y$. This has a single logarithmic singularity in the upper-half plane at $z = z_0$

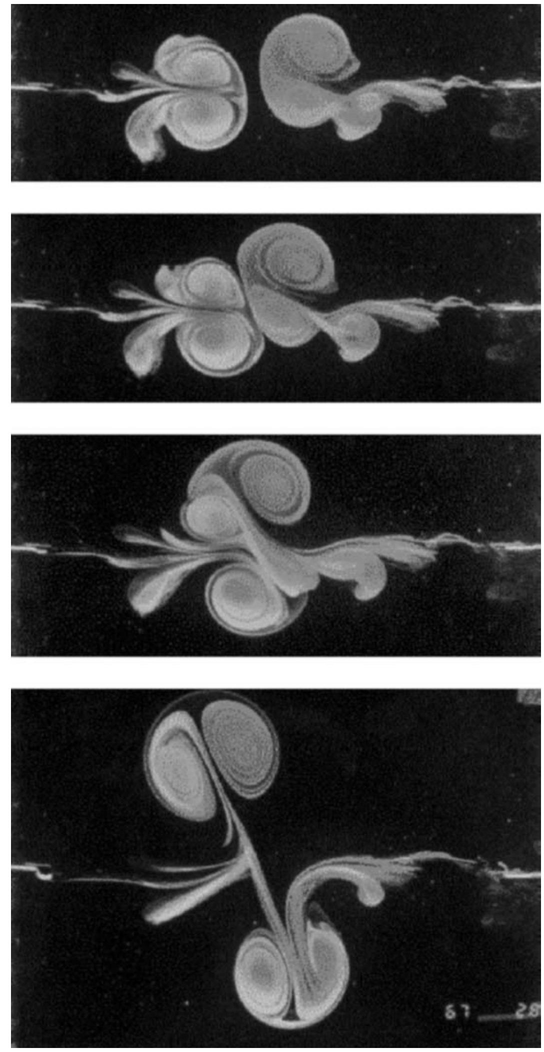

**Figure 12** A frontal collision of two dipoles as observed in a stratified fluid: after a so called “partner-exchange” two new dipoles are formed. Reproduced from van Heijst GJF and Flor JB (1989) Dipole formation and collisions in a stratified fluid. *Nature* 340: 212–215, with permission from Nature Publishing Group.

Reproduced from van Heijst GJF, Kloosterziel RC, and Williams CWM (1991) Laboratory experiments on the tripolar vortex in a rotating fluid. *Journal of Fluid Mechanics* 225: 301–331, with permission from Cambridge University Press.

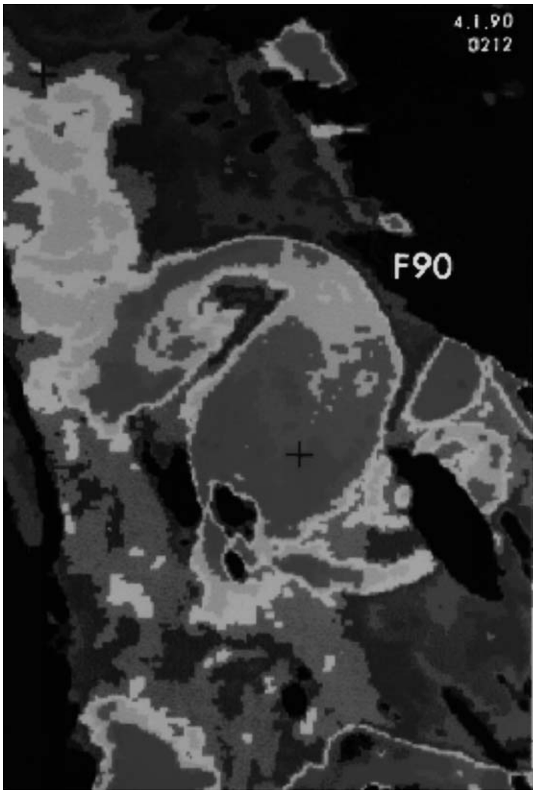

**Figure 14** Infrared image taken by NOAA11 satellite on January 4 1990 (0212 UT) shows a tripolar structure in the Bay of Biscay. The central part of the tripole measures about 50–70 km and rotates clockwise, whereas the two satellite vortices rotate anticlockwise. The dipoles persisted for a few days before it fell apart. Reproduced from Pingree RD and Le Cann B, Anticyclonic Eddy X91 in the Southern Bay of Biscay, *Journal of Geophysical Research*, 97: 14353–14362, May 1991 to February 1992. Copyright (1992) American Geophysical Union. Reproduced/modified by permission of American Geophysical Union.

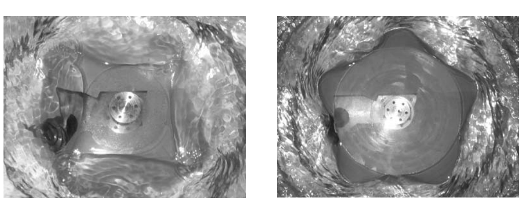

**Figure 15** The free surface of a rotating fluid will, due to the centrifugal force, be pressed radially outward. If the flow is driven by rotating the bottom plate, the axial symmetry can break spontaneously and the surface can take the shape of a rigidly rotating polygon. With water Jansson–Haspang–Jensen–Hersen–Bohr have observed polygons with up to six corners. The rotation speed of the polygons does not coincide with that of the plate, but it is often mode-locked, such that the polygon rotates by one corner for each complete rotation of the plate. Reproduced from Jansson TRN, Haspang M, Jensen KH, Hersen P, and Bohr T (2005) Rotating polygons on a fluid surface. *Preprint*, with permission from T Bohr.

(corresponding to the point vortex) and it is easily checked that $\psi=0$ on $y=0$. Therefore, no fluid penetrates the wall. Equation [24] can be written as

$$\psi(z,\bar{z}) = -\frac{\Gamma}{2\pi}\log|z-z_0| + \frac{\Gamma}{2\pi}\log|z-\overline{z_0}| \qquad [25]$$

which is the sum of the streamfunction due to a point vortex of circulation $\Gamma$ at $z_0=x_0+iy_0$ and another, one imagines, of circulation $-\Gamma$ at $\overline{z_0}=x_0-iy_0$. In this case, the image vortex distribution is simple: it is just the second vortex sitting at the reflected point in the wall. The method of images can be applied to flows in other regions bounded by straight line segments (e.g., wedge regions of various angles (Newton 2001)).

A variant of the method of images is the Milne–Thomson circle theorem relevant to planar flow around a circular cylinder. Given a complex potential $w(z)$ with the required singularities in the fluid region exterior to the cylinder, but failing to satisfy the boundary condition that the surface of the cylinder is a streamline, this theorem says that the correct potential $W(z)$ is

$$W(z) = w(z) + \overline{w}(a^2/z) \qquad [26]$$

where $a$ is the cylinder radius and $\overline{w}(z)$ is the conjugate function to $w(z)$. It is easy to verify that the imaginary part of $W(z)$, that is, the streamfunction, is zero on $|z|=a$. The second term, $\overline{w}(a^2/z)$, produces the required distribution of image vorticity inside the cylinder. A famous example is the Föppl vortex pair which is the simplest model of the trailing vortices shed in the wake of a circular aerofoil traveling at uniform speed.

### Kirchhoff–Routh–Lin Theory

The most important general mathematical tool for point vortex motion in bounded planar regions is the Hamiltonian approach associated with the names of Kirchhoff (1876) and Routh (1881), who developed the early theory. It is now known that the problem of $N$-vortex motion in a simply connected domain is a Hamiltonian dynamical system. Moreover, the Hamiltonian has simple transformation properties when a given flow domain of interest is mapped conformally to another – a result originally due to Routh. A formula for the Hamiltonian can be built from knowledge of the instantaneous Green's function associated with motion of the point vortex in the simply connected domain $D$. In fact, [24] is precisely the relevant Green's function when $D$ is the upper-half plane.

Much later, in 1941, Lin (1941a) extended these general results to the case of multiply connected fluid regions. To visualize such a region, think of a bounded region of the plane containing fluid but also a finite number of impenetrable islands whose boundaries act as barriers for the fluid motion. If the islands are infinitely thin, they can be thought of as straight wall segments immersed in the flow (see later examples). Lin (1941b) showed that both the Hamiltonian structure, and the transformation properties of the Hamiltonian under conformal mapping, are preserved in the multiply connected case.

### Lin's Special Green's Function

Since Lin's result subsumes the earlier simply connected studies, we now outline the key results as presented in Lin (1941a). Consider a fluid region $D$, with outer boundary $C_0$ and $M$ enclosed islands each having boundaries $\{C_j | j = 1, \ldots, M\}$. Lin introduced a special Green's function $G(x, y; x_0, y_0)$ satisfying the following properties:

1. the function

$$g(x, y; x_0, y_0) = -G(x, y; x_0, y_0) - \frac{1}{2\pi}\log r_0 \qquad [27]$$

is harmonic with respect to $(x, y)$ throughout the region $D$ including at the point $(x_0, y_0)$. Here, $r_0 = \sqrt{(x - x_0)^2 + (y - y_0)^2}$;

2. if $\partial G/\partial n$ is the normal derivative of $G$ on a curve then

$$G(x, y; x_0, y_0) = A_k, \quad \text{on } C_k,\ k = 1, \ldots, M$$
$$\oint_{C_k} \frac{\partial G}{\partial n}\, \mathrm{d}s = 0, \quad k = 1, \ldots, M \qquad [28]$$

where $\mathrm{d}s$ denotes an element of arc and $\{A_k\}$ are constants;

3. $G(x, y; x_0, y_0) = 0$ on $C_0$.

Flucher and Gustafsson (1997) refer to this $G$ as the hydrodynamic Green's function. (In fact, it coincides with the modified Green's function arising in abstract potential theory – a function that is dual to the usual first-type Green's function that equals zero on all the domain boundaries.) On the use of $G$, Lin established the following two key results:

**Theorem 4** *If $N$ vortices of strengths $\{\Gamma_k | k = 1, \ldots, N\}$ are present in an incompressible fluid at the points $\{(x_k, y_k) | k = 1, \ldots, N\}$ in a general multiply connected region $D$ bounded by fixed boundaries, the stream function of the fluid motion is given by*

$$\psi(x, y; x_k, y_k) = \psi_0(x, y) + \sum_{k=1}^{N} \Gamma_k G(x, y; x_k, y_k) \qquad [29]$$

*where $\psi_0(x, y)$ is the streamfunction due to outside agencies and is independent of the point vortex positions.*

**Theorem 5** *For the motion of vortices of strengths $\{\Gamma_k | k = 1, \ldots, N\}$ in a general region $D$ bounded by fixed boundaries, there exists a Kirchhoff–Routh function $H(\{x_k, y_k\})$, depending on the point vortex positions, such that*

$$\Gamma_k \frac{\mathrm{d}x_k}{\mathrm{d}t} = \frac{\partial H}{\partial y_k}, \qquad \Gamma_k \frac{\mathrm{d}y_k}{\mathrm{d}t} = -\frac{\partial H}{\partial x_k} \qquad [30]$$

*where $H(\{x_k, y_k\})$ is given by*

$$H(\{x_k, y_k\}) = \sum_{k=1}^{N} \Gamma_k \psi_0(x_k, y_k) + \sum_{\substack{k_1, k_2 = 1 \\ k_1 > k_2}}^{N} \Gamma_{k_1}\Gamma_{k_2} G(x_{k_1}, y_{k_1}; x_{k_2}, y_{k_2}) - \frac{1}{2}\sum_{k=1}^{N} \Gamma_k^2 g(x_k, y_k; x_k, y_k) \qquad [31]$$

*In rescaled coordinates $(x_k, \Gamma_k y_k)$, [30] is a Hamiltonian system in canonical form. For historical reasons, $H$ is often called the Kirchhoff–Routh path function. Analyzing the separate contributions to the path function [31] is instructive: the first term is the contribution from flows imposed from outside (e.g., background flows and round-island circulations), the second term is the "free-space" contribution (it is the relevant Hamiltonian when no boundaries are present) while the third term encodes the effect of the boundary walls (or, the effect of the "image vorticity" distribution discussed earlier).*

Lin (1941a) went on to show that, with the Hamiltonian in some $D$ given by $H$ in [31], the Hamiltonian relevant to vortex motion in another domain obtained from $D$ by a conformal mapping $z(\zeta)$ consists of [31] with some simple extra additive contributions dependent only on the derivative of the map $z(\zeta)$ evaluated at the point vortex positions.

Flucher and Gustafsson (1997) also introduce the Robin function $\mathcal{R}(x_0, y_0)$ defined as the regular part of the above hydrodynamic Green's function evaluated at the point vortex. Indeed, $\mathcal{R}(x_0, y_0) \equiv g(x_0, y_0; x_0, y_0)$, where $g$ is defined in [27]. An interesting fact is that, for single-vortex motion in a simply connected domain, $\mathcal{R}(x_0, y_0)$ satisfies the quasilinear elliptic Liouville equation everywhere in

$D$ with the boundary condition that it becomes infinite everywhere on the boundary of $D$.

By combining the Kirchhoff–Routh theory with conformal mapping theory, many interesting problems can be studied. What happens, for example, if there is a gap in the wall of **Figure 16**? In recent work, Johnson and McDonald (2005) show that if the vortex starts off, far from the gap, at a distance of less than half the gap width from the wall, then it will eventually penetrate the gap. Otherwise, it will dip towards the gap but not go through it. The trajectories are shown in **Figure 17**.

Unfortunately, Lin did not provide any explicit analytical expressions for $G$ in the multiply connected case. This has limited the applicability of his theory beyond fluid regions that are anything other than simply and doubly connected. Recently, however, Lin's theory has recently been brought to implementational fruition by Crowdy and Marshall (2005a), who, up to conformal mapping, have derived explicit formulas for the hydrodynamic Green's function in multiply connected fluid regions of arbitrary finite connectivity. Their approach makes use of elements of classical function theory dating back to the work of Poincaré, Schottky, and Klein (among others). This allows new problems involving bounded vortex motion to be tackled. For example, the motion of a single vortex around multiple circular islands has been studied in Crowdy and Marshall (2005b), thereby extending recent work on the two-island problem (Johnson and McDonald 2005). If the wall in **Figure 17** happens to have two (or more) gaps, then the fluid region is multiply connected. The two-gap (doubly connected) case was recently solved by Johnson and McDonald (2005) using Schwarz–Christoffel maps combined with elements of elliptic function theory (see **Figure 18**). Crowdy and Marshall have solved the problem of an arbitrary number of gaps in a wall by exploiting the new general theory presented in Crowdy and Marshall (2005a,b) (and related works by the authors). The case of a wall with three gaps represents a triply connected fluid region and the critical vortex trajectory is plotted in **Figure 19**.

Point vortex motion in bounded domains on the surface of a sphere has received scant attention in

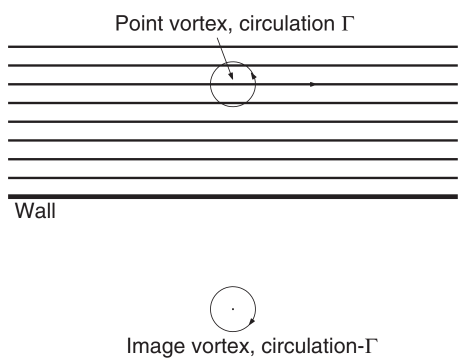

**Figure 16** The motion of a point vortex near an infinite straight wall. The vortex moves, at constant speed, maintaining a constant distance from the wall. Other possible trajectories are shown; they are all straight lines parallel to the wall. The motion can be thought of as being induced by an opposite-circulation "image" vortex at the reflected point in the wall.

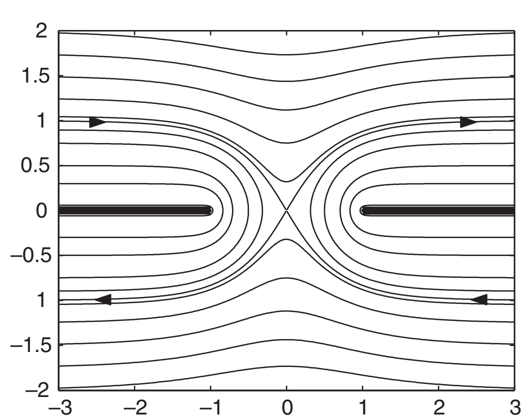

**Figure 17** Distribution of point vortex trajectories near a wall with a single gap of length 2. There is a critical trajectory which, far from the gap, is unit distance from the wall.

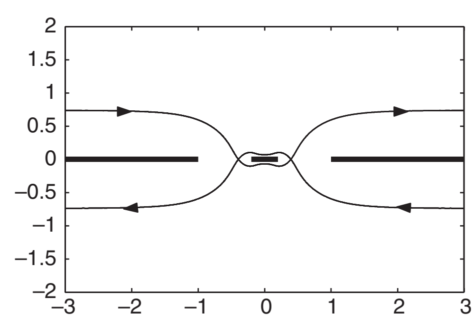

**Figure 18** The critical trajectory when there are two symmetric gaps in a wall. The fluid region is now doubly connected. This problem is solved in Johnson and McDonald (2005) and Crowdy and Marshall (2005).

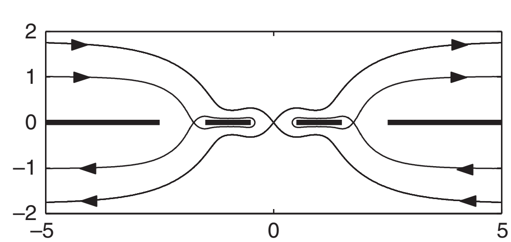

**Figure 19** The critical vortex trajectories when there are three gaps in the wall. This time the fluid region is triply connected. This problem is solved in Crowdy and Marshall (2005) using the general methods in Crowdy and Marshall (2005).

the literature, although Kidambi and Newton (2000) and Newton (2001) have recently made a contribution. Such paradigms are clearly relevant to planetary-scale oceanographic flows in which oceanic eddies interact with topography such as ridges and land masses and deserve further study.

## Introduction

The Poisson reduction techniques allow the construction of new Poisson structures out of a given one by combination of two operations: "restriction" to submanifolds that satisfy certain compatibility assumptions and passage to a "quotient space" where certain degeneracies have been eliminated. For certain kinds of reduction, it is necessary to pass first to a submanifold and then take a quotient. Before making this more explicit, we introduce the notations that will be used in this article. All manifolds in this article are finite dimensional.

### Poisson Manifolds

A "Poisson manifold" is a pair $(M, \{\cdot\,,\cdot\})$, where $M$ is a manifold and $\{\cdot\,,\cdot\}$ is a bilinear operation on $C^\infty(M)$ such that $(C^\infty(M), \{\cdot\,,\cdot\})$ is a Lie algebra and $\{\cdot\,,\cdot\}$ is a derivation (i.e., the Leibniz identity holds) in each argument. The pair $(C^\infty(M), \{\cdot\,,\cdot\})$ is also called a "Poisson algebra." The functions in the center $\mathcal{C}(M)$ of the Lie algebra $(C^\infty(M), \{\cdot\,,\cdot\})$ are called "Casimir functions." From the natural isomorphism between derivations on $C^\infty(M)$ and vector fields on $M$, it follows that each $h \in C^\infty(M)$ induces a vector field on $M$ via the expression $X_h = \{\cdot\,, h\}$, called the "Hamiltonian vector field" associated to the "Hamiltonian function" $h$. The triplet $(M, \{\cdot\,,\cdot\}, h)$ is called a "Poisson dynamical system." Any Hamiltonian system on a symplectic manifold is a Poisson dynamical system relative to the Poisson bracket induced by the symplectic structure. Given a Poisson dynamical system $(M, \{\cdot\,,\cdot\}, h)$, its "integrals of motion" or "conserved quantities" are defined as the centralizer of $h$ in $(C^\infty(M), \{\cdot\,,\cdot\})$ that is, the subalgebra of $(C^\infty(M), \{\cdot\,,\cdot\})$ consisting of the functions $f \in C^\infty(M)$ such that $\{f, h\} = 0$. Note that the terminology is justified since, by Hamilton's equations in Poisson bracket form, we have $\dot{f} = X_h[f] = \{f, h\} = 0$, that is, $f$ is constant on the flow of $X_h$. A smooth mapping $\varphi : M_1 \to M_2$, between the two Poisson manifolds $(M_1, \{\cdot\,,\cdot\}_1)$ and $(M_2, \{\cdot\,,\cdot\}_2)$, is called "canonical" or "Poisson" if for all $g$, $h \in C^\infty(M_2)$ we have $\varphi^*\{g, h\}_2 = \{\varphi^* g, \varphi^* g\}_1$. If $\varphi : M_1 \to M_2$ is a smooth map between two Poisson manifolds $(M_1, \{\cdot\,,\cdot\}_1)$ and $(M_2, \{\cdot\,,\cdot\}_2)$, then $\varphi$ is a Poisson map if and only if $T\varphi \circ X_{h\circ\varphi} = X_h \circ \varphi$ for any $h \in C^\infty(M_2)$, where $T\varphi : TM_1 \to TM_2$ denotes the tangent map (or derivative) of $\varphi$.

Let $(S, \{\cdot\,,\cdot\}^S)$ and $(M, \{\cdot\,,\cdot\}^M)$ be two Poisson manifolds such that $S \subset M$ and the inclusion $i_S : S \hookrightarrow M$ is an immersion. The Poisson manifold $(S, \{\cdot\,,\cdot\}^S)$ is called a "Poisson submanifold" of $(M, \{\cdot\,,\cdot\}^M)$ if $i_S$ is a canonical map. An immersed submanifold $Q$ of $M$ is called a "quasi-Poisson submanifold" of $(M, \{\cdot\,,\cdot\}^M)$ if for any $q \in Q$, any open neighborhood $U$ of $q$ in $M$, and any $f \in C^\infty(U)$ we have $X_f(i_Q(q)) \in T_q i_Q(T_q Q)$, where $i_Q : Q \hookrightarrow M$ is the inclusion and $X_f$ is the Hamiltonian vector field of $f$ on $U$ with respect to the Poisson bracket of $M$ restricted to $U$. If $(S, \{\cdot\,,\cdot\}^S)$ is a Poisson submanifold of $(M, \{\cdot\,,\cdot\}^M)$, then there is no other bracket $\{\cdot\,,\cdot\}'$ on $S$ making the inclusion $i : S \hookrightarrow M$ into a canonical map. If $Q$ is a quasi-Poisson submanifold of $(M, \{\cdot\,,\cdot\})$, then there exists a unique Poisson structure $\{\cdot\,,\cdot\}^Q$ on $Q$ that makes it into a Poisson submanifold of $(M, \{\cdot\,,\cdot\})$ but this Poisson structure may be different from the given one on $Q$. Any Poisson submanifold is quasi-Poisson but the converse is not true in general.

### The Poisson Tensor and Symplectic Leaves

The derivation property of the Poisson bracket implies that for any two functions $f, g \in C^\infty(M)$, the value of the bracket $\{f, g\}(z)$ at an arbitrary point $z \in M$ (and therefore $X_f(z)$ as well) depends on $f$ only through $\boldsymbol{d}f(z)$ which allows us to define a contravariant antisymmetric 2-tensor $B \in \Lambda^2(T^*M)$, called the "Poisson tensor," by $B(z)(\alpha_z, \beta_z) = \{f, g\}(z)$, where $\boldsymbol{d}f(z) = \alpha_z \in T_z^*M$ and $\boldsymbol{d}g(z) = \beta_z \in T_z^*M$. The vector bundle map $B^\sharp : T^*M \to TM$ over the identity naturally associated to $B$ is defined by $B(z)(\alpha_z, \beta_z) = \langle \alpha_z, B^\sharp(\beta_z) \rangle$. Its range $D := B^\sharp(T^*M) \subset TM$ is called the "characteristic distribution" of $(M, \{\cdot\,,\cdot\})$ since $D$ is a generalized smooth integrable distribution. Its maximal integral leaves are called the "symplectic leaves" of $M$ for they carry a symplectic structure that makes them into Poisson submanifolds. As integral leaves of an integrable distribution, the symplectic leaves $\mathcal{L}$ are "initial submanifolds" of $M$, that is, the inclusion $i : \mathcal{L} \hookrightarrow M$ is an injective immersion such that for any smooth manifold $P$, an arbitrary map $g : P \to \mathcal{L}$ is smooth if and only if $i \circ g : P \to M$ is smooth.

## Poisson Reduction

### Canonical Lie Group Actions

Let $(M, \{\cdot\,,\cdot\})$ be a Poisson manifold and let $G$ be a Lie group acting canonically on $M$ via the map $\Phi : G \times M \to M$. An action is called "canonical" if for any $h \in G$ and $f, g \in C^\infty(M)$, one has

$$\{f \circ \Phi_h, g \circ \Phi_h\} = \{f, g\} \circ \Phi_h$$

If the $G$-action is free and proper, then the orbit space $M/G$ is a smooth regular quotient manifold. Moreover, it is also a Poisson manifold with the Poisson bracket $\{\cdot\,,\cdot\}^{M/G}$, uniquely characterized by the relation

$$\{f, g\}^{M/G}(\pi(m)) = \{f \circ \pi, g \circ \pi\}(m) \qquad [1]$$

for any $m \in M$ and where $f, g : M/G \to \mathbb{R}$ are two arbitrary smooth functions. This bracket is appropriate for the reduction of Hamiltonian dynamics in the sense that if $h \in C^\infty(M)^G$ is a $G$-invariant smooth function on $M$, then the Hamiltonian flow $F_t$ of $X_h$ commutes with the $G$-action, so it induces a flow $F_t^{M/G}$ on $M/G$ that is Hamiltonian on $(M/G, \{\cdot\,,\cdot\}^{M/G})$ for the reduced Hamiltonian function $[h] \in C^\infty(M/G)$ defined by $[h] \circ \pi = h$.

If the Poisson manifold $(M, \{\cdot\,,\cdot\})$ is actually symplectic with form $\omega$ and the $G$-action has an associated momentum map $\boldsymbol{J} : M \to \mathfrak{g}^*$, then the symplectic leaves of $(M/G, \{\cdot\,,\cdot\}^{M/G})$ are given by the spaces $(M^c_{\mathcal{O}_\mu} := G \cdot \boldsymbol{J}^{-1}(\mu)^c/G, \omega^c_{\mathcal{O}_\mu})$, where $\boldsymbol{J}^{-1}(\mu)^c$ is a connected component of the fiber $\boldsymbol{J}^{-1}(\mu)$ and $\omega^c_{\mathcal{O}_\mu}$ is the restriction to $M^c_{\mathcal{O}_\mu}$ of the symplectic form $\omega_{\mathcal{O}_\mu}$ of the symplectic orbit reduced space $M_{\mathcal{O}_\mu}$ (*see* Symmetry and Symplectic Reduction). If, additionally, $G$ is compact, $M$ is connected, and the momentum map $\boldsymbol{J}$ is proper, then $M^c_{\mathcal{O}_\mu} = M_{\mathcal{O}_\mu}$.

In the remainder of this section, we characterize the situations in which new Poisson manifolds can be obtained out of a given one by a combination of restriction to a submanifold and passage to the quotient with respect to an equivalence relation that encodes the symmetries of the bracket.

**Definition 1** Let $(M, \{\cdot\,,\cdot\})$ be a Poisson manifold and $D \subset TM$ a smooth distribution on $M$. The distribution $D$ is called "Poisson" or "canonical," if the condition $\boldsymbol{d}f|_D = \boldsymbol{d}g|_D = 0$, for any $f, g \in C^\infty(U)$ and any open subset $U \subset P$, implies that $\boldsymbol{d}\{f, g\}|_D = 0$.

Unless strong regularity assumptions are invoked, the passage to the leaf space of a canonical distribution destroys the smoothness of the quotient topological space. In such situations, the Poisson algebra of functions is too small and the notion of presheaf of Poisson algebras is needed. *See* Singularity and Bifurcation Theory for more information on singularity theory.

**Definition 2** Let $M$ be a topological space with a presheaf $\mathcal{F}$ of smooth functions. A presheaf of Poisson algebras on $(M, \mathcal{F})$ is a map $\{\cdot\,,\cdot\}$ that assigns to each open set $U \subset M$ a bilinear operation $\{\cdot\,,\cdot\}_U : \mathcal{F}(U) \times \mathcal{F}(U) \to \mathcal{F}(U)$ such that the pair $(\mathcal{F}(U), \{\cdot\,,\cdot\}_U)$ is a Poisson algebra. A presheaf of Poisson algebras is denoted as a triple $(M, \mathcal{F}, \{\cdot\,,\cdot\})$. The presheaf of Poisson algebras $(M, \mathcal{F}, \{\cdot\,,\cdot\})$ is said to be "nondegenerate" if the following condition holds: if $f \in \mathcal{F}(U)$ is such that $\{f, g\}_{U \cap V} = 0$, for any $g \in \mathcal{F}(V)$ and any open set of $V$, then $f$ is constant on the connected components of $U$.

Any Poisson manifold $(M, \{\cdot\,,\cdot\})$ has a natural presheaf of Poisson algebras on its presheaf of smooth functions that associates to any open subset $U$ of $M$ the restriction $\{\cdot\,,\cdot\}|_U$ of $\{\cdot\,,\cdot\}$ to $C^\infty(U) \times C^\infty(U)$.

**Definition 3** Let $P$ be a topological space and $\mathcal{Z} = \{S_i\}_{i \in I}$ a locally finite partition of $P$ into smooth manifolds $S_i \subset P, i \in I$, that are locally closed topological subspaces of $P$ (hence their manifold topology is the relative one induced by $P$). The pair $(P, \mathcal{Z})$ is called a "decomposition" of $P$ with "pieces" in $\mathcal{Z}$, or a "decomposed space," if the following "frontier condition" holds:

**Condition** (**DS**) If $R, S \in \mathcal{Z}$ are such that $R \cap \bar{S} \neq \emptyset$, then $R \subset \bar{S}$. In this case, we write $R \preceq S$. If, in addition, $R \neq S$ we say that $R$ is incident to $S$ or that it is a boundary piece of $S$ and write $R \prec S$.

**Definition 4** Let $M$ be a differentiable manifold and $S \subset M$ a decomposed subset of $M$. Let $\{S_i\}_{i \in I}$

be the pieces of this decomposition. The topology of $S$ is not necessarily the relative topology as a subset of $M$. Then $D \subset TM|_S$ is called a "smooth distribution" on $S$ adapted to the decomposition $\{S_i\}_{i \in I}$, if $D \cap TS_i$ is a smooth distribution on $S_i$ for all $i \in I$. The distribution $D$ is said to be "integrable" if $D \cap TS_i$ is integrable for each $i \in I$.

In the situation described by the previous definition and if $D$ is integrable, the integrability of the distributions $D_{S_i} := D \cap TS_i$ on $S_i$ allows us to partition each $S_i$ into the corresponding maximal integral manifolds. Thus, there is an equivalence relation on $S_i$ whose equivalence classes are precisely these maximal integral manifolds. Doing this on each $S_i$, we obtain an equivalence relation $D_S$ on the whole set $S$ by taking the union of the different equivalence classes corresponding to all the $D_{S_i}$. Define the quotient space $S/D_S$ by

$$S/D_S := \bigcup_{i \in I} S_i/D_{S_i}$$

and let $\pi_{D_S}: S \to S/D_S$ be the natural projection.

### The Presheaf of Smooth Functions on $S/D_S$

Define the presheaf of smooth functions $C^\infty_{S/D_S}$ on $S/D_S$ as the map that associates to any open subset $V$ of $S/D_S$ the set of functions $C^\infty_{S/D_S}(V)$ characterized by the following property: $f \in C^\infty_{S/D_S}(V)$ if and only if for any $z \in V$ there exists $m \in \pi^{-1}_{D_S}(V)$,$U_m$ open neighborhood of $m$ in $M$, and $F \in C^\infty(U_m)$ such that

$$f \circ \pi_{D_S}|_{\pi^{-1}_{D_S}(V) \cap U_m} = F|_{\pi^{-1}_{D_S}(V) \cap U_m} \qquad [2]$$

$F$ is called a "local extension" of $f \circ \pi_{D_S}$ at the point $m \in \pi^{-1}_{D_S}(V)$. When the distribution $D$ is trivial, the presheaf $C^\infty_{S/D_S}$ coincides with the presheaf of Whitney smooth functions $C^\infty_{S,M}$ on $S$ induced by the smooth functions on $M$.

The presheaf $C^\infty_{S/D_S}$ is said to have the $(D, D_S)$-local extension property when the topology of $S$ is stronger than the relative topology and, at the same time, the local extensions of $f \circ \pi_{D_S}$ defined in [2] can always be chosen to satisfy

$$\mathbf{d}F(n)|_{D(n)} = 0 \quad \text{for any } n \in \pi^{-1}_{D_S}(V) \cap U_m$$

$F$ is called a "local $D$-invariant extension" of $f \circ \pi_{D_S}$ at the point $m \in \pi^{-1}_{D_S}(V)$. If $S$ is a smooth embedded submanifold of $M$ and $D_S$ is a smooth, integrable, and regular distribution on $S$, then the presheaf $C^\infty_{S/D_S}$ coincides with the presheaf of smooth functions on $S/D_S$ when considered as a regular quotient manifold.

The following definition spells out what we mean by obtaining a bracket via reduction.

**Definition 5** Let $(M, \{\cdot\,,\cdot\})$ be a Poisson manifold, $S$ a decomposed subset of $M$, and $D \subset TM|_S$ a Poisson-integrable generalized distribution adapted to the decomposition of $S$. Assume that $C^\infty_{S/D_S}$ has the $(D, D_S)$-local extension property. Then $(M, \{\cdot\,,\cdot\}, D, S)$ is said to be "Poisson reducible" if $(S/D_S, C^\infty_{S/D_S}, \{\cdot\,,\cdot\}^{S/D_S})$ is a well-defined presheaf of Poisson algebras where, for any open set $V \subset S/D_S$, the bracket $\{\cdot\,,\cdot\}^{S/D_S}_V : C^\infty_{S/D_S}(V) \times C^\infty_{S/D_S}(V) \to C^\infty_{S/D_S}(V)$ is given by

$$\{f, g\}^{S/D_S}_V(\pi_{D_S}(m)) := \{F, G\}(m)$$

for any $m \in \pi^{-1}_{D_S}(V)$ for local $D$-invariant extensions $F$,$G$ at $m$ of $f \circ \pi_{D_S}$ and $g \circ \pi_{D_S}$, respectively.

**Theorem 1** *Let $(M, \{\cdot\,,\cdot\})$ be a Poisson manifold with associated Poisson tensor $B \in \Lambda^2(T^*M)$, $S$ a decomposed space, and $D \subset TM|_S$ a Poisson-integrable generalized distribution adapted to the decomposition of $S$ (see Definitions 4 and 1). Assume that $C^\infty_{S/D_S}$ has the $(D, D_S)$-local extension property. Then $(M, \{\cdot\,,\cdot\}, D, S)$ is Poisson reducible if for any $m \in S$*

$$B^\sharp(\Delta_m) \subset \left[\Delta^S_m\right]^\circ \qquad [3]$$

*where $\Delta_m := \{\mathbf{d}F(m) | F \in C^\infty(U_m), \mathbf{d}F(z)|_{D(z)} = 0,$ for all $z \in U_m \cap S$, and for any open neighborhood $U_m$ of $m$ in $M\}$ and $\Delta^S_m := \{\mathbf{d}F(m) \in \Delta_m | F|_{U_m \cap V_m}$ is constant for an open neighborhood $U_m$ of $m$ in $M$ and an open neighborhood $V_m$ of $m$ in $S\}$.*

If $S$ is endowed with the relative topology, then $\Delta^S_m := \{\mathbf{d}F(m) \in \Delta_m | F|_{U_m \cap V_m}$ is constant for an open neighborhood $U_m$ of $m$ in $M\}$.

### Reduction by Regular Canonical Distributions

Let $(M, \{\cdot\,,\cdot\})$ be a Poisson manifold and $S$ an embedded submanifold of $M$. Let $D \subset TM|_S$ be a sub-bundle of the tangent bundle of $M$ restricted to $S$ such that $D_S := D \cap TS$ is a smooth, integrable, regular distribution on $S$ and $D$ is canonical.

**Theorem 2** *With the above hypotheses, $(M, \{\cdot\,,\cdot\}, D, S)$ is Poisson reducible if and only if*

$$B^\sharp(D^\circ) \subset TS + D \qquad [4]$$

## Applications of the Poisson Reduction Theorem

### Reduction of Coisotropic Submanifolds

Let $(M, \{\cdot\,,\cdot\})$ be a Poisson manifold with associated Poisson tensor $B \in \Lambda^2(T^*M)$ and $S$ an immersed smooth submanifold of $M$. Denote by $(TS)^\circ := \{\alpha_s \in T^*_sM | \langle \alpha_s, v_s \rangle = 0,$ for all $s \in S,$ $v_s \in T_sS\} \subset T^*M$ the

conormal bundle of the manifold $S$; it is a vector sub-bundle of $T^*M|_S$. The manifold $S$ is called "coisotropic" if $B^\sharp((TS)^\circ) \subset TS$. In the physics literature, coisotropic submanifolds appear sometimes under the name of "first-class constraints." The following are equivalent:

1. $S$ is coisotropic;
2. if $f \in C^\infty(M)$ satisfies $f|_S \equiv 0$, then $X_f|_S \in \mathfrak{X}(S)$;
3. for any $s \in S$, any open neighborhood $U_s$ of $s$ in $M$, and any function $g \in C^\infty(U_s)$ such that $X_g(s) \in T_sS$, if $f \in C^\infty(U_s)$ satisfies $\{f, g\}(s) = 0$, it follows that $X_f(s) \in T_sS$;
4. the subalgebra $\{f \in C^\infty(M) \mid f|_S \equiv 0\}$ is a Poisson subalgebra of $(C^\infty(M), \{\cdot, \cdot\})$.

The following proposition shows how to endow the coisotropic submanifolds of a Poisson manifold with a Poisson structure by using the reduction theorem 1.

**Proposition 1** *Let $(M, \{\cdot, \cdot\})$ be a Poisson manifold with associated Poisson tensor $B \in \Lambda^2(T^*M)$. Let $S$ be an embedded coisotropic submanifold of $M$ and $D := B^\sharp((TS)^\circ)$. Then*

(i) *$D = D \cap TS = D_S$ is a smooth generalized distribution on $S$.*
(ii) *$D$ is integrable.*
(iii) *If $C^\infty_{S/D_S}$ has the $(D, D_S)$-local extension property, then $(M, \{\cdot, \cdot\}, D, S)$ is Poisson reducible.*

Coisotropic submanifolds usually appear as the level sets of integrals in involution. Let $(M, \{\cdot, \cdot\})$ be a Poisson manifold with Poisson tensor $B$ and let $f_1, \ldots, f_k \in C^\infty(M)$ be $k$ smooth functions in involution, that is, $\{f_i, f_j\} = 0$, for any $i, j \in \{1, \ldots, k\}$. Assume that $\mathbf{0} \in \mathbb{R}^k$ is a regular value of the function $F := (f_1, \ldots, f_k) : M \to \mathbb{R}^k$ and let $S := F^{-1}(0)$. Since for any $s \in S$, $\operatorname{span}\{\mathbf{d}f_1(s), \ldots, \mathbf{d}f_k(s)\} \subset (T_sS)^\circ$ and the dimensions of both sides of this inclusion are equal, it follows that $\operatorname{span}\{\mathbf{d}f_1(s), \ldots, \mathbf{d}f_k(s)\} = (T_sS)^\circ$. Hence, $B^\sharp(s)((T_sS)^\circ) = \operatorname{span}\{X_{f_1}(s), \ldots, X_{f_k}(s)\}$ and $B^\sharp(s)\ ((T_sS)^\circ) \subset T_sS$ by the involutivity of the components of $F$. Consequently, $S$ is a coisotropic submanifold of $(M, \{\cdot, \cdot\})$.

### Cosymplectic Submanifolds and Dirac's Constraints Formula

The Poisson reduction theorem 2 allows us to define Poisson structures on certain embedded submanifolds that are not Poisson submanifolds.

**Definition 6** Let $(M, \{\cdot, \cdot\})$ be a Poisson manifold and let $B \in \Lambda^2(T^*M)$ be the corresponding Poisson tensor. An embedded submanifold $S \subset M$ is called cosymplectic if

(i) $B^\sharp((TS)^\circ) \cap TS = \{0\}$,
(ii) $T_sS + T_s\mathcal{L}_s = T_sM$,

for any $s \in S$ and $\mathcal{L}_s$ the symplectic leaf of $(M, \{\cdot, \cdot\})$ containing $s \in S$.

The cosymplectic submanifolds of a symplectic manifold $(M, \omega)$ are its symplectic submanifolds. Cosymplectic submanifolds appear in the physics literature under the name of "second-class constraints."

**Proposition 2** *Let $(M, \{\cdot, \cdot\})$ be a Poisson manifold, $B \in \Lambda^2(T^*M)$ the corresponding Poisson tensor, and $S$ a cosymplectic submanifold of $M$. then, for any $s \in S$,*

(i) *$T_s\mathcal{L}_s = (T_sS \cap T_s\mathcal{L}_s) \oplus B^\sharp(s)((T_sS)^\circ)$, where $\mathcal{L}_s$ is the symplectic leaf of $(M, \{\cdot, \cdot\})$ that contains $s \in S$.*
(ii) *$(T_sS)^\circ \cap \ker B^\sharp(s) = \{0\}$.*
(iii) *$T_sM = B^\sharp(s)((T_sS)^\circ) \oplus T_sS$.*
(iv) *$B^\sharp((TS)^\circ)$ is a sub-bundle of $TM|_S$ and hence $TM|_S = B^\sharp((TS)^\circ) \oplus TS$.*
(v) *The symplectic leaves of $(M, \{\cdot, \cdot\})$ intersect $S$ transversely and hence $S \cap \mathcal{L}$ is an initial submanifold of $S$, for any symplectic leaf $\mathcal{L}$ of $(M, \{\cdot, \cdot\})$.*

**Theorem 3** (The Poisson structure of a cosymplectic submanifold). *Let $(M, \{\cdot, \cdot\})$ be a Poisson manifold, $B \in \Lambda^2(T^*M)$ the corresponding Poisson tensor, and $S$ a cosymplectic submanifold of $M$. Let $D := B^\sharp\ ((TS)^\circ) \subset TM|_S$. Then,*

(i) *$(M, \{\cdot, \cdot\}, D, S)$ is Poisson reducible.*
(ii) *The corresponding quotient manifold equals $S$ and the reduced bracket $\{\cdot, \cdot\}^S$ is given by*

$$\{f, g\}^S(s) = \{F, G\}(s) \qquad [5]$$

*where $f, g \in C^\infty_{S,M}(V)$ are arbitrary and $F, G \in C^\infty(U)$ are local $D$-invariant extensions of $f$ and $g$ around $s \in S$, respectively.*
(iii) *The Hamiltonian vector field $X_f$ of an arbitrary function $f \in C^\infty_{S,M}(V)$ is given either by*

$$Ti \circ X_f = X_F \circ i \qquad [6]$$

*where $F \in C^\infty(U)$ is a local $D$-invariant extension of $f$ and $i : S \hookrightarrow M$ is the inclusion, or by*

$$Ti \circ X_f = \pi_S \circ X_{\overline{F}} \circ i \qquad [7]$$

*where $\overline{F} \in C^\infty(U)$ is an arbitrary local extension of $f$ and $\pi_S : TM|_S \to TS$ is the projection induced by the Whitney sum decomposition $TM|_S = B^\sharp((TS)^\circ) \oplus TS$ of $TM|_S$.*
(iv) *The symplectic leaves of $(S, \{\cdot, \cdot\}^S)$ are the connected components of the intersections $S \cap \mathcal{L}$, where $\mathcal{L}$ is a symplectic leaf of $(M, \{\cdot, \cdot\})$. Any*

*symplectic leaf of $(S,\{\cdot,\cdot\}^S)$ is a symplectic submanifold of the symplectic leaf of $(M,\{\cdot,\cdot\})$ that contains it.*

(v) *Let $\mathcal{L}_s$ and $\mathcal{L}_s^S$ be the symplectic leaves of $(M,\{\cdot,\cdot\})$ and $(S,\{\cdot,\cdot\}^S)$, respectively, that contain the point $s\in S$. Let $\omega_{\mathcal{L}_s}$ and $\omega_{\mathcal{L}_s^S}$ be the corresponding symplectic forms. Then $B^\sharp(s)((T_sS)^\circ)$ is a symplectic subspace of $T_s\mathcal{L}_s$ and*

$$B^\sharp(s)((T_sS)^\circ) = \left(T_s\mathcal{L}_s^S\right)^{\omega_{\mathcal{L}_s}(s)} \qquad [8]$$

*where $(T_s\mathcal{L}_s^S)^{\omega_{\mathcal{L}_s}(s)}$ denotes the $\omega_{\mathcal{L}_s}(s)$-orthogonal complement of $T_s\mathcal{L}_s^S$ in $T_s\mathcal{L}_s$.*

(vi) *Let $B_S\in\Lambda^2(T^*S)$ be the Poisson tensor associated to $(S,\{\cdot,\cdot\}^S)$. Then*

$$B_S^\sharp = \pi_S\circ B^\sharp|_S\circ\pi_S^* \qquad [9]$$

*where $\pi_S^*: T^*S\to T^*M|_S$ is the dual of $\pi_S: TM|_S\to TS$.*

The "Dirac constraints formula" is the expression in coordinates for the bracket of a cosymplectic submanifold. Let $(M,\{\cdot,\cdot\})$ be an $n$-dimensional Poisson manifold and let $S$ be a $k$-dimensional cosymplectic submanifold of $M$. Let $z_0$ be an arbitrary point in $S$ and $(U,\overline{\kappa})$ a submanifold chart around $z_0$ such that $\overline{\kappa}=(\overline{\varphi},\overline{\psi}): U\to V_1\times V_2$, where $V_1$ and $V_2$ are two open neighborhoods of the origin in two Euclidean spaces such that $\overline{\kappa}(z_0)=(\overline{\varphi}(z_0),\overline{\psi}(z_0))=(0,0)$ and

$$\overline{\kappa}(U\cap S) = V_1\times\{0\} \qquad [10]$$

Let $\overline{\varphi}=:(\overline{\varphi}^1,\ldots,\overline{\varphi}^k)$ be the components of $\overline{\varphi}$ and define $\widehat{\varphi}^1:=\overline{\varphi}^1|_{U\cap S},\ldots,\widehat{\varphi}^k:=\overline{\varphi}^k|_{U\cap S}$. Extend $\widehat{\varphi}^1,\ldots,\widehat{\varphi}^k$ to $D$-invariant functions $\varphi^1,\ldots,\varphi^k$ on $U$. Since the differentials $\boldsymbol{d}\widehat{\varphi}^1(s),\ldots,\boldsymbol{d}\widehat{\varphi}^k(s)$ are linearly independent for any $s\in U\cap S$, we can assume (by shrinking $U$ if necessary) that $\boldsymbol{d}\varphi^1(z),\ldots,\boldsymbol{d}\varphi^k(z)$ are also linearly independent for any $z\in U$. Consequently, $(U,\kappa)$ with $\kappa:=(\varphi^1,\ldots,\varphi^k,\psi^1,\ldots,\psi^{n-k})$ is a submanifold chart for $M$ around $z_0$ with respect to $S$ such that, by construction,

$$\boldsymbol{d}\varphi^1(s)|_{B^\#(s)((T_sS)^\circ)} = \cdots = \boldsymbol{d}\varphi^k(s)|_{B^\#(s)((T_sS)^\circ)} = 0$$

for any $s\in U\cap S$. This implies that for any $i\in\{1,\ldots,k\}$, $j\in\{1,\ldots,n-k\}$, and $s\in S$

$$\{\varphi^i,\psi^j\}(s) = \boldsymbol{d}\varphi^i(s)\big(X_{\psi^j}(s)\big) = 0$$

since $\boldsymbol{d}\psi^j(s)\in(T_sS)^\circ$ by [10] and hence

$$X_{\psi^j}(s)\in B^\#(s)((T_sS)^\circ) \qquad [11]$$

Additionally, since the functions $\varphi^1,\ldots,\varphi^k$ are $D$-invariant, by [6], it follows that

$$X_{\varphi^1}(s) = X_{\widehat{\varphi}^1}(s)\in T_sS,\ldots,X_{\varphi^k}(s) = X_{\widehat{\varphi}^k}(s)\in T_sS$$

for any $s\in S$. Consequently, $\{X_{\varphi^1}(s),\ldots,X_{\varphi^k}(s), X_{\psi^1}(s),\ldots,X_{\psi^{n-k}}(s)\}$ spans $T_s\mathcal{L}_s$ with

$$\{X_{\varphi^1}(s),\ldots,X_{\varphi^k}(s)\}\subset T_sS\cap T_s\mathcal{L}_s$$

and

$$\{X_{\psi^1}(s),\ldots,X_{\psi^{n-k}}(s)\}\subset B^\#(s)((T_sS)^\circ)$$

By Proposition 2(i),

$$\operatorname{span}\{X_{\varphi^1}(s),\ldots,X_{\varphi^k}(s)\} = T_sS\cap T_s\mathcal{L}_s$$

and

$$\operatorname{span}\{X_{\psi^1}(s),\ldots,X_{\psi^{n-k}}(s)\} = B^\#(s)((T_sS)^\circ)$$

Since $\dim(B^\#(s)((T_sS)^\circ))=n-k$ by Proposition 2(iii), it follows that $\{X_{\psi^1}(s),\ldots,X_{\psi^{n-k}}(s)\}$ is a basis of $B^\#(s)((T_sS)^\circ)$.

Since $B^\#(s)((T_sS)^\circ)$ is a symplectic subspace of $T_s\mathcal{L}_s$ by Theorem 3(v), there exists some $r\in\mathbb{N}$ such that $n-k=2r$ and, additionally, the matrix $C(s)$ with entries

$$C^{ij}(s) := \{\psi^i,\psi^j\}(s),\quad i,j\in\{1,\ldots,n-k\}$$

is invertible. Therefore, in the coordinates $(\varphi^1,\ldots,\varphi^k,\psi^1,\ldots,\psi^{n-k})$, the matrix associated to the Poisson tensor $B(s)$ is

$$B(s) = \begin{pmatrix} B_S(s) & 0 \\ 0 & C(s)\end{pmatrix}$$

where $B_S\in\Lambda^2(T^*S)$ is the Poisson tensor associated to $(S,\{\cdot,\cdot\}^S)$. Let $C_{ij}(s)$ be the entries of the matrix $C(s)^{-1}$.

**Proposition 3** (Dirac formulas). *In the coordinate neighborhood $(\varphi^1,\ldots,\varphi^k,\psi^1,\ldots,\psi^{n-k})$ constructed above and for $s\in S$ we have, for any $f,g\in C^\infty_{S,M}(V)$:*

$$X_f(s) = X_F(s) - \sum_{i,j=1}^{n-k}\{F,\psi^i\}(s)C_{ij}(s)X_{\psi^j}(s) \qquad [12]$$

and

$$\{f,g\}^S(s) = \{F,G\}(s) - \sum_{i,j=1}^{n-k}\{F,\psi^i\}(s)C_{ij}(s)\{\psi^j,G\}(s) \qquad [13]$$

*where $F,G\in C^\infty(U)$ are arbitrary local extensions of $f$ and $g$, respectively, around $s\in S$.*

# Polygonal Billiards

**S Tabachnikov**, Pennsylvania State University, University Park, PA, USA

## Mechanical Examples. Unfolding Billiard Trajectories

The billiard system inside a polygon $P$ has a very simple description: a point moves rectilinearly with the unit speed until it hits a side of $P$; there it instantaneously changes its velocity according to the rule "the angle of incidence equals the angle of reflection," and continues the rectilinear motion. If the point hits a corner, its further motion is not defined. (*see* Billiards in Bounded Convex Domains). From the point of view of the theory of dynamical systems, polygonal billiards provide an example of parabolic dynamics in which nearby trajectories diverge with subexponential rate.

One of the motivations for the study of polygonal billiards comes from the mechanics of elastic particles in dimension 1. For example, consider the system of two point-masses $m_1$ and $m_2$ on the positive half-line $x \geq 0$. The collision between the points is elastic, that is, the energy and momentum are conserved. The reflection off the left endpoint of the half-line is also elastic: if a point hits the "wall" $x = 0$, its velocity changes sign. The configuration space of this system is the wedge $0 \leq x_1 \leq x_2$. After the rescaling $\bar{x}_i = \sqrt{m_i} x_i$, $i = 1, 2$, this system identifies with the billiard inside a wedge with the angle measure $\arctan \sqrt{m_1/m_2}$.

Likewise, the system of two elastic point-masses on a segment is the billiard system in a right triangle; a system of a number of elastic point-masses on the positive half-line or a segment is the billiard inside a multidimensional polyhedral cone or a polyhedron, respectively. The system of three elastic point-masses on a circle has three degrees of freedom; one can reduce one by assuming that the center of mass of the system is fixed. The resulting two-dimensional system is the billiard inside an acute triangle with the angles

$$\arctan\left(m_i\sqrt{\frac{m_1+m_2+m_3}{m_1 m_2 m_3}}\right), \quad i = 1, 2, 3$$

For comparison, the more realistic system of elastic balls identifies with the billiard system in a domain with nonflat boundary components.

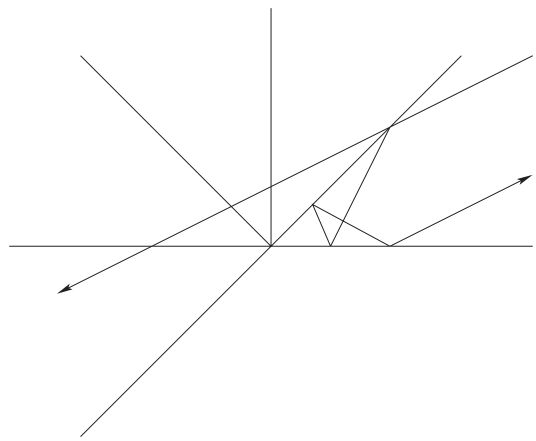

**Figure 1** Unfolding a billiard trajectory in a wedge.

A useful elementary method of study is unfolding: instead of reflecting the billiard trajectory in the sides of the polygon, reflect the polygon in the respective side and unfold the billiard trajectory to a straight line. This method yields an upper bound

$$\left\lceil \frac{\pi}{\arctan \sqrt{m_1/m_2}} \right\rceil$$

for the number of collisions in the system of two point-masses $m_1$ and $m_2$ on the positive half-line. Likewise, the number of collisions for any number of elastic point-masses on the positive half-line is bounded above by a constant depending on the masses only. Similar results are known for systems of elastic balls (Figure 1).

Similarly, one studies the billiard inside the unit square. Unfolding the square yields a square grid in the plane, acted upon by the group of parallel translations $2\mathbf{Z} \oplus 2\mathbf{Z}$. Factorizing by this group action yields a torus, and the billiard flow in a given direction becomes a constant flow on the torus. If the slope is rational, then all orbits are periodic, and if the slope is irrational, then all orbits are dense and the billiard flow is ergodic. Its metric entropy is equal to zero. Periodic trajectories of the billiard in a square come in bands of parallel ones. Let $f(\ell)$ be the number of such bands of length not greater than $\ell$. Then, $f(\ell)$ equals the number of coprime lattice points inside the circle of radius $\ell$, that is, $f(\ell)$ has quadratic growth in $\ell$.

## Periodic Trajectories

The simplest example of a periodic orbit in a polygonal billiard is the 3-periodic Fangano trajectory in an acute triangle: it connects the bases of the three altitudes of the triangle and has minimal perimeter among inscribed triangles. The Fagnano trajectory belongs to a band of 6-periodic ones. It is not known whether every acute triangle has other periodic trajectories.

For a right triangle, one has the following result: almost every (in the sense of the Lebesgue measure) billiard trajectory that leaves a leg in the perpendicular direction returns to the same leg in the same direction and is therefore periodic. A similar existence result holds for polygons whose sides have only two directions.

In general, not much is known about the existence of periodic billiard trajectories in polygons. Conjecturally, every polygon has one, but this is not known even for all obtuse triangles. Recently, R Schwartz proved that every obtuse triangle with the angles not exceeding 100° has a periodic billiard path. This work substantially relies on a computer program, McBilliards, written by Schwartz and Hooper.

If an arbitrary small perturbation of the vertices of a billiard polygon leads to a perturbation of a periodic billiard trajectory, but not to its destruction, then this trajectory is called stable. Label the sides of the polygon $1, 2, \ldots, k$. Then a periodic trajectory is coded by the word consisting of the labels of the consecutively visited sides. An even-periodic trajectory is stable if and only if the numbers in the respective word can be partitioned in pairs of equal numbers, so that the number from each pair appears once at an even position, and once at an odd one. As a consequence, if the angles of a polygon are independent over the rational numbers, then every periodic billiard trajectory in it is stable.

## Complexity of Billiard Trajectories

The encoding of billiard trajectories by the consecutively visited sides of the billiard polygon provides a link between billiard and symbolic dynamics. For a billiard $k$-gon $P$, denote by $\Sigma$ the set of words in letters $1, 2, \ldots, k$ corresponding to billiard trajectories in $P$, and let $\Sigma_n$ be the set of such words of length $n$.

One has a general theorem: *the topological entropy of the billiard flow is zero*. This implies that a number of quantities, associated with a polygonal billiard, grow slower than exponentially, as functions of $n$: the cardinality $|\Sigma_n|$, the number of strips of $n$-periodic trajectories, the number of generalized diagonals with $n$ links (i.e., billiard trajectories that start and end at corners of the billiard polygon), etc. Conjecturally, all these quantities have polynomial growth in $n$.

The complexity of the billiard in a polygon is defined as the function $p(n) = |\Sigma_n|$. Likewise, one may consider the billiard trajectories in a given direction $\theta$ and define the corresponding complexity $p_\theta(n)$.

In the case of a square, one modifies the encoding using only two symbols, say, 0 and 1, to indicate that a trajectory reflects in a horizontal or a vertical side, respectively. If $\theta$ is a direction with an irrational slope, then $p_\theta(n) = n + 1$. This is a classical result by Hedlund and Morse. The sequences with complexity $p(n) = n + 1$ are called Sturmian; this is the smallest complexity of aperiodic sequences. A generalization for multidimensional cubes and parallelepipeds, due to Yu Baryshnikov, is known.

For a $k$-gon $P$, let $N$ be the least common denominator of its $\pi$-rational angles and $s$ be the number of its distinct $\pi$-irrational angles. Then,

$$p_\theta(n) \leq kNn\left(1 + \frac{n}{2}\right)^s$$

Concerning billiard trajectories in all directions, one has a lower bound for complexity: $p(n) \geq cn^2$ for a constant $c$ depending on the polygon. A similar estimate holds for a $d$-dimensional polyhedron with the exponent 2 replaced by $d$.

## Rational Polygons and Flat Surfaces

The only class of polygons for which the billiard dynamics is well understood are rational one, the polygons satisfying the property that the angles between all pairs of sides are rational multiples of $\pi$.

Let $P$ be a simply connected (without holes) rational $k$-gon with angles $\pi m_i/n_i$, where $m_i$ and $n_i$ are coprime integers. The reflections in the sides of $P$ generate a subgroup of the group of isometries of the plane. Let $G(P) \subset \mathrm{O}(2)$ consist of the linear parts of the elements of this group. Then, $G(P)$ is the dihedral group $D_N$ consisting of $2N$ elements. When a billiard trajectory reflects in a side of $P$, its direction changes by the action of the group $G(P)$, and the orbit of a generic direction $\theta \neq k\pi/N$ on the unit circle consists of $2N$ points.

The phase space of the billiard flow is the unit tangent bundle $P \times S^1$. Let $M_\theta$ be the subset of points whose projection to $S^1$ belongs to the orbit of $\theta$ under $G(P) = D_N$. Then, $M_\theta$ is an invariant surface of the billiard flow in $P$. The surface $M_\theta$ is obtained from $2N$ copies of $P$ by gluing their sides according to the action of $D_N$. This oriented compact surface depends only on the polygon $P$, but not on the choice of $\theta$, and may be denoted by $M$. The directional billiard flows $F_\theta$ on $M$ in directions $\theta$

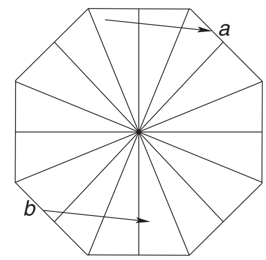

**Figure 2** The invariant surface for a right triangle with acute angle $\pi/8$ has genus 2.

are obtained, one from another, by rotations. The genus of $M$ is given by the formula

$$1 + \frac{N}{2}\left(k - 2 - \sum \frac{1}{n_i}\right)$$

For example, if $P$ is a right triangle with an acute angle $\pi/8$, then $M$ is a surface of genus 2 (Figure 2).

The cases when $M$ is a torus are as follows: the angles of $P$ are all of the form $\pi/n_i$, where $n_i$ are equal, up to permutations, to

$$(3, 3, 3), (2, 4, 4), (2, 3, 6), (2, 2, 2, 2)$$

and the respective polygons are an equilateral triangle, an isosceles right triangle, a right triangle with an acute angle $\pi/6$, and a square. All these polygons tile the plane.

The billiard flow on the surface $M$ has saddle singularities at the points obtained from the vertices of $P$. The surface $M$ inherits a flat metric from $P$ with a finite number of cone-type singularities, corresponding to the vertices of $P$, with cone angles multiples of $2\pi$ (Figure 3).

A flat surface $M$ is a compact smooth surface with a distinguished finite set of points $\Sigma$. On $M \setminus \Sigma$, one has coordinate charts $v = (x, y)$ such that the transition functions on the overlaps are of the form

$$v \to v + c \quad \text{or} \quad v \to -v + c$$

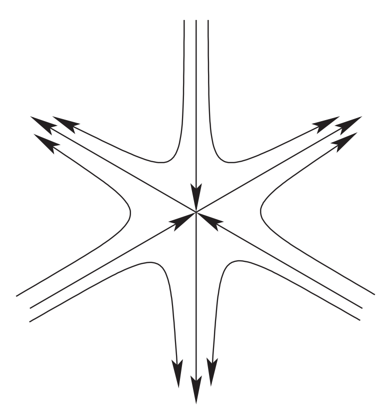

**Figure 3** A cone singularity for the flow on an invariant surface.

In particular, one may talk about directions on a flat surface.

The group PSL$(2, \boldsymbol{R})$ acts on the space of flat structures. From the point of view of complex analysis, a flat surface is a Riemann surface with a holomorphic quadratic differential; the set of cone points $\Sigma$ corresponds to the zeros of the quadratic differential. Not every flat surface is associated with a polygonal billiard.

Concerning ergodicity, one has the theorem of Kerckhoff, Masur, and Smillie: given a flat surface of genus not less than 2, for almost all directions $\theta$ (in the sense of the Lebesgue measure), the flow $F_\theta$ is uniquely ergodic. Furthermore, the Hausdorff dimension of the set of angles $\theta$ for which ergodicity fails does not exceed 1/2, and this bound is sharp. As a consequence, the billiard flow on the invariant surface is uniquely ergodic for almost all directions. Another corollary: *there is a dense $G_\delta$ subset in the space of polygons consisting of polygons for which the billiard flow is ergodic. If a billiard polygon admits approximation by rational polygons at a superexponentially fast rate, then the billiard flow in it is ergodic.*

Concerning periodic orbits, one has the following theorem due to H Masur: given a flat surface of genus not less than 2, there exists a dense set of angles $\theta$ such that $F_\theta$ has a closed trajectory. As a consequence, for any rational billiard polygon, there is a dense set of directions each with a periodic orbit. Furthermore, periodic points are dense in the phase space of the billiard flow in a rational polygon.

Similarly to the case of a square, let $f(\ell)$ be the number of strips of periodic trajectories of length not greater than $\ell$ in a rational polygon $P$. By a theorem of H Masur, there exist constants $c$ and $C$ such that for sufficiently large $\ell$ one has: $c\ell^2 < f(\ell) < C\ell^2$, and likewise for flat surfaces.

There is a class of flat surfaces, called Veech (or lattice) surfaces, for which more refined results are available. The groups of affine transformations of a flat surface determine a subgroup in $SL(2, \boldsymbol{R})$. If this subgroup is a lattice in $SL(2, \boldsymbol{R})$, then the flat surface is called a Veech surface. Similarly, one defines a Veech rational polygon. For example, regular polygons and isosceles triangles with equal angles $\pi/n$ are Veech. All acute Veech triangles are described.

For a Veech surface, one has the following Veech dichotomy: for any direction $\theta$, either the flow $F_\theta$ is minimal or its every leaf is closed (unless it is a saddle connection, i.e., a segment connecting cone points). For a Veech surface (and polygon), the quadratic bounds for the counting function $f(\ell)$ become quadratic asymptotics: $f(\ell)/\ell^2$ has a limit as $\ell \to \infty$. The value of this limit is expressed in arithmetical terms.

A generic flat surface also has quadratic asymptotics. The value of the limit depends only on the stratum of the Teichmuller space that contains this surface. These values are known, due to Eskin, Masur, Okunkov, and Zorich. Since a generic flat surface does not correspond to a rational polygon, this result does not immediately apply to polygonal billiards. However, quadratic asymptotics are established for rectangular billiards with barriers.

Note, in conclusion, a close relation of billiards in rational polygons and interval exchange transformations; the reduction of the former to the latter is a particular case of the reduction of the billiard flow to the billiard ball map. On an invariant surface $M$ of the billiard flow, consider a segment $I$, perpendicular to the directional flow. Since "the width of a beam" is an invariant transversal measure for the constant flow, the first return map to $I$ is a piecewise orientation preserving isometry, that is, an interval exchange transformation.

# Positive Maps on C*-Algebras

**F Cipriani**, Politecnico di Milano, Milan, Italy

## Introduction

The theme of positive maps on $^*$-algebras and other ordered vector spaces, dates back to the Perron–Frobenius theory of matrices with positive entries, the Shur's product of matrices, the study of doubly stochastic matrices describing discrete-time random walks and the behavior of limits of powers of positive matrices in ergodic theory.

A long experience proved that far-reaching generalizations of the above situations have to be considered in various fields of mathematical physics and that $C^*$-algebras, their positive cones, and other associated ordered vector spaces provide a rich unifying framework of functional analysis to treat them.

It is the scope of this note to review some of the basic aspects both of the general theory and of the applications.

In the next section we briefly recall the definitions of $C^*$-algebras and their positive cones. However, throughout this article we refer to C*-Algebras and their Classification and von Neumann Algebras: Introduction, Modular Theory and Classification Theory as sources of the definitions and general properties of the objects of these operator algebras. We then introduce positive maps, illustrate their general properties, and discuss some relevant classes of them. The correspondence between states and representations is described next, as well as the appearance of vector, normal and non-normal states in applications. We then illustrate the structure of completely positive maps and their relevance in mathematical physics. Finally, we describe the relevance of the class of completely positive maps to understand the structure of nuclear $C^*$-algebras.

## Positive Cones in $C^*$-Algebras

A $C^*$-algebra $A$ is a complex Banach algebra with a conjugate-linear involution $a \mapsto a^*$ such that $\|a^*a\| = \|a\|^2$ for all $a \in A$.

When $A$ has a unit $1_A$, the spectrum $\mathrm{Sp}(a)$ of an element $a$ is the subset of all complex numbers $\lambda$ such that $a - \lambda \cdot 1_A$ is not invertible in $A$. When $A$ is realized as a subalgebra of some $\mathcal{B}(\mathcal{H})$, and this is always possible, the set $\mathrm{Sp}(a)$ coincides with the spectrum of the bounded operator $a$ on the Hilbert space $\mathcal{H}$.

The involution determines the self-adjoint part $A_h := \{a \in A: a = a^*\}$ of $A$, a real subspace such that $A = A_h + \mathrm{i}A_h$. A self-adjoint element $a$ of $A$ satisfies $\mathrm{Sp}(a) \subseteq \mathbb{R}$ and, if $k \geq 0$, one has $\|a\| \leq k$ if and only if $\mathrm{Sp}(a) \subseteq [-k, k]$.

The involution determines another important subset of $A$: $A_+ := \{a^*a: a \in A\}$. This subset of $A_h$ is closed in the norm topology of $A$ and contains the sums of its elements as well as their multiples by positive scalars: in other words, it is a closed convex cone. From a spectral point of view, one has the following characterization: a self-adjoint element $a$ belongs to $A_+$ if and only if its spectrum is positive $\mathrm{Sp}(a) \subset [0, +\infty)$. It is this property that allows us to call $A_+$ the positive cone of $A$ and its elements positive. If it exists, a unit $1_A$ in $A$ is always positive and a Hermitian element $a$ is positive if and only if $\|1_A - a/\|a\|\,\| \leq 1$.

The continuous functional calculus in $A$ allows to write any self-adjoint element of $A_h$ as a difference of elements of $A_+$: $A_h = A_+ - A_+$. Moreover, $A_+ \cap (-A_+) = \{0\}$ and the decomposition $a = b - c$ of a self-adjoint element $a$ as difference of positive elements $b$ and $c$ is unique provided one requires that $bc = cb = 0$. In this case, it is called the orthogonal decomposition.

The cone $A_+$ determines an underlying structure of order space on $A$: for $a, b \in A$ one says that $a$ is less than or equal to $b$, in symbols $a \leq b$, if and only if $b - a \in A_+$. In particular, $a \geq 0$ just means that $a$ is positive.

Another fundamental characterization of the positive cone is the following: a self-adjoint element $a = a^*$ is positive if and only if there exists an element $b$ in $A$ such that $a = b^2$. Moreover, among the elements $b$ with this property, there exists one and only one which is positive, the square root of $a$. Some examples of positive cones are provided in the following.

**Example 1** By a fundamental result of I M Gelfand, a commutative $C^*$-algebra $A$ is isomorphic to the $C^*$-algebra $C_0(X)$ of all complex continuous functions vanishing at infinity on a locally compact Hausdorff topological space $X$. The algebraic operations have the usual pointwise meaning and the norm is the uniform one. The constant function 1 represents the unit precisely when $X$ is compact. The positive cone $C_0(X)_+$ coincides with that of the positive continuous functions in $C_0(X)$.

**Example 2** Finite dimensional $C^*$-algebras $A$ are classified as finite sums $M_{n_1}(\mathbb{C}) \oplus M_{n_2}(\mathbb{C}) \oplus \cdots \oplus M_{n_k}(\mathbb{C})$ of full matrix algebras $M_{n_i}(\mathbb{C})$. An element

$a_1 \oplus a_2 \oplus \cdots \oplus a_k$ is positive if and only if the matrices $a_i$ have positive eigenvalues.

**Example 3** When a C*-algebra $A \subseteq \mathcal{B}(\mathcal{H})$ is represented as a self-adjoint closed algebra of operators on a Hilbert space $\mathcal{H}$, its positive elements are those which have non-negative spectrum.

## Positive Maps on $C^*$-Algebras

Among the various relevant classes of maps between $C^*$-algebras, we are going to consider the following ones, whose properties are connected with the underlying structures of ordered vector spaces.

**Definition 1** Given two C*-algebras $A$ and $B$, a map $\phi : A \longrightarrow B$ is called positive if $\phi(A_+) \subseteq B_+$. In other words, a map is positive if and only if it transforms the positive elements of $A$ into positive elements of $B$:

$$a \in A \Rightarrow \phi(a^*a) \in B_+ \qquad [1]$$

If $A$ and $B$ have units, the map is called unital provided $\phi(1_A) = 1_B$.

### Morphisms and Jordan Morphisms

A $^*$-morphism between C*-algebras $\phi : A \longrightarrow B$ is positive; in fact, $\phi(a^*a) = \phi(a)^*\phi(a) \geq 0$.

This also the case for Jordan $^*$-morphism, the linear maps satisfying $\phi(a^*) = \phi(a)^*$ and $\phi(\{a, b\}) = \{\phi(a), \phi(b)\}$, where $\{a, b\} = ab + ba$ denotes the Jordan product. In fact, if $a = a^*$ then $\phi(a^2) = \phi(a)^2$ is positive.

### Shur's Product of Matrices

Let $A \in M_n(\mathbb{C})$ be a positive matrix and define a linear map $\phi : M_n(\mathbb{C}) \longrightarrow M_n(\mathbb{C})$ through the Shur's product of matrices: $\phi_A(B) := [A_{ij}B_{ij}]_{i,j=1}^n$. Since the Shur's product of positive matrices is positive too (i.e., the positive cone of $M_n(\mathbb{C})$ is a semigroup under matrix product), the above map is positive.

### Positive-Definite Function on Groups

Positive maps also arise naturally in harmonic analysis. Let $G$ be a locally compact topological group with identity $e$ and left Haar's measure $m$. Let $p : G \longrightarrow \mathbb{C}$ be a continuous positive-definite function on $G$. This just means that for all $n \geq 1$ and all $s_1, \ldots, s_n \in G$, the matrix $\{p(s_i^{-1}s_j)\}_{i,j=1}^n$ belongs to the positive cone of $M_n(\mathbb{C})$: $\sum_{i,j=1}^n p(s_i^{-1}s_j)\overline{\alpha}_i\alpha_j \geq 0$ for all $\alpha_1, \ldots, \alpha_n$. Such functions are necessarily bounded with $\|p\|_\infty \leq p(e)$, so that an operator $\phi : L^1(G, m) \longrightarrow L^1(G, m)$ is well defined by pointwise multiplication: $\phi(f)(s) := p(s)f(s)$. This map extends to a positive map $\phi : C^*(G) \longrightarrow C^*(G)$, which is unital when $p(e) = 1$, on the full group $C^*$-algebra $C^*(G)$. When $G$ is amenable, this algebra coincides with reduced C*-algebra $C_r(G)$ so that, if $G$ is also unimodular (as is the case if $G$ is compact), the positive elements can be approximated by positive-definite functions in $L^1(G, m)$ and the positivity of $\phi$ follows exactly as in the previous example.

### Positive Maps in Commutative $C^*$-Algebras

Positive maps $\phi : C_0(Y) \longrightarrow C_0(X)$ between commutative $C^*$-algebras have the following structure: $\phi(a)(x) = \int_Y k(x, \mathrm{d}y)a(y), a \in C_0(Y)$. Here the kernel $x \mapsto k(x, \cdot)$ is a continuous map from $X$ to the space of positive Radon measures on $Y$. In case $X$ and $Y$ are compact, the map is unital provided $k(x, \cdot)$ is a probability measure for each $x \in X$. In fact, for a fixed $x \in X$, the map $a \mapsto \phi(a)(x)$ is a positive linear functional from $C_0(Y)$ to $\mathbb{C}$ and Riesz's theorem guarantees that it can be represented by a positive Radon measure on $Y$.

In probability theory, one-parameter semigroups $\phi_t \circ \phi_s = \phi_{t+s}$ of positive maps $\phi_t : C_0(X) \longrightarrow C_0(X)$ such that $\phi_t(1) \leq 1$ for all $t \geq 0$, are called Markovian semigroups (conservative, if the maps are unital). They represent the expectation at time $t > 0$ of Markovian stochastic processes on $X$. In this case, the time-dependent kernel $k(t, x, \cdot)$ represents the distribution probability at time $t$ of a particle starting in $x \in X$ at time $t = 0$.

These kinds of maps arise also in potential theory, where the dependence of the solution $\phi(a)$ of a Dirichlet problem on a bounded domain $\Omega$, with nice boundary $\partial\Omega$, upon the continuous boundary data $a \in C(\partial\Omega)$ gives rise to a linear unital map $\phi : C(\partial\Omega) \longrightarrow C(\Omega \cup \partial\Omega)$, whose positivity and unitality translates the "maximum principle" for harmonic functions. When $\Omega$ is the unit disk, $k$ is the familiar Poisson's kernel.

### Continuity and Algebraic Properties of Positive Maps

Since the order structure of a $C^*$-algebra $A$ is defined by its positive cone $A_+$, positive maps are

1. real: $\phi(a^*) = \phi(a)^*$ and
2. order preserving: $\phi(a) \leq \phi(b)$ whenever $a \leq b$.

From this follows an important interplay between positivity and continuity:

a positive map $\phi : A \longrightarrow B$
between $C^*$-algebras is continuous

In case $A$ has a unit, this follows by the fact that $\phi$ is order preserving and that, for self-adjoint $a$, one has

$-\|a\|1_A \le a \le +\|a\|1_A$, so that $-\|a\|\phi(1_A) \le \phi(a) \le +\|a\|\phi(1_A)$ and then $\|\phi(a)\| \le \|\phi(1_A)\| \cdot \|a\|$. In general, splitting $a = b + ic$ as a combination of Hermitian elements $b$ and $c$, as $\|b\| \le \|a\|$ and $\|c\| \le \|a\|$, one obtains

$$\begin{aligned}\|\phi(a)\| &\le \|\phi(b)\| + \|\phi(c)\| \\ &\le \|\phi(1_A)\|(\|b\| + \|c\|) \\ &\le 2\|\phi(1_A)\| \cdot \|a\|\end{aligned}$$

The second general result concerning positivity and continuity is the following:

Let $\phi : A \longrightarrow B$ be a linear map between $C^*$-algebras with unit such that $\phi(1_A) = 1_B$; then $\phi$ is positive if and only if $\|\phi\| = 1$.

The result relies, among other things, on the generalized Schwarz inequality for unital positive maps on normal elements,

$$\phi(a^*)\phi(a) \le \phi(a^*a), \quad a^*a = aa^*$$

These results may be used to reveal the strong interplay between the algebraic, continuity and positivity properties of maps:

Let $\phi : A \longrightarrow B$ be an invertible linear map between unital $C^*$-algebras such that $\phi(1_A) = 1_B$. The following properties are equivalent:

1. $\phi$ is Jordan isomorphism,
2. $\phi$ is an isometry, and
3. $\phi$ is an order isomorphism ($\phi$ and $\phi^{-1}$ are order preserving).

The above conclusions can be strengthened if, instead of individual maps, continuous groups of maps are considered.

Let $t \mapsto \alpha_t$ be a strongly continuous, one-parameter group of maps of a unital $C^*$-algebra $A$ and assume that $\alpha_t(1_A) = 1_A$ for all $t \in \mathbb{R}$. The following properties are equivalent:

1. $\alpha_t$ is a $^*$-automorphism of $A$ for all $t \in \mathbb{R}$,
2. $\|\alpha_t\| \le 1$ for all $t \in \mathbb{R}$, and
3. $\alpha_t$ is positive for all $t \in \mathbb{R}$.

An analogous result holds true for $w^*$-continuous groups on abelian, or factors, von Neumann algebras.

## States on $C^*$-Algebras

A state on a $C^*$-algebra $A$ is a positive functional $\phi : A \longrightarrow \mathbb{C}$ of norm 1:

- $\phi(a^*a) \ge 0$ for all $a \in A$, and
- $\|\phi\| = 1$.

As $\mathbb{C}$ is a $C^*$-algebra, when $A$ is unital, a state on it is just a unital positive map:

- $\phi(a^*a) \ge 0$ for all $a \in A$, and
- $\phi(1_A) = 1$.

States for which $\phi(ab) = \phi(ba)$ are called tracial states.

States constitute a distinguished class of positive maps, both from a mathematical viewpoint and for application to mathematical physics. We will see below that states are deeply connected to representations of $C^*$-algebras (*see* $C^*$-Algebras and their Classification).

### States on Commutative $C^*$-Algebras

Since this is a subcase of positive maps in commutative $C^*$-algebras we only add a comment. As far as a $C^*$-algebra represents observable quantities of a physical system, states carry our actual knowledge about the system itself. The smallest $C^*$-sub-algebra $\{f(a): f \in C_0(\mathbb{R})\}$ of $A$ containing a given self-adjoint element $a \in A$, representing a certain observable quantity, is isomorphic to the algebra $C(\mathrm{Sp}(a))$ of continuous functions on the spectrum of $a$. A state on $A$ induces, by restriction, a state on $C(\mathrm{Sp}(a))$, which, by the Riesz representation theorem, is associated to a probability measure $\mu_a$ on $\mathrm{Sp}(a)$ through the formula

$$\phi(f(a)) = \int_{\mathrm{Sp}(a)} f(x)\mu_a(\mathrm{d}x)$$

Since $\mathrm{Sp}(a)$ represents the possible values of the observable associated to $a$, $\mu_a$ represents the distribution of these values when the physical state of the system is represented by $\phi$.

### Vector States and Density Matrices

In case $A$ is acting on a Hilbert space $h$, $A \subseteq \mathcal{B}(h)$, each unit vector $\xi \in h$ gives rise to a vector state $\phi_\xi(a) = (\xi|a\xi)$. In the quantum-mechanical description of a finite system, as far as observables with discrete spectrum are concerned, one can assume $A$ to be the $C^*$-algebra $\mathcal{K}(h)$ of compact operators on the Hilbert space $h$. In this case every state is a convex superposition of vector states, in the sense that it can be represented by the formula

$$\phi(a) = \mathrm{tr}(\rho a)/\mathrm{tr}(\rho), \quad a \in \mathcal{K}(h)$$

for a suitable density matrix $\rho$, that is, a positive, compact operator with finite trace. In quantum statistical mechanics, the grand canonical Gibbs equilibrium state of a finite system at inverse temperature $\beta$ and chemical potential $\mu$, with Hamiltonian $H$ and number operator $N$, is of the above type

$$\phi_{\beta,\mu}(a) = \mathrm{tr}(\mathrm{e}^{-\beta K}a)/\mathrm{tr}(\mathrm{e}^{-\beta K})$$

where $K = H - \mu N$, and the spectrum of $H$ is assumed to be discrete and such that $e^{-\beta K}$ is trace-class. For infinite systems, $A$ is a quasilocal $C^*$-algebra generated by a net $\{A_\alpha\}_\alpha$ of $C^*$-subalgebras describing observables referred to finite-volume regions. Infinite-volume equilibrium states on $A$ can then be obtained as thermodynamic limits of finite-volume Gibbs equilibrium states of the above type.

### Normal and Singular States

When observables with continuous spectrum have to be considered and one chooses the algebra $\mathcal{B}(h)$ of all bounded operators, the above formula, although still meaningful, does not describe all states on $\mathcal{B}(h)$ but only the important subclass of the normal ones. To this class, which can be considered on any von Neumann algebra $\mathcal{M}$, belong states $\phi$ which are $\sigma$-weakly continuous functionals. Equivalently, these are the states such that for all increasing net $a_\alpha \in \mathcal{M}_+$ with least upper bound $a \in \mathcal{M}_+, \phi(a)$ is least upper bound of the net $\phi(a_\alpha)$.

In general, each state $\phi$ on a von Neumann algebra $\mathcal{M}$ splits as a sum of a maximal normal piece and a singular one. Singular traces appear in noncommutative geometry as very useful tools to get back local objects from spectral ones via the familiar principle that local properties of functions depend on the asymptotics of their Fourier coefficients.

This is best illustrated on a compact, Riemannian $n$-manifold $M$ by the formula

$$\int_M f\, \mathrm{d}m = c_n \cdot \tau_\omega(M_f |D|^{-n})$$

which expresses the Riemannian integral of a nice function $f$ in terms of the Dirac operator $D$ acting on the Hilbert space of square-integrable spinors, the multiplication operator $M_f$ by $f$, and the singular Dixmier tracial state $\tau_\omega$ on $\mathcal{B}(H)$. Here the compactness of $M$ implies the compactness of the operator $M_f|D|^{-n}$ and $\tau_\omega$ is a limiting procedure depending only on the asymptotic behavior of the eigenvalues of $M_f|D|^{-n}$. Similar formulas are valid on self-similar fractals as well as on quasiconformal manifolds. Local index formulas represent cyclic cocycles in Connes' spectral geometry (*see* Noncommutative Geometry and the Standard Model; Noncommutative Geometry from Strings; Path-Integrals in Noncommutative Geometry).

### States and Representations: The GNS Construction

A fundamental tool in studying a $C^*$-algebra $A$ are its representations. These are morphisms of $C^*$-algebras $\pi : A \longrightarrow \mathcal{B}(\mathcal{H})$ from $A$ to the algebra of all bounded operators on some Hilbert space $\mathcal{H}$. There is a symbiotic appearance of states and representations on $C^*$-algebras. In fact, given a representation $\pi : A \longrightarrow \mathcal{B}(\mathcal{H})$, one easily constructs states on $A$ by unit vectors $\xi \in H$ by

$$\phi_\xi(a) = (\xi | \pi(a)\xi)$$

In fact, one checks that $\phi_\xi(a^*a) = (\xi|\pi(a^*a)\,\xi) = (\xi|\pi(a^*)\pi(a)\,\xi) = \|\pi(a)\,\xi\|^2 \geq 0$ and, at least if a unit exists, that $\phi_\xi(1_A) = \|\xi\|^2 = 1$.

A fundamental construction due to Gelfand, Naimark, and Segal allows to associate a representation to each state in such a way that each state is a vector state for a suitable representation.

"Let $\omega$ be a state over the $C^*$-algebra $A$. It follows that there exists cyclic representation $(\pi_\omega, \mathcal{H}_\omega, \xi_\omega)$ of $A$ such that

$$\omega(a) = (\xi_\omega | \pi_\omega(a)\xi_\omega)$$

Moreover, the representation is unique up to unitary equivalence. It is called the canonical cyclic representation of $A$ associated with $\omega$."

The positivity property of the state allows to introduce the positive-semidefinite scalar product $\langle a|b\rangle = \omega(a^*b)$ on the vector space $A$. Moreover, its kernel $\mathcal{I}_\omega = \{a \in A\colon \omega(a^*a) = 0\}$ is a left-ideal of $A$: in fact, if $a \in A$ and $b \in \mathcal{I}_\omega$ then $\omega((ba)^*(ba)) \leq \|a\|^2\omega(b^*b) = 0$. This allows to define, on the quotient pre-Hilbert space $A/\mathcal{I}_\omega$, an action of the elements $a \in A$: $\pi_\omega(a)(b + \mathcal{I}_\omega) := ab + \mathcal{I}_\omega$. It is the extension of this action to the Hilbert space completion $\mathcal{H}_\omega$ of $A/\mathcal{I}_\omega$ that gives the representation associated to $\omega$. When $A$ has a unit, the cyclic vector $\xi_\omega$ with the stated properties is precisely the image of $1_A + \mathcal{I}_\omega$. By definition, the cyclicity of the representation amounts to check that $\pi_\omega(A)\xi_\omega$ is dense in $\mathcal{H}_\omega$.

## Completely Positive Maps

In a sense, the order structure of a $C^*$-algebra $A$ is better understood through the sequence of $C^*$-algebras $A \otimes M_n(\mathbb{C}) \cong M_n(A)$, obtained as tensor products of $A$ and full matrix algebras $M_n(\mathbb{C})$. For example, $C^*$-algebras are matrix-ordered vector spaces as $\alpha^*(M_m(A))_+\alpha \subseteq (M_n(A))_+$ for all matrices $\alpha \in M_{m\times n}(\mathbb{C})$.

In this respect, one is naturally led to consider stronger notion of positivity:

"A map $\phi : A \longrightarrow B$ is called $n$-positive if its extension

$$\phi \otimes 1_n : A \otimes M_n(\mathbb{C}) \longrightarrow B \otimes M_n(\mathbb{C})$$
$$(\phi \otimes 1_n)[a_{i,j}]_{i,j} = [\phi(a_{i,j})]_{i,j}$$

is positive and completely positive (CP map for short) if this happens for all $n$."

Equivalently, $n$-positive means that $\sum_{i,j=1}^{n} b_i^* \phi \times (a_i^* a_j) b_j \geq 0$ for all $a_1, \ldots, a_n \in A$ and $b_1, \ldots, b_n \in b$. In particular, if $\phi$ is $n$-positive then it is $k$-positive for all $k \leq n$. Many positive maps we considered are in fact CP maps:

1. morphisms of $C^*$-algebras are CP maps;
2. positive maps $\phi : A \longrightarrow B$ are automatically CP maps provided $A, B$ or both are commutative and states are, in particular, CP maps; and
3. an important class of CP maps is the following. A norm one projection $\varepsilon : A \longrightarrow B$, from a $C^*$-algebra $A$ onto a $C^*$-subalgebra $B$, is a contraction such that $\varepsilon(b) = b$ for all $b \in B$. It can be proved that these maps satisfy $\varepsilon(bac) = b\varepsilon(a)c$ for all $a \in A$ and $b, c \in B$ and for this reason they are called conditional expectations. This property then implies that they are CP maps.

However, the identity map from a $C^*$-algebra $A$ into its opposite $A^\circ$ is positive but not 2-positive unless $A$ is commutative, the transposition $a \mapsto a^t$ in $M_n(\mathbb{C})$ is positive and not 2-positive if $n \geq 2$ and, for all $n$, there exist $n$-positive maps which are not $(n+1)$-positive.

### CP Maps in Mathematical Physics

In several fields of application, the transition of a state of a system into another state can be described by a completely positive map $\phi : A \longrightarrow B$ between $C^*$-algebras: for any given state $\omega$ of $B$, $\omega \circ \phi$ is then a state of $A$.

1. In the theory of quantum communication processes (*see* Channels in Quantum Information Theory; Optimal Cloning of Quantum States; Source Coding in Quantum Information Theory; Capacity for Quantum Information), for example, $B$ and $A$ represent the input and output systems, respectively, $\omega$ the signal to be transmitted, $\omega \circ \phi$ the received signal, and $\phi$ the system of transmission, called the channel.
2. In quantum probability and in the theory of quantum open systems, continuous semigroups of CP maps (*see* Quantum Dynamical Semigroups) describe dissipative time evolutions of a system due to interaction with an external one (heat bath).
3. In the theory of measurement in quantum mechanics, an observable can be described by a positive-operator-valued (POV) measure $M$ which assigns a positive element $m(E)$ in a $C^*$-algebra $A$ to each Borel subset $E$ of a topological space $X$. For each $a \in C_0(X)$, one can define its integral $\phi(f) := \int_X f \, dE$ as an element of $A$. The map $\phi : C_0(X) \longrightarrow A$, called the observation channel, is then a CP map.
4. Another field of mathematical physics in which CP maps play a distinguished role is in the construction and application of the quantum dynamical entropy, an extension of the Kolmogorov–Sinai entropy of measure preserving transformations (*see* Quantum Entropy). When dealing with a noncommutative dynamical system $(\mathcal{M}, \alpha, \tau)$ in which $\tau$ is a normal trace state on a finite von Neumann algebra $\mathcal{M}$, the Connes–Størmer entropy $h_\tau(\alpha)$ is defined through the consideration of an entropy functional $H_\tau(N_1, \ldots, N_k)$ of finite-dimensional von Neumann subalgebras $N_1, \ldots, N_k \subset \mathcal{M}$. To extend the definition to more general $C^*$-algebras and states on them, one has to face the fact that $C^*$-algebras may have no nontrivial $C^*$-subalgebras. To circumvent the problem A Connes, H Narnhofer, and W Thirring (CNT) introduced an entropy functional $H(\gamma_1, \ldots, \gamma_k)$ associated to a set $\gamma_i : A_i \longrightarrow A$ of CP maps (finite channels) from finite-dimensional $C^*$-algebras $A_i$ into $A$. This led to the CNT entropy $h_\omega(\alpha)$ of a noncommutative dynamical system $(A, \alpha, \omega)$, where $\omega$ is a state on $A$ and $\alpha$ is an automorphism or a CP map preserving it: $\omega \circ \alpha = \omega$.

### CP Maps and Continuity

Since for an element $a \in A$ of a unital $C^*$-algebra, one has $\|a\| \leq 1$ precisely when

$$\begin{pmatrix} 1 & a \\ a^* & 1 \end{pmatrix}$$

is positive in $M_2(A)$, it follows that

2-positive unital maps are contractive

Unital 2-positive maps satisfy, in particular, the generalized Schwarz inequality for all $a \in A$,

$$\phi(a^*)\phi(a) \leq \phi(a^* a)$$

In particular,

"CP maps are completely bounded as $\sup_n \|\phi \otimes 1_n\| = \|\phi(1_A)\|$ and completely contractive if they are unital. Conversely unital, completely contractive maps are CP maps."

### CP Maps and Matrix Algebras

When the domain or the target space of a map are matrix algebras, one has the following equivalences concerning positivity. Let $[e_{i,j}]_{i,j}$ denote the standard

matrix units in $M_n(\mathbb{C})$ and $\phi : M_n(\mathbb{C}) \longrightarrow B$ into a $C^*$-algebra $B$. The following conditions are equivalent:

1. $\phi$ is a CP map,
2. $\phi$ is $n$-positive, and
3. $[\phi(e_{i,j})]_{i,j}$ is positive in $M_n(B)$.

Associating to a linear map $\phi : A \longrightarrow M_n(\mathbb{C})$, the linear functional $s_\phi : M_n(A) \longrightarrow \mathbb{C}$ by $s_\phi([a_{i,j}]) := \sum_{i,j} \phi(a_{i,j})_{i,j}$, one has the following equivalent properties:

1. $\phi$ is a CP map,
2. $\phi$ is $n$-positive,
3. $s_\phi$ is positive, and
4. $s_\phi$ is positive on $A_+ \otimes M_n(\mathbb{C})_+$.

#### Stinspring Representation of CP Maps

CP maps are relatively easy to handle, thanks to the following dilation result due to W F Stinspring. It describes a CP map as the compression of a morphism of $C^*$-algebras.

Let $A$ be a unital $C^*$-algebra and $\phi : A \longrightarrow \mathcal{B}(\mathcal{H})$ a linear map. Then $\phi$ is a CP map if and only if it has the form

$$\phi(a) = V^* \pi(a) V$$

for some representation $\pi : A \longrightarrow \mathcal{B}(\mathcal{K})$ on a Hilbert space $\mathcal{K}$, and some bounded linear map $V : \mathcal{H} \longrightarrow \mathcal{K}$. If $A$ is a von Neumann algebra and $\phi$ is normal then $\pi$ can be taken to be normal. When $A = \mathcal{B}(\mathcal{H})$ and $\mathcal{H}$ is separable, one has, for some $b_n \in \mathcal{B}(\mathcal{H})$,

$$\phi(a) = \sum_{n=1}^{\infty} b_n^* a b_n$$

The proof of this result is reminiscent of the GNS construction for states and its extension, by G Kasparov, to $C^*$-modules is central in bivariant $K$-homology theory.

Despite the above satisfactory result, one should be aware that positive but not CP maps are much less understood and only for maps on very low dimensional matrix algebras do we have a definitive classification. To have an idea of the intricacies of the matter, one may consult Størmer (1963).

#### Positive Semigroups on Standard Forms of von Neumann Algebras and Ground State for Physical Hamiltonians

The above result allows one to derive the structure of generators of norm-continuous dynamical semigroups in terms of dissipative operators.

Strongly continuous positive semigroups, which are KMS symmetric with respect to a KMS state $\omega$ of a given automorphism group of a $C^*$-algebra $A$, can be analyzed as positive semigroups in the standard representation $(\mathcal{M}, \mathcal{H}, \mathcal{P}, J)$ (*see* Tomita–Takesaki Modular Theory) of the von Neumann algebra $\mathcal{M} := \pi_\omega(A)''$. A semigroup on $A$ gives rise to a corresponding $w^*$-continuous positive semigroup on $\mathcal{M}$ and to a strongly continuous positive semigroup on the ordered Hilbert space $(\mathcal{H}, \mathcal{P})$ of the standard form. In the latter framework, one can develop an infinite-dimensional, noncommutative extension of the classical Perron–Frobenius theory for matrices with positive entries. This applies, in particular, to semigroups generated by physical Hamiltonians and has been used to prove existence and uniqueness of the ground state for bosons and fermions systems in quantum field theory (one may consult Gross (1972)).

## Nuclear $C^*$-Algebras and Injective von Neumann Algebras

The nonabelian character of the product in $C^*$-algebras may prevent the existence of nontrivial morphisms between them, while one may have an abundance of CP maps. For example, there are no nontrivial morphisms from the algebra of compact operators to $\mathbb{C}$, but there exist sufficiently many states to separate its elements. A much more well-behaved category of $C^*$-algebras is obtained by considering CP maps as morphisms. This is true, in particular, for nuclear $C^*$-algebras: those for which any tensor product $A \otimes B$ with any other $C^*$-algebra $B$ admits a unique $C^*$-cross norm (*see* $C^*$-Algebras and their Classification). The intimate relation between this class of algebras and CP maps is illustrated by the following characterization:

1. $A$ is nuclear;
2. the identity map of $A$ is a pointwise limit of CP maps of finite rank;
3. the identity map of $A$ can be approximately factorized, $\lim_\alpha (T_\alpha \circ S_\alpha) a \to a$ for all $a \in A$, through matrix algebras and nets of CP maps $S_\alpha : A \to M_n(\mathbb{C}), T_\alpha : M_n(\mathbb{C}) \to A$.

A second important relation between nuclear $C^*$-algebras and CP maps emerges in connection to the lifting problem.

"Let $A$ be a nuclear $C^*$-algebra and $J$ a closed two-sided ideal in a $C^*$-algebra $B$. Then every CP map $\phi : A \to B/J$ can be lifted to a CP map $\phi' : A \to B$. In other words, $\phi$ factors through $B$ by the quotient map $q : B \to B/J$: $\phi = q \circ \phi$."

This and related results are used to prove that the Brown–Douglas–Fillmore $K$-homology invariant Ext($A$) is a group for separable, nuclear $C^*$-algebras.

Our last basic result, due to W Arveson, about CP maps concerns the extension problem.

> "Let $A$ be a unital $C^*$-algebra and $N$ a self-adjoint closed subspace of $A$ containing the identity. Then every CP map $\phi: N \to \mathcal{B}(\mathcal{H})$ from $N$ into a type I factor $\mathcal{B}(\mathcal{H})$ can be extended to a CP map $\phi: A \to \mathcal{B}(\mathcal{H})$."

This result can be restated by saying that type I factors are injective von Neumann algebras. It may suggest how the notion of a completely positive map plays a fundamental role along Connes' proof of one culminating result of the theory of von Neumann algebras, namely the fact that the class of injective von Neumann algebras coincides with the class of approximately finite-dimensional ones (*see* von Neumann Algebras: Introduction, Modular Theory and Classification Theory).

# Pseudo-Riemannian Nilpotent Lie Groups

**P E Parker**, Wichita State University, Wichita, KS, USA

## Nilpotent Lie Groups

While not much had been published on the geometry of nilpotent Lie groups with a left-invariant Riemannian metric till around 1990, the situation is certainly better now; see the references in Eberlein (2004). However, there is still very little that is conspicuous about the more general pseudo-Riemannian case. In particular, the two-step nilpotent groups are nonabelian and as close as possible to being abelian, but display a rich variety of new and interesting geometric phenomena (Cordero and Parker 1999). As in the Riemannian case, one of many places where they arise naturally is as groups of isometries acting on horospheres in certain (pseudo-Riemannian) symmetric spaces. Another is in the Iwasawa decomposition $G = KAN$ of semisimple groups with the Killing metric tensor, which need not be (positive or negative) definite even on $N$. Here, $K$ is compact and $A$ is abelian.

An early motivation for this study was the observation that there are two nonisometric pseudo-Riemannian metrics on the Heisenberg group $H_3$, one of which is flat. This is a strong contrast to the Riemannian case in which there is only one (up to positive homothety) and it is *not* flat. This is not an anomaly, as we now well know.

While the idea of more than one timelike dimension has appeared a few times in the physics literature, both in string/M-theory and in brane-world scenarios, essentially all work to date assumes only one. Thus, all applications so far are of Lorentzian or definite nilpotent groups. Guediri and co-workers led the Lorentzian studies, and most of their results stated near the end of the section "Lorentzian groups" concern a major, perennial interest in relativity: the (non)existence of closed timelike geodesics in compact Lorentzian manifolds.

Others have made use of nilpotent Lie groups with left-invariant (positive or negative) definite metric tensors, such as Hervig's (2004) constructions of black hole spacetimes from solvmanifolds (related to solvable groups: those with Iwasawa decomposition $G = AN$), including the so-called BTZ constructions. Definite groups and their applications, already having received thorough surveys elsewhere, most notably those of Eberlein, are not included here.

Although the geometric properties of Lie groups with left-invariant definite metric tensors have been studied extensively, the same has not occurred for indefinite metric tensors. For example, while the paper of Milnor (1976) has already become a classic reference, in particular for the classification of positive-definite (Riemannian) metrics on three-dimensional Lie groups, a classification of the left-invariant Lorentzian metric tensors on these groups became available only in 1997. Similarly, only a few partial results in the line of Milnor's study of definite metrics were previously known for indefinite metrics. Moreover, in dimension 3, there are only two types of metric tensors: Riemannian (definite) and Lorentzian (indefinite). But in higher dimensions, there are many distinct types of indefinite metrics while there is still essentially only one type of definite metric. This is another reason why this area has special interest now.

The list in "Further reading" at the end of this article consists of general survey articles and a select few of the more historically important papers. Precise bibliographical information for references merely mentioned or alluded to in this article may be found in those. The main, general reference on pseudo-Riemannian geometry is O'Neill's (1983) book. Eberlein's (2004) article covers the Riemannian case. At this time, there is no other comprehensive survey of the pseudo-Riemannian case. One may use Cordero and Parker (1999) and Guediri (2003) and their reference lists to good advantage, however.

## Inner Product and Signature

By an inner product on a vector space $V$ we shall mean a nondegenerate, symmetric bilinear form on $V$, generally denoted by $\langle\, , \rangle$. In particular, we *do not* assume that it is positive definite. It has become customary to refer to an ordered pair of non-negative integers $(p, q)$ as the signature of the inner product, where $p$ denotes the number of positive eigenvalues and $q$ the number of negative eigenvalues. Then nondegeneracy means that $p + q = \dim V$. Note that there is no real geometric difference between $(p, q)$ and $(q, p)$; indeed, O'Neill gives handy conversion procedures for this and for the other major sign variant (e.g., curvature) (see O'Neill (1983, pp. 92 and 89, respectively)).

A Riemannian inner product has signature $(p, 0)$. In view of the preceding remark, one might as well regard signature $(0, q)$ as also being Riemannian, so that "Riemannian geometry is that of definite metric tensors." Similarly, a Lorentzian inner product has either $p = 1$ or $q = 1$. In this case, both sign conventions are used in relativistic theories with the proviso that the "1" axis is always timelike.

If neither $p$ nor $q$ is 1, there is no physical convention. We shall say that $v \in V$ is *timelike* if $\langle v, v \rangle > 0$, *null* if $\langle v, v \rangle = 0$, and *spacelike* if $\langle v, v \rangle < 0$. (In a Lorentzian example, one may wish to revert to one's preferred relativistic convention.) We shall refer to these collectively as the *causal type* of a vector (or of a curve to which a vector is tangent).

Considering indefinite inner products (and metric tensors) thus greatly expands one's purview, from one type of geometry (Riemannian), or possibly two (Riemannian and Lorentzian), to a total of $\lfloor (p + q)/2 \rfloor + 1$ distinctly different types of geometries on the same underlying differential manifolds.

## Rise of 2-Step Groups

Throughout, $N$ will denote a connected (and simply connected, usually), nilpotent Lie group with Lie algebra $\mathfrak{n}$ having center $\mathfrak{z}$. We shall use $\langle\, , \rangle$ to denote either an inner product on $\mathfrak{n}$ or the induced left-invariant pseudo-Riemannian (indefinite) metric tensor on $N$.

For all nilpotent Lie groups, the exponential map $\exp : \mathfrak{n} \to N$ is surjective. Indeed, it is a diffeomorphism for simply connected $N$; in this case, we shall denote the inverse by log.

One of the earliest papers on the Riemannian geometry of nilpotent Lie groups was Wolf (1964). Since then, a few other papers about general nilpotent Lie groups have appeared, including Karidi (1994) and Pauls (2001), but the area has not seen a lot of progress.

However, everything changed with Kaplan's (1981) publication. Following this paper and its successor (Kaplan 1983), almost all subsequent work on the left-invariant geometry of nilpotent groups has been on two-step groups.

Briefly, Kaplan defined a new class of nilpotent Lie groups, calling them *of Heisenberg type*. This was soon abbreviated to $H$-type, and has since been called also as Heisenberg-like and (unfortunately) "generalized Heisenberg." (Unfortunate, because that term was already in use for another class, not all of which are of $H$-type.) What made them so

compelling was that (almost) everything was explicitly calculable, thus making them the next great test bed after symmetric spaces.

**Definition 1** We say that $N$ (or $\mathfrak{n}$) is 2-step nilpotent when $[\mathfrak{n},\mathfrak{n}] \subseteq \mathfrak{z}$. Then $[[\mathfrak{n},\mathfrak{n}],\mathfrak{n}]=0$ and the generalization to $k$-step nilpotent is clear:

$$[[\cdots[[[\mathfrak{n},\mathfrak{n}],\mathfrak{n}],\mathfrak{n}]\cdots],\mathfrak{n}] = 0$$

with $k+1$ copies of $\mathfrak{n}$ (or $k$ nested brackets, if you prefer).

It soon became apparent that $H$-type groups comprised a subclass of 2-step groups; for a nice, modern proof see Berndt *et al.* (1995). By around 1990, they had also attracted the attention of the spectral geometry community, and Eberlein produced the seminal survey (with important new results) from which the modern era began. (It was published in 1994 (Eberlein 1994), but the preprint had circulated widely since 1990.) Since then, activity around 2-step nilpotent Lie groups has mushroomed; see the references in Eberlein (2004).

Finally, turning to pseudo-Riemannian nilpotent Lie groups, with perhaps one or two exceptions, all results so far have been obtained only for 2-step groups. Thus, the remaining sections of this article will be devoted almost exclusively to them.

The Baker–Campbell–Hausdorff formula takes on a particularly simple form in these groups:

$$\exp(x)\exp(y) = \exp\left(x + y + \tfrac{1}{2}[x,y]\right) \qquad [1]$$

**Proposition 1** *In a pseudo-Riemannian 2-step nilpotent Lie group, the exponential map preserves causal character. Alternatively, one-parameter subgroups are curves of constant causal character.*

Of course, one-parameter subgroups need not be geodesics.

### Lattices and Completeness

We shall need some basic facts about lattices in $N$. In nilpotent Lie groups, a lattice is a discrete subgroup $\Gamma$ such that the homogeneous space $M=\Gamma\backslash N$ is compact. Here we follow the convention that a lattice acts on the left, so that the coset space consists of left cosets and this is indicated by the notation. Other subgroups will generally act on the right, allowing better separation of the effects of two simultaneous actions.

Lattices do not always exist in nilpotent Lie groups.

**Theorem 1** *The simply connected, nilpotent Lie group $N$ admits a lattice if and only if there exists a basis of its Lie algebra $\mathfrak{n}$ for which the structure constants are rational.*

Such a group is said to have a rational structure, or simply to be rational.

A *nilmanifold* is a (compact) homogeneous space of the form $\Gamma\backslash N$, where $N$ is a connected, simply connected (rational) nilpotent Lie group and $\Gamma$ is a lattice in $N$. An *infranilmanifold* has a nilmanifold as a finite covering space. They are commonly regarded as a noncommutative generalization of tori, the Klein bottle being the simplest example of an infranilmanifold that is not a nilmanifold.

We recall the result of Marsden from O'Neill (1983).

**Theorem 2** *A compact, homogeneous pseudo-Riemannian space is geodesically complete.*

Thus, if a rational $N$ is provided with a bi-invariant metric tensor $\langle\,,\rangle$, then $M$ becomes a compact, homogeneous pseudo-Riemannian space which is therefore complete. It follows that $(N,\langle\,,\rangle)$ is itself complete. In general, however, the metric tensor is not bi-invariant and $N$ need not be complete.

For 2-step nilpotent Lie groups, things work nicely as shown by this result first published by Guediri.

**Theorem 3** *On a 2-step nilpotent Lie group, all left-invariant pseudo-Riemannian metrics are geodesically complete.*

No such general result holds for 3- and higher-step groups, however.

## 2-Step Groups

In the Riemannian (positive-definite) case, one splits $\mathfrak{n}=\mathfrak{z}\oplus\mathfrak{v}=\mathfrak{z}\oplus\mathfrak{z}^{\perp}$, where the superscript denotes the orthogonal complement with respect to the inner product $\langle\,,\rangle$. In the general pseudo-Riemannian case, however, $\mathfrak{z}\oplus\mathfrak{z}^{\perp}\neq\mathfrak{n}$. The problem is that $\mathfrak{z}$ might be a degenerate subspace; that is, it might contain a null subspace $\mathfrak{U}$ for which $\mathfrak{U}\subseteq\mathfrak{U}^{\perp}$.

It turns out that this possible degeneracy of the center causes the essential differences between the Riemannian and pseudo-Riemannian cases. So far, the only general success in studying groups with degenerate centers was in Cordero and Parker (1999) where an adapted Witt decomposition of $\mathfrak{n}$ was used together with an involution $\iota$ exchanging the two null parts.

Observe that if $\mathfrak{z}$ is degenerate, the null subspace $\mathfrak{U}$ is well defined invariantly. We shall use a decomposition

$$\mathfrak{n} = \mathfrak{z}\oplus\mathfrak{v} = \mathfrak{U}\oplus\mathfrak{Z}\oplus\mathfrak{V}\oplus\mathfrak{E} \qquad [2]$$

in which $\mathfrak{z} = \mathfrak{U} \oplus \mathfrak{Z}$ and $\mathfrak{v} = \mathfrak{V} \oplus \mathfrak{E}$, $\mathfrak{U}$ and $\mathfrak{V}$ are complementary null subspaces, and $\mathfrak{U}^\perp \cap \mathfrak{V}^\perp = \mathfrak{Z} \oplus \mathfrak{E}$. Although the choice of $\mathfrak{V}$ is not well defined invariantly, once a $\mathfrak{V}$ has been chosen then $\mathfrak{Z}$ and $\mathfrak{E}$ are well defined invariantly. Indeed, $\mathfrak{Z}$ is the portion of the center $\mathfrak{z}$ in $\mathfrak{U}^\perp \cap \mathfrak{V}^\perp$, and $\mathfrak{E}$ is its orthocomplement in $\mathfrak{U}^\perp \cap \mathfrak{V}^\perp$. This is a Witt decomposition of $\mathfrak{n}$ given $\mathfrak{U}$, easily seen by noting that $(\mathfrak{U} \oplus \mathfrak{V})^\perp = \mathfrak{Z} \oplus \mathfrak{E}$, adapted to the special role of the center in $\mathfrak{n}$.

We shall also need to use an involution $\iota$ that interchanges $\mathfrak{U}$ and $\mathfrak{V}$ and which reduces to the identity on $\mathfrak{Z} \oplus \mathfrak{E}$ in the Riemannian (positive-definite) case. (The particular choice of such an involution is not significant.) It turns out that $\iota$ is an isometry of $\mathfrak{n}$ which does not integrate to an isometry of $N$. The adjoint with respect to $\langle\,,\rangle$ of the adjoint representation of the Lie algebra $\mathfrak{n}$ on itself is denoted by $\mathrm{ad}^\dagger$.

**Definition 2** The linear mapping

$$j : \mathfrak{U} \oplus \mathfrak{Z} \to \mathrm{End}(\mathfrak{V} \oplus \mathfrak{E})$$

is given by

$$j(a)x = \iota\, \mathrm{ad}_x^\dagger\, \iota a$$

Formulas for the connection and curvatures, and explicit forms for many examples, may be found in Cordero and Parker (1999). It turns out there is a relatively large class of flat spaces, a clear distinction from the Riemannian case in which there are none.

Let $x, y \in \mathfrak{n}$. Recall that homaloidal planes are those for which the numerator $\langle R(x,y)y, x\rangle$ of the sectional curvature formula vanishes. This notion is useful for degenerate planes tangent to spaces that are not of constant curvature.

**Definition 3** A submanifold of a pseudo-Riemannian manifold is flat if and only if every plane tangent to the submanifold is homaloidal.

**Theorem 4** *The center $Z$ of $N$ is flat.*

**Corollary 1** *The only $N$ of constant curvature are flat.*

The degenerate part of the center can have a profound effect on the geometry of the whole group.

**Theorem 5** *If $[\mathfrak{n}, \mathfrak{n}] \subseteq \mathfrak{U}$ and $\mathfrak{E} = \{0\}$, then $N$ is flat.*

Among these spaces, those that also have $\mathfrak{Z} = \{0\}$ (which condition itself implies $[\mathfrak{n}, \mathfrak{n}] \subseteq \mathfrak{U}$) are fundamental, with the more general ones obtained by making nondegenerate central extensions. It is also easy to see that the product of any flat group with a nondegenerate abelian factor is still flat.

This is the best possible result in general. Using weaker hypotheses in place of $\mathfrak{E} = \{0\}$, such as $[\mathfrak{V}, \mathfrak{V}] = \{0\} = [\mathfrak{E}, \mathfrak{E}]$, it is easy to construct examples which are not flat.

**Corollary 2** *If* $\dim Z \geq \lceil n/2 \rceil$, *then there exists a flat metric on $N$.*

Here $\lceil r \rceil$ denotes the least integer greater than or equal to $r$ and $n = \dim N$.

Before continuing, we pause to collect some facts about the condition $[\mathfrak{n}, \mathfrak{n}] \subseteq \mathfrak{U}$ and its consequences.

**Remark 1** Since it implies $j(z) = 0$ for all $z \in \mathfrak{Z}$, this latter is possible with no pseudo-Euclidean de Rham factor, unlike the Riemannian case. (On the other hand, a pseudo-Euclidean de Rham factor is characterized in terms of the Kaplan-Eberlein map $j$ whenever the center is nondegenerate.)

Also, it implies $j(u)$ interchanges $\mathfrak{V}$ and $\mathfrak{E}$ for all $u \in \mathfrak{U}$ if and only if $[\mathfrak{V}, \mathfrak{V}] = [\mathfrak{E}, \mathfrak{E}] = \{0\}$. Examples are the Heisenberg group and the groups $H(p, 1)$ for $p \geq 2$ with null centers.

Finally, we note that it implies that, for every $u \in \mathfrak{U}$, $j(u)$ maps $\mathfrak{V}$ to $\mathfrak{V}$ if and only if $j(u)$ maps $\mathfrak{E}$ to $\mathfrak{E}$ if and only if $[\mathfrak{V}, \mathfrak{E}] = \{0\}$.

**Proposition 2** *If $j(z) = 0$ for all $z \in \mathfrak{Z}$ and $j(u)$ interchanges $\mathfrak{V}$ and $\mathfrak{E}$ for all $u \in \mathfrak{U}$, then $N$ is Ricci flat.*

**Proposition 3** *If $j(z) = 0$ for all $z \in \mathfrak{Z}$, then $N$ is scalar flat. In particular, this occurs when $[\mathfrak{n}, \mathfrak{n}] \subseteq \mathfrak{U}$.*

Much like the Riemannian case, we would expect that $(N, \langle\,,\rangle)$ should in some sense be similar to flat pseudo-Euclidean space. This is seen, for example, via the existence of totally geodesic subgroups (Cordero and Parker 1999). (O'Neill (1983, ex. 9, p. 125) has extended the definition of totally geodesic to degenerate submanifolds of pseudo-Riemannian manifolds.)

**Example 1** For any $x \in \mathfrak{n}$ the one-parameter subgroup $\exp(tx)$ is a geodesic if and only if $x \in \mathfrak{z}$ or $x \in \mathfrak{U} \oplus \mathfrak{E}$. This is essentially the same as the Riemannian case, but with some additional geodesic one-parameter subgroups coming from $\mathfrak{U}$.

**Example 2** Abelian subspaces of $\mathfrak{V} \oplus \mathfrak{E}$ are Lie subalgebras of $\mathfrak{n}$, and give rise to complete, flat, totally geodesic abelian subgroups of $N$, just as in the Riemannian case. Eberlein's construction is valid in general, and shows that if $\dim \mathfrak{V} \oplus \mathfrak{E} \geq 1 + k + k \dim \mathfrak{z}$, then every nonzero element of $\mathfrak{V} \oplus \mathfrak{E}$ lies in an abelian subspace of dimension $k + 1$.

**Example 3** The center $Z$ of $N$ is a complete, flat, totally geodesic submanifold. Moreover, it determines a foliation of $N$ by its left translates, so each leaf is flat and totally geodesic, as in the Riemannian

case. In the pseudo-Riemannian case, this foliation in turn is the orthogonal direct sum of two foliations determined by $\mathfrak{U}$ and $\mathfrak{Z}$, and the leaves of the $\mathfrak{U}$-foliation are also null. All these leaves are complete.

There is also the existence of $\dim \mathfrak{z}$ independent first integrals, a familiar result in pseudo-Euclidean space, and the geodesic equations are completely integrable; in certain cases (mostly when the center is nondegenerate), one can obtain explicit formulas. Unlike the Riemannian case, there are flat groups (nonabelian) which are isometric to pseudo-Euclidean spaces (abelian).

**Theorem 6** *If* $[\mathfrak{n}, \mathfrak{n}] \subseteq \mathfrak{U}$ *and* $\mathfrak{E} = \{0\}$, *then* $N$ *is geodesically connected. Consequently, so is any nilmanifold with such a universal covering space.*

Thus, these compact nilmanifolds are much like tori. This is also illustrated by the computation of their period spectrum.

### Isometry Group

The main new feature is that when the center is degenerate, the isometry group can be strictly larger in a significant way than when the center is nondegenerate (which includes the Riemannian case).

Letting $\mathrm{Aut}(N)$ denote the automorphism group of $N$ and $I(N)$ the isometry group of $N$, set $O(N) = \mathrm{Aut}(N) \cap I(N)$. In the Riemannian case, $I(N) = O(N) \ltimes N$, the semidirect product where $N$ acts as left translations. We have chosen the notation $O(N)$ to suggest an analogy with the pseudo-Euclidean case in which this subgroup is precisely the (general, including reflections) pseudo-orthogonal group. According to Wilson (1982), this analogy is good for any nilmanifold (not necessarily 2-step).

To see what is true about the isometry group in general, first consider the (left-invariant) splitting of the tangent bundle $TN = \mathfrak{z}N \oplus \mathfrak{v}N$.

**Definition 4** Denote by $I^{\mathrm{spl}}(N)$ the subgroup of the isometry group $I(N)$ which preserves the splitting $TN = \mathfrak{z}N \oplus \mathfrak{v}N$. Further, let $I^{\mathrm{aut}}(N) = O(N) \ltimes N$, where $N$ acts by left translations.

**Proposition 4** *If* $N$ *is a simply connected, 2-step nilpotent Lie group with left-invariant metric tensor, then* $I^{\mathrm{spl}}(N) \leq I^{\mathrm{aut}}(N)$.

There are examples to show that $I^{\mathrm{spl}} < I^{\mathrm{aut}}$ is possible when $\mathfrak{U} \neq \{0\}$.

When the center is degenerate, the relevant group analogous to a pseudo-orthogonal group may be larger.

**Proposition 5** *Let* $\tilde{O}(N)$ *denote the subgroup of* $I(N)$ *which fixes* $1 \in N$. *Then* $I(N) \cong \tilde{O}(N) \ltimes N$, *where* $N$ *acts by left translations.*

The proof is obvious from the definition of $\tilde{O}$. It is also obvious that $O \leq \tilde{O}$. Examples show that $O < \tilde{O}$, hence $I^{\mathrm{aut}} < I$, is possible when the center is degenerate.

Thus, we have three groups of isometries, not necessarily equal in general: $I^{\mathrm{spl}} \leq I^{\mathrm{aut}} \leq I$. When the center is nondegenerate ($\mathfrak{U} = \{0\}$), the Ricci transformation is block-diagonalizable and the rest of Kaplan's proof using it now also works.

**Corollary 3** *If the center is nondegenerate, then* $I(N) = I^{\mathrm{spl}}(N)$ *whence* $\tilde{O}(N) \cong O(N)$.

In the next few results, we use the phrase "a subgroup isometric to" a group to mean that the isometry is also an isomorphism of groups.

**Proposition 6** *For any* $N$ *containing a subgroup isometric to the flat three-dimensional Heisenberg group,*

$$I^{\mathrm{spl}}(N) < I^{\mathrm{aut}}(N) < I(N)$$

Unfortunately, this class does not include our flat groups in which $[\mathfrak{n}, \mathfrak{n}] \subseteq \mathfrak{U}$ and $\mathfrak{E} = \{0\}$. However, it does include many groups that do not satisfy $[\mathfrak{n}, \mathfrak{n}] \subseteq \mathfrak{U}$, such as the simplest quaternionic Heisenberg group.

**Remark 2** A direct computation shows that on this flat $H_3$ with null center, the only Killing fields with geodesic integral curves are the nonzero scalar multiples of a vector field tangent to the center.

**Proposition 7** *For any* $N$ *containing a subgroup isometric to the flat* $H_3 \times \mathbb{R}$ *with null center,*

$$I^{\mathrm{spl}}(N) < I^{\mathrm{aut}}(N) < I(N)$$

Many of our flat groups in which $[\mathfrak{n}, \mathfrak{n}] \subseteq \mathfrak{U}$ and $\mathfrak{E} = \{0\}$ have such a subgroup isometrically embedded, as in fact do many others which are not flat.

### Lattices and Periodic Geodesics

In this subsection, we assume that $N$ is rational and let $\Gamma$ be a lattice in $N$.

Certain tori $T_F$ and $T_B$ provide the model fiber and the base for a submersion of the coset space $\Gamma \backslash N$. This submersion may not be pseudo-Riemannian in the usual sense, because the tori may be degenerate. We began the study of periodic geodesics in these compact nilmanifolds, and obtained a complete calculation of the period spectrum for certain flat spaces.

To the compact nilmanifold $\Gamma\backslash N$ we may associate two flat (possibly degenerate) tori.

**Definition 5** Let $N$ be a simply connected, two-step nilpotent Lie group with lattice $\Gamma$ and let $\pi : \mathfrak{n} \to \mathfrak{v}$ denote the projection. Define

$$T_{\mathfrak{z}} = \mathfrak{z}/(\log \Gamma \cap \mathfrak{z})$$
$$T_{\mathfrak{v}} = \mathfrak{v}/\pi(\log \Gamma)$$

Observe that $\dim T_{\mathfrak{z}} + \dim T_{\mathfrak{v}} = \dim \mathfrak{z} + \dim \mathfrak{v} = \dim \mathfrak{n}$.

Let $m = \dim \mathfrak{z}$ and $n = \dim \mathfrak{v}$. It is a consequence of a theorem of Palais and Stewart that $\Gamma\backslash N$ is a principal $T^m$-bundle over $T^n$. The model fiber $T^m$ can be given a geometric structure from its closed embedding in $\Gamma\backslash N$; we denote this geometric $m$-torus by $T_F$. Similarly, we wish to provide the base $n$-torus with a geometric structure so that the projection $p_B : \Gamma\backslash N \twoheadrightarrow T_B$ is the appropriate generalization of a pseudo-Riemannian submersion (O'Neill 1983) to (possibly) degenerate spaces. Observe that the splitting $\mathfrak{n} = \mathfrak{z} \oplus \mathfrak{v}$ induces splittings $TN = \mathfrak{z}N \oplus \mathfrak{v}N$ and $T(\Gamma\backslash N) = \mathfrak{z}(\Gamma\backslash N) \oplus \mathfrak{v}(\Gamma\backslash N)$, and that $p_{B*}$ just mods out $\mathfrak{z}(\Gamma\backslash N)$. Examining O'Neill's definition, we see that the key is to construct the geometry of $T_B$ by defining

$$p_{B*} : \mathfrak{v}_\eta(\Gamma\backslash N) \to T_{p_B(\eta)}(T_B) \quad \text{for each } \eta \in \Gamma\backslash N \text{ is an isometry} \qquad [3]$$

and

$$\nabla^{T_B}_{p_{B*}x} p_{B*}y = p_{B*}(\pi \nabla_x y) \quad \text{for all } x, y \in \mathfrak{v} = \mathfrak{V} \oplus \mathfrak{E} \qquad [4]$$

where $\pi : \mathfrak{n} \to \mathfrak{v}$ is the projection. Then the rest of the usual results will continue to hold, provided that sectional curvature is replaced by the numerator of the sectional curvature formula at least when elements of $\mathfrak{V}$ are involved:

$$\langle R_{T_B}(p_{B*}x, p_{B*}y)\, p_{B*}y, p_{B*}x\rangle = \langle R_{\Gamma\backslash N}(x, y)y, x\rangle + \tfrac{3}{4}\langle [x, y], [x, y]\rangle \qquad [5]$$

Now $p_B$ will be a pseudo-Riemannian submersion in the usual sense if and only if $\mathfrak{U} = \mathfrak{V} = \{0\}$, as is always the case for Riemannian spaces.

In the Riemannian case, Eberlein showed that $T_F \cong T_{\mathfrak{z}}$ and $T_B \cong T_{\mathfrak{v}}$. In general, $T_B$ is flat only if $N$ has a nondegenerate center or is flat.

**Remark 3** Observe that the torus $T_B$ may be decomposed into a topological product $T_E \times T_V$ in the obvious way. It is easy to check that $T_E$ is flat and isometric to $(\log \Gamma \cap \mathfrak{E})\backslash \mathfrak{E}$, and that $T_V$ has a linear connection not coming from a metric and not flat in general. Moreover, the geometry of the product is "twisted" in a certain way. It would be interesting to determine which tori could appear as such a $T_V$ and how.

**Theorem 7** *Let $N$ be a simply connected, 2-step nilpotent Lie group with lattice $\Gamma$, a left-invariant metric tensor, and tori as above. The fibers $T_F$ of the (generalized) pseudo-Riemannian submersion $\Gamma\backslash N \twoheadrightarrow T_B$ are isometric to $T_{\mathfrak{z}}$. If in addition the center $Z$ of $N$ is nondegenerate, then the base $T_B$ is isometric to $T_{\mathfrak{v}}$.*

We recall that elements of $N$ can be identified with elements of the isometry group $I(N)$: namely, $n \in N$ is identified with the isometry $\phi = L_n$ of left translation by $n$. We shall abbreviate this by writing $\phi \in N$.

**Definition 6** We say that $\phi \in N$ translates the geodesic $\gamma$ by $\omega$ if and only if $\phi\gamma(t) = \gamma(t + \omega)$ for all $t$. If $\gamma$ is a unit-speed geodesic, we say that $\omega$ is a period of $\phi$.

Recall that unit speed means that $|\dot\gamma| = |\langle \dot\gamma, \dot\gamma\rangle|^{1/2} = 1$. Since there is no natural normalization for null geodesics, we do not define periods for them. In the Riemannian case and in the timelike Lorentzian case in strongly causal spacetimes, unit-speed geodesics are parametrized by arclength and this period is a translation distance. If $\phi$ belongs to a lattice $\Gamma$, it is the length of a closed geodesic in $\Gamma\backslash N$.

In general, recall that if $\gamma$ is a geodesic in $N$ and if $p_N : N \twoheadrightarrow \Gamma\backslash N$ denotes the natural projection, then $p_N\gamma$ is a periodic geodesic in $\Gamma\backslash N$ if and only if some $\phi \in \Gamma$ translates $\gamma$. We say *periodic* rather than *closed* here because in pseudo-Riemannian spaces it is possible for a null geodesic to be closed but not periodic. If the space is geodesically complete or Riemannian, however, then this does not occur; the former is in fact the case for our 2-step nilpotent Lie groups. Further, recall that free homotopy classes of closed curves in $\Gamma\backslash N$ correspond bijectively with conjugacy classes in $\Gamma$.

**Definition 7** Let $\mathcal{C}$ denote either a nontrivial, free homotopy class of closed curves in $\Gamma\backslash N$ or the corresponding conjugacy class in $\Gamma$. We define $\wp(\mathcal{C})$ to be the set of all periods of periodic unit-speed geodesics that belong to $\mathcal{C}$.

In the Riemannian case, this is the set of lengths of closed geodesics in $\mathcal{C}$, frequently denoted by $\ell(\mathcal{C})$.

**Definition 8** The *period spectrum* of $\Gamma\backslash N$ is the set

$$\mathrm{spec}_\wp(\Gamma\backslash N) = \bigcup_{\mathcal{C}} \wp(\mathcal{C})$$

where the union is taken over all nontrivial, free homotopy classes of closed curves in $\Gamma\backslash N$.

In the Riemannian case, this is the length spectrum $\mathrm{spec}_\ell(\Gamma\backslash N)$.

**Example 4** Similar to the Riemannian case, we can compute the period spectrum of a flat torus $\Gamma\backslash\mathbb{R}^m$, where $\Gamma$ is a lattice (of maximal rank, isomorphic to $\mathbb{Z}^m$). Using calculations in an analogous way as for finding the length spectrum of a Riemannian flat torus, we easily obtain

$$\mathrm{spec}_\wp(\Gamma\backslash\mathbb{R}^m) = \{|g| \neq 0 \mid g \in \Gamma\}$$

It is also easy to see that the nonzero d'Alembertian spectrum is related to the analogous set produced from the dual lattice $\Gamma^*$, multiplied by factors of $\pm 4\pi^2$, almost as in the Riemannian case.

As in this example, simple determinacy of periods of unit-speed geodesics helps make calculation of the period spectrum possible purely in terms of $\log\Gamma \subseteq \mathfrak{n}$.

For the rest of this subsection, we assume that $N$ is a simply connected, two-step nilpotent Lie group with left-invariant pseudo-Riemannian metric tensor $\langle\,,\rangle$. Note that non-null geodesics may be taken to be of unit speed. Most non-identity elements of $N$ translate some geodesic, but not necessarily one of unit speed.

For our special class of flat 2-step nilmanifolds, we can calculate the period spectrum completely.

**Theorem 8** *If* $[\mathfrak{n},\mathfrak{n}] \subseteq \mathfrak{U}$ *and* $\mathfrak{E} = \{0\}$, *then* $\mathrm{spec}_\wp(M)$ *can be completely calculated from* $\log\Gamma$ *for any* $M = \Gamma\backslash N$.

Thus, we see again just how much these flat, two-step nilmanifolds are like tori. All periods can be calculated purely from $\log\Gamma \subseteq \mathfrak{n}$, although some will not show up from the tori in the fibration.

**Corollary 4** $\mathrm{spec}_\wp(T_B)$ (*respectively*, $T_F$) *is* $\cup_{\mathcal{C}}\wp(\mathcal{C})$ *where the union is taken over all those free homotopy classes* $\mathcal{C}$ *of closed curves in* $M = \Gamma\backslash N$ *that* do not (*respectively*, do) *contain an element in the center of* $\Gamma \cong \pi_1(M)$, *except for those periods arising only from unit-speed geodesics in* $M$ *that project to null geodesics in both* $T_B$ *and* $T_F$.

We note that one might consider using this to assign periods to some null geodesics in the tori $T_B$ and $T_F$.

When the center is nondegenerate, we obtain results similar to Eberlein's. Here is part of them.

**Theorem 9** *Assume* $\mathfrak{U} = \{0\}$. *Let* $\phi \in N$ *and write* $\log\phi = z^* + e^*$. *Assume* $\phi$ *translates the unit-speed geodesic* $\gamma$ *by* $\omega > 0$. *Let* $z'$ *denote the component of* $z^*$ *orthogonal to* $[e^*,\mathfrak{n}]$ *and set* $\omega^* = |z' + e^*|$. *Let* $\dot\gamma(0) = z_0 + e_0$. *Then*

(i) $|e^*| \leq \omega$. *In addition,* $\omega < \omega^*$ *for timelike (spacelike) geodesics with* $\omega z_0 - z'$ *timelike (spacelike), and* $\omega > \omega^*$ *for timelike (spacelike) geodesics with* $\omega z_0 - z'$ *spacelike (timelike);*

(ii) $\omega = |e^*|$ *if and only if* $\gamma(t) = \exp(te^*/|e^*|)$ *for all* $t \in \mathbb{R}$; *and*

(iii) $\omega = \omega^*$ *if and only if* $\omega z_0 - z'$ *is null.*

Although $\omega^*$ need not be an upper bound for periods as in the Riemannian case, it nonetheless plays a special role among all periods, as seen in (iii) above, and we shall refer to it as the distinguished period associated with $\phi \in N$. When the center is definite, for example, we do have $\omega \leq \omega^*$.

Now the following definitions make sense at least for $N$ with a nondegenerate center.

**Definition 9** Let $\mathcal{C}$ denote either a nontrivial, free homotopy class of closed curves in $\Gamma\backslash N$ or the corresponding conjugacy class in $\Gamma$. We define $\wp^*(\mathcal{C})$ to be the distinguished periods of periodic unit-speed geodesics that belong to $\mathcal{C}$.

**Definition 10** The *distinguished period spectrum* of $\Gamma\backslash N$ is the set

$$\mathcal{D}\mathrm{spec}_\wp(\Gamma\backslash N) = \bigcup_{\mathcal{C}} \wp^*(\mathcal{C})$$

where the union is taken over all nontrivial, free homotopy classes of closed curves in $\Gamma\backslash N$.

Then we get this result:

**Corollary 5** *Assume the center is nondegenerate. If* $\mathfrak{n}$ *is nonsingular, then* $\mathrm{spec}_\wp(T_B)$ (*respectively*, $T_F$) *is precisely the period spectrum (respectively, the distinguished period spectrum) of those free homotopy classes* $\mathcal{C}$ *of closed curves in* $M = \Gamma\backslash N$ *that do not (respectively, do) contain an element in the center of* $\Gamma \cong \pi_1(M)$, *except for those periods arising only from unit-speed geodesics in* $M$ *that project to null geodesics in both* $T_B$ *and* $T_F$.

## Conjugate Loci

This is the only general result on conjugate points.

**Proposition 8** *Let* $N$ *be a simply connected, 2-step nilpotent Lie group with left-invariant metric tensor* $\langle\,,\rangle$, *and let* $\gamma$ *be a geodesic with* $\dot\gamma(0) = a \in \mathfrak{z}$. *If* $\mathrm{ad}^\dagger_\bullet a = 0$, *then there are no conjugate points along* $\gamma$.

In the rest of this subsection, we assume that the center of $N$ is nondegenerate.

For convenience, we shall use the notation $J_z = \mathrm{ad}^\dagger_\bullet z$ for any $z \in \mathfrak{z}$. (Since the center is

nondegenerate, the involution $\iota$ may be omitted.) We follow Ciatti (2000) for this next definition. As in the Riemannian case, one might as well make 2-step nilpotency part of the definition since it effectively is so anyway.

**Definition 11** $N$ is said to be of *pseudoH-type* if and only if

$$J_z^2 = -\langle z, z\rangle I$$

for any $z \in \mathfrak{z}$.

Complete results on conjugate loci have been obtained only for these groups (Jang *et al.* 2005). For example, using standard results from analytic function theory, one can show that the conjugate locus is an analytic variety in $N$. This is probably true for general two-step groups, but the proof we know works only for pseudo$H$-type.

**Definition 12** Let $\gamma$ denote a geodesic and assume that $\gamma(t_0)$ is conjugate to $\gamma(0)$ along $\gamma$. To indicate that the multiplicity of $\gamma(t_0)$ is $m$, we shall write $\text{mult}_{\text{cp}}(t_0) = m$. To distinguish the notions clearly, we shall denote the multiplicity of $\lambda$ as an eigenvalue of a specified linear transformation by $\text{mult}_{\text{ev}}\lambda$.

Let $\gamma$ be a geodesic with $\gamma(0) = 1$ and $\dot\gamma(0) = z_0 + x_0 \in \mathfrak{z} \oplus \mathfrak{v}$, respectively, and let $J = J_{z_0}$. If $\gamma$ is not null, we may assume that $\gamma$ is normalized so that $\langle\dot\gamma,\dot\gamma\rangle = \pm 1$. As usual, $\mathbb{Z}^*$ denotes the set of all integers with 0 removed.

**Theorem 10** *Under these assumptions, if $N$ is of pseudoH-type, then*:

(i) *if $z_0 = 0$ and $x_0 \neq 0$, then $\gamma(t)$ is conjugate to $\gamma(0)$ along $\gamma$ if and only if $\langle x_0, x_0\rangle < 0$ and*

$$-\frac{12}{t^2} = \langle x_0, x_0\rangle$$

*in which case* $\text{mult}_{\text{cp}}(t) = \dim \mathfrak{z}$;

(ii) *if $z_0 \neq 0$ and $x_0 = 0$, then $\gamma(t)$ is conjugate to $\gamma(0)$ along $\gamma$ if and only if $\langle z_0, z_0\rangle > 0$ and*

$$t \in \frac{2\pi}{|z_0|}\mathbb{Z}^*$$

*in which case* $\text{mult}_{\text{cp}}(t) = \dim \mathfrak{v}$.

**Theorem 11** *Let $\gamma$ be such a geodesic in a pseudoH-type group $N$ with $z_0 \neq 0 \neq x_0$.*

(i) *If $\langle z_0, z_0\rangle = \alpha^2$ with $\alpha > 0$, then $\gamma(t_0)$ is conjugate to $\gamma(0)$ along $\gamma$ if and only if*

$$t_0 \in \frac{2\pi}{\alpha}\mathbb{Z}^* \cup \mathbb{A}_1 \cup \mathbb{A}_2$$

*where*

$$\mathbb{A}_1 = \left\{ t \in \mathbb{R} \,\middle|\, \langle x_0, x_0\rangle \frac{\alpha t}{2}\cot\frac{\alpha t}{2} = \langle\dot\gamma,\dot\gamma\rangle \right\}$$

*and*

$$\mathbb{A}_2 = \left\{ t \in \mathbb{R} \,\middle|\, \alpha t = \frac{\langle x_0, x_0\rangle}{\langle\dot\gamma,\dot\gamma\rangle + \langle z_0, z_0\rangle}\sin\alpha t \right\}$$

*when* $\dim\mathfrak{z} \geq 2$

*If $t_0 \in (2\pi/\alpha)\mathbb{Z}^*$, then*

$$\text{mult}_{\text{cp}}(t_0) = \begin{cases} \dim\mathfrak{v} - 1 & \textit{if } \langle\dot\gamma,\dot\gamma\rangle + \langle z_0, z_0\rangle \neq 0 \\ \dim\mathfrak{n} - 2 & \textit{if } \langle\dot\gamma,\dot\gamma\rangle + \langle z_0, z_0\rangle = 0 \end{cases}$$

*If $t_0 \notin (2\pi/\alpha)\mathbb{Z}^*$, then*

$$\text{mult}_{\text{cp}}(t_0) = \begin{cases} 1 & \textit{if } t_0 \in \mathbb{A}_1 - \mathbb{A}_2 \\ \dim\mathfrak{z} - 1 & \textit{if } t_0 \in \mathbb{A}_2 - \mathbb{A}_1 \\ \dim\mathfrak{z} & \textit{if } t_0 \in \mathbb{A}_1 \cap \mathbb{A}_2 \end{cases}$$

(ii) *If $\langle z_0, z_0\rangle = -\beta^2$ with $\beta > 0$, then $\gamma(t_0)$ is a conjugate point along $\gamma$ if and only if $t_0 \in \mathbb{B}_1 \cup \mathbb{B}_2$ where*

$$\mathbb{B}_1 = \left\{ t \in \mathbb{R} \,\middle|\, \langle x_0, x_0\rangle \frac{\beta t}{2}\coth\frac{\beta t}{2} = \langle\dot\gamma,\dot\gamma\rangle \right\}$$

*and*

$$\mathbb{B}_2 = \left\{ t \in \mathbb{R} \,\middle|\, \beta t = \frac{\langle x_0, x_0\rangle}{\langle\dot\gamma,\dot\gamma\rangle + \langle z_0, z_0\rangle}\sinh\beta t \right\}$$

*when* $\dim\mathfrak{z} \geq 2$

*The multiplicity is*

$$\text{mult}_{\text{cp}}(t_0) = \begin{cases} 1 & \textit{if } t_0 \in \mathbb{B}_1 - \mathbb{B}_2 \\ \dim\mathfrak{z} - 1 & \textit{if } t_0 \in \mathbb{B}_2 - \mathbb{B}_1 \\ \dim\mathfrak{z} & \textit{if } t_0 \in \mathbb{B}_1 \cap \mathbb{B}_2 \end{cases}$$

(iii) *If $\langle z_0, z_0\rangle = 0$, then $\gamma(t_0)$ is a conjugate point along $\gamma$ if and only if*

$$t_0^2 = -\frac{12}{\langle x_0, x_0\rangle}$$

*and* $\text{mult}_{\text{cp}}(t_0) = \dim\mathfrak{z} - 1$.

This covers all cases for a pseudo$H$-type group with a center of any dimension.

Some results on other two-step groups and examples (including pictures in dimension 3) may be found in the references cited in Jang *et al.* (2005). When the groups are not pseudo$H$-type, however, complete results are available only when the center is one dimensional. Guediri (2004) has results in the timelike Lorentzian case.

## Lorentzian Groups

Not too long ago, only a few partial results in the line of Milnor's study of definite metrics were known for indefinite metrics (Barnet 1989, Nomizu 1979), and they were Lorentzian.

Guediri (2003) and others have made special study of Lorentzian two-step groups, partly because of their relevance to general relativity, where they can be used to provide interesting and important (counter)examples. Special features of Lorentzian geometry frequently enable them to obtain much more complete and explicit results than are possible in general.

For example, Guediri (2003) was able to provide a complete and explicit integration of the geodesic equations for Lorentzian 2-step groups. This includes the case of a degenerate center, which only required extremely careful handling through a number of cases. He also paid special attention to the existence of closed timelike geodesics, reflecting the relativistic concerns.

As usual, $N$ denotes a connected and simply connected 2-step nilpotent Lie group. For the rest of this section, we assume that the left-invariant metric tensor is Lorentzian. Whenever a lattice is mentioned, we also assume that the group is rational.

**Proposition 9** *If the center is degenerate, then no timelike geodesic can be translated by a central element.*

Thus, there can be no closed timelike geodesics parallel to the center in any nilmanifold obtained from such an $N$.

**Theorem 12** *If the center is Lorentzian, then $\Gamma\backslash N$ contains no timelike or null closed geodesics for any lattice $\Gamma$.*

To handle degenerate centers, three refined notions for nonsingular are used: *almost*, *weakly*, and *strongly* nonsingular. The precise definitions involve an adapted Witt decomposition (as in the general pseudo-Riemannian case, but a rather different one here) and are quite technical, as is typical. We refer to Guediri (2003) for details.

**Theorem 13** *If $N$ is weakly nonsingular, then no timelike geodesic can be translated by an element of $N$.*

**Corollary 6** *If $N$ is flat, then no timelike geodesic can be translated by a non-identity element.*

**Corollary 7** *If $N$ is flat, then $\Gamma\backslash N$ contains no closed timelike geodesics for any lattice $\Gamma$.*

**Corollary 8** *If $N$ is weakly nonsingular, then $\Gamma\backslash N$ contains no closed timelike geodesic.*

**Corollary 9** *If $N = H_{2k+1}$ is a Lorentzian Heisenberg group with degenerate center, then $\Gamma\backslash N$ contains no closed timelike geodesic.*

Guediri also has the only non-Riemannian results so far about the phenomenon Eberlein called "in resonance." Roughly speaking, this occurs when the eigenvalues of the map $j$ have rational ratios. (The Lorentzian case actually requires a slightly more complicated condition when the center is degenerate.)

**Theorem 14** *If $N$ is almost nonsingular, then $N$ is in resonance if and only if every geodesic of $N$ is translated by some element of $N$.*

## $q$-Special Functions

**T H Koornwinder**, University o
f Amsterdam, Amsterdam, The Netherlands

### Introduction

In this article we give a brief introduction to $q$-special functions, that is, $q$-analogs of the classical special functions. Here $q$ is a deformation parameter, usually $0 < q < 1$, where $q = 1$ is the classical case. The deformation is such that the calculus simultaneously deforms to a $q$-calculus involving $q$-derivatives and $q$-integrals. The main topics to be treated are $q$-hypergeometric series, with some selected evaluation and transformation formulas, and some $q$-hypergeometric orthogonal polynomials, most notably the Askey–Wilson polynomials. In several variables, we discuss Macdonald polynomials associated with root systems, with most emphasis on the $A_n$ case. The rather new theory of elliptic hypergeometric series gets some attention. While much of the theory of $q$-special functions keeps $q$ fixed, some of the deeper aspects with number-theoretic and combinatorial flavor emphasize expansion in $q$. Finally, we indicate applications and interpretations in quantum groups, Chevalley groups, affine Lie algebras, combinatorics, and statistical mechanics.

#### Conventions

$q \in \mathbb{C}\backslash\{1\}$ in general, but $0 < q < 1$ in all infinite sums and products.
$n, m, N$ will be non-negative integers unless mentioned otherwise.

### $q$-Hypergeometric Series

#### Definitions

For $a, q \in \mathbb{C}$ the $q$-shifted factorial $(a;q)_k$ is defined as a product of $k$ factors:

$$(a;q)_k := (1-a)(1-aq)\cdots(1-aq^{k-1}) \quad (k \in \mathbb{Z}_{>0}); \quad (a;q)_0 := 1 \qquad [1]$$

If $|q| < 1$ this definition remains meaningful for $k = \infty$ as a convergent infinite product:

$$(a;q)_\infty := \prod_{j=0}^{\infty}(1-aq^j) \qquad [2]$$

We also write $(a_1, \ldots, a_r; q)_k$ for the product of $r$ $q$-shifted factorials:

$$(a_1, \ldots, a_r; q)_k := (a_1;q)_k \ldots (a_r;q)_k \quad (k \in \mathbb{Z}_{\geq 0} \text{ or } k = \infty) \qquad [3]$$

A $q$-hypergeometric series is a power series (for the moment still formal) in one complex variable $z$ with power series coefficients which depend, apart from $q$, on $r$ complex upper parameters $a_1, \ldots, a_r$ and $s$ complex lower parameters $b_1, \ldots, b_s$ as follows:

$$\begin{aligned} {}_r\phi_s\left[\begin{matrix} a_1, \ldots, a_r \\ b_1, \ldots, b_s \end{matrix}; q, z\right] &= {}_r\phi_s(a_1, \ldots, a_r; b_1, \ldots, b_s; q, z) \\ &:= \sum_{k=0}^{\infty} \frac{(a_1, \ldots, a_r; q)_k}{(b_1, \ldots, b_s; q)_k (q;q)_k} \\ &\quad \times \left((-1)^k q^{(1/2)k(k-1)}\right)^{s-r+1} z^k \quad (r, s \in \mathbb{Z}_{\geq 0}) \end{aligned} \qquad [4]$$

Clearly the above expression is symmetric in $a_1, \ldots, a_r$ and symmetric in $b_1, \ldots, b_s$. On the right-hand side of [4], we have that

$$\frac{(k+1)\text{th term}}{k\text{th term}} = \frac{(1-a_1q^k)\cdots(1-a_rq^k)(-q^k)^{s-r+1}z}{(1-b_1q^k)\cdots(1-b_sq^k)(1-q^{k+1})} \qquad [5]$$

is rational in $q^k$. Conversely, any rational function in $q^k$ can be written in the form of the right-hand side of [5]. Hence, any series $\sum_{k=0}^{\infty} c_k$ with $c_0 = 1$ and $c_{k+1}/c_k$ rational in $q^k$ is of the form of a $q$-hypergeometric series [4].

In order to avoid singularities in the terms of [4], we assume that $b_1, \ldots, b_s \neq 1, q^{-1}, q^{-2}, \ldots$. If, for some $i, a_i = q^{-n}$, then all terms in the series [4] with $k > n$ will vanish. If none of the $a_i$ is equal to $q^{-n}$

and if $|q| < 1$, then the radius of convergence of the power series [4] equals $\infty$ if $r < s+1$, 1 if $r = s+1$, and 0 if $r > s+1$.

We can view the $q$-shifted factorial as a $q$-analog of the shifted factorial (or Pochhammer symbol) by the limit formula

$$\lim_{q\to 1}\frac{(q^a;q)_k}{(1-q)^k} = (a)_k := a(a+1)\cdots(a+k-1) \quad [6]$$

Hence the $q$-binomial coefficient

$$\begin{bmatrix} n \\ k \end{bmatrix}_q := \frac{(q;q)_n}{(q;q)_k(q;q)_{n-k}} \quad (n,k\in\mathbb{Z}, n\geq k\geq 0) \quad [7]$$

tends to the binomial coefficient for $q \to 1$:

$$\lim_{q\to 1}\begin{bmatrix} n \\ k \end{bmatrix}_q = \binom{n}{k} \quad [8]$$

and a suitably renormalized $q$-hypergeometric series tends (at least formally) to a hypergeometric series as $q \uparrow 1$:

$$\lim_{q\uparrow 1} {}_{r+r'}\phi_{s+s'}\left[\begin{matrix} q^{a_1},\ldots,q^{a_r},c_1,\ldots,c_{r'} \\ q^{b_1},\ldots,q^{b_s},d_1,\ldots,d_{s'}\end{matrix};q,(q-1)^{1+s-r}z\right]$$
$$= {}_rF_s\left(\begin{matrix} a_1,\ldots,a_r \\ b_1,\ldots,b_s\end{matrix};\frac{(c_1-1)\cdots(c_{r'}-1)z}{(d_1-1)\cdots(d_{s'}-1)}\right) \quad [9]$$

At least formally, there are limit relations between $q$-hypergeometric series with neighboring $r, s$:

$$\lim_{a_r\to\infty} {}_r\phi_s\left[\begin{matrix} a_1,\ldots,a_r \\ b_1,\ldots,b_s\end{matrix};q,\frac{z}{a_r}\right] = {}_{r-1}\phi_s\left[\begin{matrix} a_1,\ldots,a_{r-1} \\ b_1,\ldots,b_s\end{matrix};q,z\right] \quad [10]$$

$$\lim_{b_s\to\infty} {}_r\phi_s\left[\begin{matrix} a_1,\ldots,a_r \\ b_1,\ldots,b_s\end{matrix};q,b_s z\right] = {}_r\phi_{s-1}\left[\begin{matrix} a_1,\ldots,a_r \\ b_1,\ldots,b_{s-1}\end{matrix};q,z\right] \quad [11]$$

A terminating $q$-hypergeometric series $\sum_{k=0}^{n} c_k z^k$ rewritten as $z^n \sum_{k=0}^{n} c_{n-k} z^{-k}$ yields another terminating $q$-hypergeometric series, for instance:

$$\begin{aligned} &{}_{s+1}\phi_s\left[\begin{matrix} q^{-n},a_1,\ldots,a_s \\ b_1,\ldots,b_s\end{matrix};q,z\right] \\ &= (-1)^n q^{-(1/2)n(n+1)}\frac{(a_1,\ldots,a_n;q)_n}{(b_1,\ldots,b_s;q)_n} z^n \\ &\times {}_{s+1}\phi_s\left[\begin{matrix} q^{-n},q^{-n+1}b_1^{-1},\ldots,q^{-n+1}b_s^{-1} \\ q^{-n+1}a_1^{-1},\ldots,q^{-n+1}a_s^{-1}\end{matrix}; q,\frac{q^{n+1}b_1\cdots b_s}{a_1\cdots a_s z}\right] \end{aligned} \quad [12]$$

Often, in physics and quantum groups related literature, the following notation is used for $q$-number, $q$-factorial, and $q$-Pochhammer symbol:

$$[a]_q := \frac{q^{(1/2)a}-q^{-(1/2)a}}{q^{1/2}-q^{-1/2}} \qquad [k]_q! := \prod_{j=1}^{k}[j]_q$$
$$([a]_q)_k := \prod_{j=0}^{k-1}[a+j]_q \quad (k\in\mathbb{Z}_{\geq 0}) \quad [13]$$

For $q \to 1$, these symbols tend to their classical counterparts without the need for renormalization. They are expressed in terms of the standard notation [1] as follows:

$$\begin{aligned} [k]_q! &= q^{-(1/4)k(k-1)}\frac{(q;q)_k}{(1-q)^k} \\ ([a]_q)_k &= q^{-(1/2)k(a-1)}\,q^{-(1/4)k(k-1)}\frac{(q^a;q)_k}{(1-q)^k} \end{aligned} \quad [14]$$

### Special Cases

For $s = r-1$, formula [4] simplifies to

$$\begin{aligned} &{}_r\phi_{r-1}\left[\begin{matrix} a_1,\ldots,a_r \\ b_1,\ldots,b_{r-1}\end{matrix};q,z\right] \\ &= \sum_{k=0}^{\infty}\frac{(a_1,\ldots,a_r;q)_k}{(b_1,\ldots,b_{r-1};q)_k\,(q;q)_k}z^k \end{aligned} \quad [15]$$

which has radius of convergence 1 in the nonterminating case. The case $r = 2$ of [15] is the $q$-analog of the Gauss hypergeometric series.

#### $q$-Binomial series

$${}_1\phi_0(a;-;q,z) = \sum_{k=0}^{\infty}\frac{(a;q)_k z^k}{(q;q)_k} = \frac{(az;q)_\infty}{(z;q)_\infty}$$
(if series is not terminating, then $|z| < 1$) [16]

#### $q$-Exponential series

$$\begin{aligned} e_q(z) &:= {}_1\phi_0(0;-;q,z) \\ &= \sum_{k=0}^{\infty}\frac{z^k}{(q;q)_k} = \frac{1}{(z;q)_\infty} \quad (|z|<1) \end{aligned} \quad [17]$$

$$\begin{aligned} E_q(z) &:= {}_0\phi_0(-;-;q,-z) = \sum_{k=0}^{\infty}\frac{q^{(1/2)k(k-1)}z^k}{(q;q)_k} \\ &= (-z;q)_\infty = \left(e_q(-z)\right)^{-1} \quad (z\in\mathbb{C}) \end{aligned} \quad [18]$$

$$\begin{aligned} \varepsilon_q(z) &:= {}_1\phi_1(0;-q^{1/2};q^{1/2},-z) \\ &= \sum_{k=0}^{\infty}\frac{q^{(1/4)k(k-1)}}{(q;q)_k}z^k \quad (z\in\mathbb{C}) \end{aligned} \quad [19]$$

**Jackson's $q$-Bessel functions**

$$J_\nu^{(1)}(x;q) := \frac{(q^{\nu+1};q)_\infty}{(q;q)_\infty}\left(\frac{1}{2}x\right)^\nu \times {}_2\phi_1\left[\begin{matrix}0,0\\ q^{\nu+1}\end{matrix};q,-\frac{1}{4}x^2\right] \quad (0<x<2) \qquad [20]$$

$$J_\nu^{(2)}(x;q) := \frac{(q^{\nu+1};q)_\infty}{(q;q)_\infty}\left(\frac{1}{2}x\right)^\nu {}_0\phi_1\left[\begin{matrix}-\\ q^{\nu+1}\end{matrix};q,-\frac{1}{4}q^{\nu+1}x^2\right] = \left(-\frac{1}{4}x;q\right)_\infty J_\nu^{(1)}(x;q) \quad (x>0) \qquad [21]$$

$$J_\nu^{(3)}(x;q) := \frac{(q^{\nu+1};q)_\infty}{(q;q)_\infty}\left(\frac{1}{2}x\right)^\nu \times {}_1\phi_1\left[\begin{matrix}0\\ q^{\nu+1}\end{matrix};q,\frac{1}{4}qx^2\right] \quad (x>0) \qquad [22]$$

See [90] for the orthogonality relation for $J_\nu^{(3)}(x;q)$.

If $\exp_q(z)$ denotes one of the three $q$-exponentials [17]–[19], then $(1/2)(\exp_q(\mathrm{i}x)+\exp_q(-\mathrm{i}x))$ is a $q$-analog of the cosine and $-(1/2)\mathrm{i}(\exp_q(\mathrm{i}x) - \exp_q(-\mathrm{i}x))$ is a $q$-analog of the sine. The three $q$-cosines are essentially the case $\nu=-1/2$ of the corresponding $q$-Bessel functions [20]–[22], and the three $q$-sines are essentially the case $\nu=1/2$ of $x$ times the corresponding $q$-Bessel functions.

### *q*-Derivative and *q*-Integral

The $q$-derivative of a function $f$ given on a subset of $\mathbb{R}$ or $\mathbb{C}$ is defined by

$$(D_qf)(x) := \frac{f(x)-f(qx)}{(1-q)x} \quad (x\neq 0,\ q\neq 1) \qquad [23]$$

where $x$ and $qx$ should be in the domain of $f$. By continuity, we set $(D_qf)(0):=f'(0)$, provided $f'(0)$ exists. If $f$ is differentiable on an open interval $I$, then

$$\lim_{q\uparrow 1}(D_qf)(x) = f'(x) \quad (x\in I) \qquad [24]$$

For $a\in\mathbb{R}\backslash\{0\}$ and a function $f$ given on $(0,a]$ or $[a,0)$, we define the $q$-integral by

$$\int_0^a f(x)\,\mathrm{d}_qx := a(1-q)\sum_{k=0}^\infty f(aq^k)\,q^k = \sum_{k=0}^\infty f(aq^k)\,(aq^k-aq^{k+1}) \qquad [25]$$

provided the infinite sum converges absolutely (e.g., if $f$ is bounded). If $F(a)$ is given by the left-hand side of [25], then $D_qF=f$. The right-hand side of [25] is an infinite Riemann sum. For $q\uparrow 1$ it converges, at least formally, to $\int_0^a f(x)\,\mathrm{d}x$.

For nonzero $a,b\in\mathbb{R}$ we define

$$\int_a^b f(x)\,\mathrm{d}_qx := \int_0^b f(x)\,\mathrm{d}_qx - \int_0^a f(x)\,\mathrm{d}_qx \qquad [26]$$

For a $q$-integral over $(0,\infty)$, we have to specify a $q$-lattice $\{aq^k\}_{k\in\mathbb{Z}}$ for some $a>0$ (up to multiplication by an integer power of $q$):

$$\int_0^{a.\infty} f(x)\,\mathrm{d}_qx := a(1-q)\sum_{k=-\infty}^\infty f(aq^k)\,q^k = \lim_{n\to\infty}\int_0^{q^{-n}a} f(x)\,\mathrm{d}_qx \qquad [27]$$

### The *q*-Gamma and *q*-Beta Functions

The $q$-gamma function is defined by

$$\Gamma_q(z) := \frac{(q;q)_\infty(1-q)^{1-z}}{(q^z;q)_\infty} \quad (z\neq 0,-1,-2,\ldots) \qquad [28]$$

$$= \int_0^{(1-q)^{-1}} t^{z-1}E_q(-(1-q)qt)\,\mathrm{d}_qt \quad (\Re z>0) \qquad [29]$$

Then

$$\Gamma_q(z+1) = \frac{1-q^z}{1-q}\Gamma_q(z) \qquad [30]$$

$$\Gamma_q(n+1) = \frac{(q;q)_n}{(1-q)^n} \qquad [31]$$

$$\lim_{q\uparrow 1}\Gamma_q(z) = \Gamma(z) \qquad [32]$$

The $q$-beta function is defined by

$$B_q(a,b) := \frac{\Gamma_q(a)\Gamma_q(b)}{\Gamma_q(a+b)} = \frac{(1-q)\,(q,q^{a+b};q)_\infty}{(q^a,q^b;q)_\infty} \quad (a,b\neq 0,-1,-2,\ldots) \qquad [33]$$

$$= \int_0^1 t^{b-1}\frac{(qt;q)_\infty}{(q^at;q)_\infty}\,\mathrm{d}_qt \quad (\Re b>0,\ a\neq 0,-1,-2,\ldots) \qquad [34]$$

### The *q*-Gauss Hypergeometric Series

**$q$-Analog of Euler's integral representation**

$${}_2\phi_1(q^a,q^b;q^c;q,z) = \frac{\Gamma_q(c)}{\Gamma_q(a)\Gamma_q(c-b)}\int_0^1 t^{b-1}\frac{(tq;q)_\infty}{(tq^{c-b};q)_\infty} \times \frac{(tzq^a;q)_\infty}{tz;q)_\infty}\,\mathrm{d}_qt \quad (\Re b>0,\ |z|<1) \qquad [35]$$

By substitution of [25], formula [35] becomes a transformation formula:

$$ {}_2\phi_1(a,b;c;q,z) = \frac{(az;q)_\infty}{(z;q)_\infty}\frac{(b;q)_\infty}{(c;q)_\infty}\,{}_2\phi_1(c/b,z;az;q,b) \quad [36] $$

Note the mixing of argument $z$ and parameters $a,b,c$ on the right-hand side.

**Evaluation formulas in special points**

$$ {}_2\phi_1(a,b;c;q,c/(ab)) = \frac{(c/a,c/b;q)_\infty}{(c,c/(ab);q)_\infty} \quad (|c/(ab)|<1) \quad [37] $$

$$ {}_2\phi_1(q^{-n},b;c;q,cq^n/b) = \frac{(c/b;q)_n}{(c;q)_n} \quad [38] $$

$$ {}_2\phi_1(q^{-n},b;c;q,q) = \frac{(c/b;q)_n\,b^n}{(c;q)_n} \quad [39] $$

**Two general transformation formulas**

$$ {}_2\phi_1\left[\begin{matrix}a,b\\c\end{matrix};q,z\right] = \frac{(az;q)_\infty}{(z;q)_\infty}\,{}_2\phi_2\left[\begin{matrix}a,c/b\\c,az\end{matrix};q,bz\right] \quad [40] $$

$$ = \frac{(abz/c;q)_\infty}{(z;q)_\infty}\,{}_2\phi_1\left[\begin{matrix}c/a,c/b\\c\end{matrix};q,\frac{abz}{c}\right] \quad [41] $$

**Transformation formulas in the terminating case**

$$ {}_2\phi_1\left[\begin{matrix}q^{-n},b\\c\end{matrix};q,z\right] = \frac{(c/b;q)_n}{(c;q)_n}\,{}_3\phi_2\left[\begin{matrix}q^{-n},b,q^{-n}bc^{-1}z\\q^{1-n}bc^{-1},0\end{matrix};q,q\right] \quad [42] $$

$$ = (q^{-n}bc^{-1}z;q)_n\,{}_3\phi_2\left[\begin{matrix}q^{-n},cb^{-1},0\\c,qcb^{-1}z^{-1}\end{matrix};q,q\right] \quad [43] $$

$$ = \frac{(c/b;q)_n}{(c;q)_n}b^n\,{}_3\phi_1\left[\begin{matrix}q^{-n},b,qz^{-1}\\q^{1-n}bc^{-1}\end{matrix};q,\frac{z}{c}\right] \quad [44] $$

**Second order $q$-difference equation**

$$ z(q^c-q^{a+b+1}z)(D_q^2u)(z) + \left(\frac{1-q^c}{1-q} - \left(q^b\frac{1-q^a}{1-q} + q^a\frac{1-q^{b+1}}{1-q}\right)z\right)(D_qu)(z) - \frac{1-q^a}{1-q}\frac{1-q^b}{1-q}u(z) = 0 \quad [45] $$

Some special solutions of [45] are:

$$ u_1(z) := {}_2\phi_1(q^a,q^b;q^c;q,z) \quad [46] $$

$$ u_2(z) := z^{1-c}{}_2\phi_1(q^{1+a-c},q^{1+b-c};q^{2-c};q,z) \quad [47] $$

$$ u_3(z) := z^{-a}{}_2\phi_1(q^a,q^{a-c+1};q^{a-b+1};q,q^{-a-b+c+1}z^{-1}) \quad [48] $$

They are related by:

$$ u_1(z) + \frac{(q^a,q^{1-c},q^{c-b};q)_\infty}{(q^{c-1},q^{a-c+1},q^{1-b};q)_\infty} \times \frac{(q^{b-1}z,q^{2-b}z^{-1};q)_\infty}{(q^{b-c}z,q^{c-b+1}z^{-1};q)_\infty}u_2(z) = \frac{(q^{1-c},q^{a-b+1};q)_\infty}{(q^{1-b},q^{a-c+1};q)_\infty} \times \frac{(q^{a+b-c}z,q^{c-a-b+1}z^{-1};q)_\infty z^a}{(q^{b-c}z,q^{c-b+1}z^{-1};q)_\infty}u_3(z) \quad [49] $$

## Summation and Transformation Formulas for ${}_r\phi_{r-1}$ Series

An ${}_r\phi_{r-1}$ series [15] is called "balanced" if $b_1\ldots b_{r-1} = qa_1\ldots a_r$ and $z=q$, and the series is called "very well-poised" if $qa_1 = a_2b_1 = a_3b_2 = \cdots = a_rb_{r-1}$ and $qa_1^{1/2} = a_2 = -a_3$. The following more compact notation is used for very well-poised series:

$$ {}_rW_{r-1}(a_1;a_4,a_5,\ldots,a_r;q,z) := {}_r\phi_{r-1}\left[\begin{matrix}a_1,qa_1^{1/2},-qa_1^{1/2},a_4,\ldots,a_r\\a_1^{1/2},-a_1^{1/2},qa_1/a_4,\ldots,qa_1/a_r\end{matrix};q,z\right] \quad [50] $$

Below only a few of the most important identities are given. See Gasper and Rahman (2004) for many more. An important tool for obtaining complicated identities from more simple ones is Bailey's Lemma, which can moreover be iterated (Bailey chain), see Andrews (1986, ch.3).

**The $q$-Saalschütz sum for a terminating balanced ${}_3\phi_2$**

$$ {}_3\phi_2\left[\begin{matrix}a,b,q^{-n}\\c,q^{1-n}abc^{-1}\end{matrix};q,q\right] = \frac{(c/a,c/b;q)_n}{(c,c/(ab);q)_n} \quad [51] $$

**Jackson's sum for a terminating balanced ${}_8W_7$**

$$ {}_8W_7(a;b,c,d,q^{n+1}a^2/(bcd),q^{-n};q,q) = \frac{(qa,qa/(bc),qa/(bd),qa/(cd);q)_n}{(qa/b,qa/c,qa/d,qa/(bcd);q)_n} \quad [52] $$

**Watson's transformation of a terminating $_8W_7$ into a terminating balanced $_4\phi_3$**

$$
{}_8W_7\left(a;b,c,d,e,q^{-n};q,\frac{q^{n+2}a^2}{bcde}\right) = \frac{(qa,qa/(de);q)_n}{(qa/d,qa/e;q)_n} \times {}_4\phi_3\left[\begin{matrix} q^{-n},d,e,qa/(bc) \\ qa/b,qa/c,q^{-n}de/a \end{matrix};q,q\right] \qquad [53]
$$

**Sears' transformation of a terminating balanced $_4\phi_3$**

$$
{}_4\phi_3\left[\begin{matrix} q^{-n},a,b,c \\ d,e,f \end{matrix};q,q\right] = \frac{(e/a,f/a;q)_n}{(e,f;q)_n}a^n\,{}_4\phi_3\left[\begin{matrix} q^{-n},a,d/b,d/c \\ d,q^{1-n}a/e,q^{1-n}a/f \end{matrix};q,q\right] \qquad [54]
$$

By iteration and by symmetries in the upper and in the lower parameters, many other versions of this identity can be found. An elegant comprehensive formulation of all these versions is as follows.

Let $x_1x_2x_3x_4x_5x_6 = q^{1-n}$. Then the following expression is symmetric in $x_1,x_2,x_3,x_4,x_5,x_6$:

$$
\frac{q^{(1/2)n(n-1)}(x_1x_2x_3x_4,x_1x_2x_3x_5,x_1x_2x_3x_6;q)_n}{(x_1x_2x_3)^n} \times {}_4\phi_3\left[\begin{matrix} q^{-n},x_2x_3,x_1x_3,x_1x_2 \\ x_1x_2x_3x_4,x_1x_2x_3x_5,x_1x_2x_3x_6 \end{matrix};q,q\right] \qquad [55]
$$

Similar formulations involving symmetry groups can be given for other transformations, see Van der Jeugt and Srinivasa Rao (1999).

**Bailey's transformation of a terminating balanced $_{10}W_9$**

$$
{}_{10}W_9\left(a;b,c,d,e,f,\frac{q^{n+2}a^3}{bcdef},q^{-n};q,q\right) = \frac{(qa,qa/(ef),(qa)^2/(bcde),(qa)^2/(bcdf);q)_n}{(qa/e,qa/f,(qa)^2/(bcdef),(qa)^2/(bcd);q)_n} \times {}_{10}W_9\left(\frac{qa^2}{bcd};\frac{qa}{cd},\frac{qa}{bd},\frac{qa}{bc},e,f,\frac{q^{n+2}a^3}{bcdef},q^{-n};q,q\right) \qquad [56]
$$

### Rogers–Ramanujan Identities

$$
{}_0\phi_1(-;0;q,q) = \sum_{k=0}^{\infty}\frac{q^{k^2}}{(q;q)_k} = \frac{1}{(q,q^4;q^5)_\infty} \qquad [57]
$$

$$
{}_0\phi_1(-;0;q,q^2) = \sum_{k=0}^{\infty}\frac{q^{k(k+1)}}{(q;q)_k} = \frac{1}{(q^2,q^3;q^5)_\infty} \qquad [58]
$$

### Bilateral Series

Definition [1] can be extended by

$$
(a;q)_k := \frac{(a;q)_\infty}{(aq^k;q)_\infty} \quad (k\in\mathbb{Z}) \qquad [59]
$$

Define a bilateral $q$-hypergeometric series by the Laurent series

$$
{}_r\psi_s\left[\begin{matrix} a_1,\ldots,a_r \\ b_1,\ldots,b_s \end{matrix};q,z\right] = {}_r\psi_s(a_1,\ldots,a_r;b_1,\ldots,b_s;q,z) := \sum_{k=-\infty}^{\infty}\frac{(a_1,\ldots,a_r;q)_k}{(b_1,\ldots,b_s;q)_k}\left((-1)^k q^{(1/2)k(k-1)}\right)^{s-r} z^k
$$
$$
(a_1,\ldots,a_r,b_1,\ldots,b_s\neq 0,\ s\geq r) \qquad [60]
$$

The Laurent series is convergent if $|b_1\ldots b_s/(a_1\ldots a_r)| < |z|$ and moreover, for $s=r$, $|z|<1$.

**Ramanujan's $_1\psi_1$ summation formula**

$$
{}_1\psi_1(b;c;q,z) = \frac{(q,c/b,bz,q/(bz);q)_\infty}{(c,q/b,z,c/(bz);q)_\infty} \quad (|c/b| < |z < 1) \qquad [61]
$$

This has as a limit case

$$
{}_0\psi_1(-;c;q,z) = \frac{(q,z,q/z;q)_\infty}{(c,c/z;q)_\infty} \quad (|z| > |c|) \qquad [62]
$$

and as a further specialization the Jacobi triple product identity

$$
\sum_{k=-\infty}^{\infty}(-1)^k q^{(1/2)k(k-1)} z^k = (q,z,q/z;q)_\infty \quad (z\neq 0) \qquad [63]
$$

which can be rewritten as a product formula for a theta function:

$$
\theta_4(x;q) := \sum_{k=-\infty}^{\infty}(-1)^k q^{k^2} e^{2\pi ikx} = \prod_{k=1}^{\infty}(1-q^{2k}) \times\left(1-2q^{k-1}\cos(2\pi x)+q^{4k-2}\right) \qquad [64]
$$

## *q*-Hypergeometric Orthogonal Polynomials

Here we discuss families of orthogonal polynomials $\{p_n(x)\}$ which are expressible as terminating $q$-hypergeometric series $(0<q<1)$ and for which either (1) $P_n(x):=p_n(x)$ or (2) $P_n(x):=p_n$

$((1/2)(x+x^{-1}))$ are eigenfunctions of a second-order $q$-difference operator, that is,

$$A(x)\,P_n(qx) + B(x)\,P_n(x) + C(x)\,P_n(q^{-1}x) = \lambda_n\,P_n(x) \quad [65]$$

where $A(x), B(x)$, and $C(x)$ are independent of $n$, and where the $\lambda_n$ are the eigenvalues. The generic cases are the four-parameter classes of "Askey–Wilson polynomials" (continuous weight function) and $q$-Racah polynomials (discrete weights on finitely many points). They are of type (2) (quadratic $q$-lattice). All other cases can be obtained from the generic cases by specialization or limit transition. In particular, one thus obtains the generic three-parameter classes of type (1) (linear $q$-lattice). These are the big $q$-Jacobi polynomials (orthogonality by $q$-integral) and the $q$-Hahn polynomials (discrete weights on finitely many points).

#### Askey–Wilson Polynomials

**Definition as $q$-hypergeometric series**

$$p_n(\cos\theta) = p_n(\cos\theta; a,b,c,d\,|\,q) := \frac{(ab,ac,ad;q)_n}{a^n}\,{}_4\phi_3\left[\begin{matrix} q^{-n}, q^{n-1}abcd, ae^{i\theta}, ae^{-i\theta} \\ ab, ac, ad \end{matrix}; q, q\right] \quad [66]$$

This is symmetric in $a,b,c,d$.

**Orthogonality relation** Assume that $a,b,c,d$ are four reals, or two reals and one pair of complex conjugates, or two pairs of complex conjugates. Also assume that $|ab|, |ac|, |ad|, |bc|, |bd|, |cd| < 1$. Then

$$\int_{-1}^{1} p_n(x)p_m(x)w(x)\,dx + \sum_k p_n(x_k)\,p_m(x_k)\omega_k = h_n\,\delta_{n,m} \quad [67]$$

where

$$2\pi\sin\theta\,w(\cos\theta) = \left|\frac{(e^{2i\theta};q)_\infty}{(ae^{i\theta}, be^{i\theta}, ce^{i\theta}, de^{i\theta};q)_\infty}\right|^2 \quad [68]$$

$$h_0 = \frac{(abcd;q)_\infty}{(q,ab,ac,ad,bc,bd,cd;q)_\infty}$$

$$\frac{h_n}{h_0} = \frac{1-abcdq^{n-1}}{1-abcdq^{2n-1}} \times \frac{(q,ab,ac,ad,bc,bd,cd;q)_n}{(abcd;q)_n} \quad [69]$$

and the $x_k$ are the points $(1/2)(eq^k + e^{-1}q^{-k})$ with $e$ any of the $a,b,c,d$ of absolute value $>1$; the sum is over the $k \in \mathbb{Z}_{\geq 0}$ with $|eq^k| > 1$. The $\omega_k$ are certain weights which can be given explicitly. The sum in [67] does not occur if moreover $|a|, |b|, |c|, |d| < 1$.

A more uniform way of writing the orthogonality relation [67] is by the contour integral

$$\frac{1}{2\pi i}\oint_C p_n\left(\frac{1}{2}(z+z^{-1})\right)p_m\left(\frac{1}{2}(z+z^{-1})\right) \times \frac{(z^2, z^{-2};q)_\infty}{(az, az^{-1}, bz, bz^{-1}, cz, cz^{-1}, dz, dz^{-1};q)_\infty}\frac{dz}{z} = 2h_n\delta_{n,m} \quad [70]$$

where $C$ is the unit circle traversed in positive direction with suitable deformations to separate the sequences of poles converging to zero from the sequences of poles diverging to $\infty$.

The case $n=m=0$ of [70] or [67] is known as the Askey–Wilson integral.

***q*-Difference equation**

$$A(z)P_n(qz) - \big(A(z)+A(z^{-1})\big)P_n(z) + A(z^{-1})P_n(q^{-1}z) = (q^{-n}-1)(1-q^{n-1}abcd)P_n(z) \quad [71]$$

where $P_n(z) = p_n(\frac{1}{2}(z+z^{-1}))$ and $A(z) = (1-az)(1-bz)(1-cz)\,(1-dz)/((1-z^2)(1-qz^2))$

**Special cases** These include the continuous $q$-Jacobi polynomials (two parameters), the continuous $q$-ultraspherical polynomials (symmetric one-parameter case of continuous $q$-Jacobi), the Al-Salam-Chihara polynomials (Askey–Wilson with $c=d=0$), and the continuous $q$-Hermite polynomials (Askey–Wilson with $a=b=c=d=0$).

#### Continuous *q*-Ultraspherical Polynomials

**Definitions as finite Fourier series and as special Askey–Wilson polynomial**

$$C_n(\cos\theta;\beta\,|\,q) := \sum_{k=0}^{n}\frac{(\beta;q)_k(\beta;q)_{n-k}}{(q;q)_k(q;q)_{n-k}}\,e^{i(n-2k)\theta} \quad [72]$$

$$= \frac{(\beta;q)_n}{(q;q)_n}p_n(\cos\theta;\beta^{1/2}, q^{1/2}\beta^{1/2}, -\beta^{1/2}, -q^{1/2}\beta^{1/2}\mid q) \quad [73]$$

Orthogonality relation $(-1 < \beta < 1)$

$$\frac{1}{2\pi}\int_0^{\pi} C_n(\cos\theta;\beta,q)C_m(\cos\theta;\beta,q)\left|\frac{(e^{2i\theta};q)_\infty}{(\beta e^{2i\theta};q)_\infty}\right|^2 d\theta = \frac{(\beta,q\beta;q)_\infty}{(\beta^2,q;q)_\infty}\frac{1-\beta}{1-\beta q^n}\frac{(\beta^2;q)_n}{(q;q)_n}\delta_{n,m} \quad [74]$$

*q*-Difference equation

$$A(z)P_n(qz) - \left(A(z)+A(z^{-1})\right)P_n(z) + A(z^{-1})P_n(q^{-1}z) = (q^{-n}-1)(1-q^n\beta^2)P_n(z) \quad [75]$$

where $P_n(z) = C_n(\frac{1}{2}(z+z^{-1});\beta\,|\,q)$ and $A(z) = (1-\beta z^2)(1-q\beta z^2)/((1-z^2)(1-qz^2))$.

Generating function

$$\frac{(\beta e^{i\theta}z,\beta e^{-i\theta}z;q)_\infty}{(e^{i\theta}z,e^{-i\theta}z;q)_\infty} = \sum_{n=0}^{\infty} C_n(\cos\theta;\beta|q)z^n \quad (|z|<1, 0\le\theta\le\pi, -1<\beta<1) \quad [76]$$

Special case: the continuous *q*-Hermite polynomials

$$H_n(x|q) = (q;q)_n\, C_n(x;0|q) \quad [77]$$

Special cases: the Chebyshev polynomials

$$C_n(\cos\theta;q|q) = U_n(\cos\theta) := \frac{\sin((n+1)\theta)}{\sin\theta} \quad [78]$$

$$\lim_{\beta\uparrow 1}\frac{(q;q)_n}{(\beta;q)_n}C_n(\cos\theta;\beta|q) = T_n(\cos\theta) := \cos(n\theta)\ (n>0) \quad [79]$$

### *q*-Racah Polynomials

Definition as *q*-hypergeometric series $(n = 0, 1, \ldots, N)$

$$R_n(q^{-y}+\gamma\delta q^{y+1};\alpha,\beta,\gamma,\delta|q) := {}_4\phi_3\left[\begin{matrix} q^{-n},\alpha\beta q^{n+1},q^{-y},\gamma\delta q^{y+1} \\ q\alpha,q\beta\delta,q\gamma\end{matrix};q,q\right] \quad (\alpha,\beta\delta \text{ or } \gamma = q^{-N-1}) \quad [80]$$

Orthogonality relation

$$\sum_{y=0}^{N} R_n(q^{-y}+\gamma\delta q^{y+1})R_m(q^{-y}+\gamma\delta q^{y+1})\omega_y = h_n\delta_{n,m} \quad [81]$$

where $\omega_y$ and $h_n$ can be explicitly given.

### Big *q*-Jacobi Polynomials

Definition as *q*-hypergeometric series

$$P_n(x) = P_n(x;a,b,c;q) := {}_3\phi_2\left[\begin{matrix} q^{-n},q^{n+1}ab,x \\ qa,qc\end{matrix};q,q\right] \quad [82]$$

Orthogonality relation

$$\int_{qc}^{qa} P_n(x)P_m(x)\frac{(a^{-1}x,c^{-1}x;q)_\infty}{(x,bc^{-1}x;q)_\infty}d_qx = h_n\,\delta_{n,m}, \quad (0<a<q^{-1}, 0<b<q^{-1}, c<0) \quad [83]$$

where $h_n$ can be explicitly given.

*q*-Difference equation

$$A(x)P_n(qx) - (A(x)+C(x))P_n(x) + C(x)P_n(q^{-1}x) = (q^{-n}-1)(1-abq^{n+1})P_n(x) \quad [84]$$

where $A(x) = aq(x-1)(bx-c)/x^2$ and $C(x) = (x-qa)(x-qc)/x^2$

Limit case: Jacobi polynomials $P_n^{(\alpha,\beta)}(x)$

$$\lim_{q\uparrow 1} P_n(x;q^\alpha,q^\beta,-q^{-1}d;q) = \frac{n!}{(\alpha+1)_n}P_n^{(\alpha,\beta)}\left(\frac{2x+d-1}{d+1}\right) \quad [85]$$

Special case: the little *q*-Jacobi polynomials

$$p_n(x;a,b;q) = (-b)^{-n}q^{-(1/2)n(n+1)} \times \frac{(qb;q)_n}{(qa;q)_n}P_n(qbx;b,a,0;q) \quad [86]$$

$$= {}_2\phi_1(q^{-n},q^{n+1}ab;qa;q,qx) \quad [87]$$

which satisfy orthogonality relation (for $0 < a < q^{-1}$ and $b < q^{-1}$)

$$\int_0^1 p_n(x;a,b;q)p_m(x;a,b;q)\frac{(qx;q)_\infty}{(qbx;q)_\infty}x^{\log_q a}d_qx = \frac{(q,qab;q)_\infty}{(qa,qb;q)_\infty}\frac{(1-q)(qa)^n}{1-abq^{2n+1}}\frac{(q,qb;q)_n}{(qa,qab;q)_n}\delta_{n,m} \quad [88]$$

Limit case: Jackson's third *q*-Bessel function (see [22])

$$\lim_{N\to\infty} p_{N-n}(q^{N+k};q^\nu,b;q) = \frac{(q;q)_\infty}{(q^{\nu+1};q)_\infty}q^{-\nu(n+k)} \times J_\nu^{(3)}(2q^{(1/2)(n+k)};q) \quad (\nu > -1) \quad [89]$$

by which [88] tends to the orthogonality relation for $J_\nu^{(3)}(x;q)$:

$$\sum_{k=-\infty}^{\infty} J_\nu^{(3)}(2q^{(1/2)(n+k)};q)\,J_\nu^{(3)}(2q^{(1/2)(m+k)};q)q^k = \delta_{n,m}q^{-n} \quad (n,m\in\mathbb{Z}) \qquad [90]$$

### q-Hahn Polynomials

Definition as $q$-hypergeometric series

$$Q_n(x;\alpha,\beta,N;q) := {}_3\phi_2\left[\begin{matrix} q^{-n}, q^{n+1}\alpha\beta, x \\ q\alpha, q^{-N}\end{matrix}; q, q\right] \quad (n=0,1,\ldots,N) \qquad [91]$$

Orthogonality relation

$$\sum_{y=0}^{N} Q_n(q^{-y})Q_m(q^{-y})\frac{(q\alpha,q^{-N};q)_y(q\alpha\beta)^{-y}}{(q^{-N}\beta^{-1},q;q)_y} = h_n\delta_{n,m} \qquad [92]$$

where $h_n$ can be explicitly given.

### Stieltjes–Wigert Polynomials

Definition as $q$-hypergeometric series

$$S_n(x;q) = \frac{1}{(q;q)_n}\,{}_1\phi_1\left[\begin{matrix} q^{-n} \\ 0\end{matrix}; q, -q^{n+1}x\right] \qquad [93]$$

The orthogonality measure is not uniquely determined:

$$\int_0^\infty S_n(q^{1/2}x;q)S_m(q^{1/2}x;q)w(x)\,\mathrm{d}x = \frac{1}{q^n(q;q)_n}\delta_{n,m},$$

where, for instance

$$w(x) = \frac{q^{1/2}}{\log(q^{-1})(q,-q^{1/2}x,-q^{1/2}x^{-1};q)_\infty} \quad \text{or} \quad \frac{q^{1/2}}{\sqrt{2\pi\log(q^{-1})}}\exp\left(-\frac{\log^2 x}{2\log(q^{-1})}\right) \qquad [94]$$

### Rahman–Wilson Biorthogonal Rational Functions

The following functions are rational in their first argument:

$$R_n\left(\tfrac{1}{2}(z+z^{-1});a,b,c,d,e\right) := {}_{10}W_9(a/e;q/(be),q/(ce), q/(de),az,a/z,q^{n-1}abcd,q^{-n};q,q) \qquad [95]$$

They satisfy the biorthogonality relation

$$\frac{1}{2\pi\mathrm{i}}\oint_C R_n\left(\frac{1}{2}(z+z^{-1});a,b,c,d,e\right) \times R_m\left(\frac{1}{2}(z+z^{-1});a,b,c,d,\frac{q}{abcde}\right)w(z)\frac{\mathrm{d}z}{z} = 2h_n\delta_{n,m} \qquad [96]$$

where the contour $C$ is as in [70], and where

$$w(z) = \frac{(z^2,z^{-2},abcdez,abcde/z;q)_\infty}{(az,a/z,bz,b/z,cz,c/z,dz,d/z,ez,e/z;q)_\infty} \qquad [97]$$

$$h_0 = \frac{(bcde,acde,abde,abce,abcd;q)_\infty}{(q,ab,ac,ad,ae,bc,bd,be,cd,ce,de;q)_\infty} \qquad [98]$$

and $h_n/h_0$ can also be given explicitly. For $ab=q^{-N}, n,m\in\{0,1,\ldots,N\}$, there is a related discrete biorthogonality of the form

$$\sum_{k=0}^{N} R_n\left(\frac{1}{2}(aq^k+a^{-1}q^{-k});a,b,c,d,e\right) \times R_m\left(\frac{1}{2}(aq^k+a^{-1}q^{-k});a,b,c,d,\frac{q}{abcde}\right)w_k = 0 \quad (n\neq m) \qquad [99]$$

## Identities and Functions Associated with Root Systems

### η-Function Identities

Let $R$ be a root system on a Euclidean space of dimension $l$. Then Macdonald (1972) generalizes Weyl's denominator formula to the case of an affine root system. The resulting formula can be written as an explicit expansion in powers of $q$ of

$$\prod_{n=1}^{\infty}\left((1-q^n)^l\prod_{\alpha\in R}(1-q^ne^\alpha)\right)$$

which expansion takes the form of a sum over a lattice related to the root system. For root system $A_1$ this reduces to Jacobi's triple product identity [63]. Macdonald's formula implies a similar expansion in powers of $q$ of $\eta(q)^{l+|R|}$, where $\eta(q)$ is "Dedekind's $\eta$-function" $\eta(q) := q^{1/24}(q;q)_\infty$.

### Constant Term Identities

Let $R$ be a reduced root system, $R^+$ the positive roots, and $k\in\mathbb{Z}_{>0}$. Macdonald conjectured the second equality in

$$\frac{\int_T\prod_{\alpha\in R^+}(e^{-\alpha};q)_k(qe^\alpha;q)_k\,\mathrm{d}x}{\int_T\mathrm{d}x} = \mathrm{CT}\left(\prod_{\alpha\in R^+}\prod_{i=1}^{k}(1-q^{i-1}e^{-\alpha})(1-q^ie^\alpha)\right) = \prod_{i=1}^{l}\begin{bmatrix} kd_i \\ k\end{bmatrix}_q \qquad [100]$$

where $T$ is a torus determined by $R$, CT means the constant term in the Laurent expansion in $e^{\alpha}$, and the $d_i$ are the degrees of the fundamental invariants of the Weyl group of $R$. The conjecture was extended for real $k > 0$, for several parameters $k$ (one for each root length), and for root system $BC_n$, where Gustafson's five-parameter $n$-variable analog of the Askey–Wilson integral ([70] for $n = 0$) settles:

$$\int_{[0,2\pi]^n} |\Delta(e^{i\theta_1}, \ldots, e^{i\theta_n})|^2 \frac{d\theta_1 \ldots \theta_n}{(2\pi)^n} = 2^n n! \times \prod_{j=1}^{n} \frac{(t, t^{n+j-2}abcd; q)_\infty}{(t^j, q, abt^{j-1}, act^{j-1}, \ldots, cdt^{j-1}; q)_\infty} \quad [101]$$

where

$$\Delta(z) := \prod_{1 \le i < j \le n} \frac{(z_i z_j, z_i/z_j; q)_\infty}{(tz_i z_j, tz_i/z_j; q)_\infty} \times \prod_{j=1}^{n} \frac{(z_j^2; q)_\infty}{(az_j, bz_j, cz_j, dz_j; q)_\infty} \quad [102]$$

Further extensions were in Macdonald's conjectures for the quadratic norms of Macdonald polynomials associated with root systems (see the subsection "Macdonald–Koornwinder polynomials"), and finally proved by Cherednik.

### Macdonald Polynomials for Root System $A_{n-1}$

Let $n \in \mathbb{Z}_{>0}$. We work with partitions $\lambda = (\lambda_1, \ldots, \lambda_n)$ of length $\le n$, where $\lambda_1 \ge \cdots \ge \lambda_n \ge 0$ are integers. On the set of such partitions, we take the partial order $\lambda \le \mu \Rightarrow \lambda_1 + \cdots + \lambda_n = \mu_1 + \cdots + \mu_n$ and $\lambda_1 + \cdots + \lambda_i \le \mu_1 + \cdots + \mu_i$ ($i = 1, \ldots, n-1$). Write $\lambda < \mu$ iff $\lambda \le \mu$ and $\lambda \ne \mu$. The monomials are $z^\alpha = z_1^{\alpha_1} \ldots z_n^{\alpha_n}$ ($\alpha_1, \ldots, \alpha_n \in \mathbb{Z}_{\ge 0}$). For $\lambda$ a partition the symmetrized monomials $m_\lambda(z)$ and the Schur functions $s_\lambda(z)$ are defined by:

$$m_\lambda(z) := \sum_\alpha z^\alpha \quad \text{(sum over all distinct permutations } \alpha \text{ of } (\lambda_1, \ldots, \lambda_n)) \quad [103]$$

$$s_\lambda(z) := \frac{\det(z_i^{\lambda_j + n - j})_{i,j=1,\ldots,n}}{\det(z_i^{n-j})_{i,j=1,\ldots,n}} \quad [104]$$

We integrate a function over the torus $T := \{z \in \mathbb{C}^n \mid |z_1| = \cdots = |z_n| = 1\}$ as

$$\int_T f(z)\, dz := \frac{1}{(2\pi)^n} \times \int_0^{2\pi} \cdots \int_0^{2\pi} f(e^{i\theta_1}, \ldots, e^{i\theta_n}) d\theta_1 \ldots d\theta_n \quad [105]$$

**Definition** For $\lambda$ a partition and for $0 \le t \le 1$, the (analytically defined) Macdonald polynomial $P_\lambda(z) = P_\lambda(z; q, t)$ is of the form

$$P_\lambda(z) = P_\lambda(z; q, t) = m_\lambda(z) + \sum_{\mu < \lambda} u_{\lambda,\mu} m_\mu(z) \quad (u_{\lambda,\mu} \in \mathbb{C})$$

such that for all $\mu < \lambda$

$$\int_T P_\lambda(z)\, \overline{m_\mu(z)}\, \Delta(z)\, dz = 0$$

where

$$\Delta(z) = \Delta(z; q, t) := \prod_{i \ne j} \frac{(z_i z_j^{-1}; q)_\infty}{(tz_i z_j^{-1}; q)_\infty} \quad [106]$$

**Orthogonality relation**

$$\frac{1}{n!} \int_T P_\lambda(z)\, \overline{P_\mu(z)}\, \Delta(z)\, dz = \prod_{i<j} \frac{(q^{\lambda_i - \lambda_j} t^{j-i}, q^{\lambda_i - \lambda_j + 1} t^{j-i}; q)_\infty}{(q^{\lambda_i - \lambda_j} t^{j-i+1}, q^{\lambda_i - \lambda_j + 1} t^{j-i-1}; q)_\infty} \delta_{\lambda,\mu} \quad [107]$$

***q*-Difference equation**

$$\sum_{i=1}^{n} \prod_{j \ne i} \frac{tz_i - z_j}{z_i - z_j} \tau_{q,z_i} P_\lambda(z; q, t) = \left( \sum_{i=1}^{n} q^{\lambda_i} t^{n-i} \right) P_\lambda(z; q, t) \quad [108]$$

where $\tau_{q,z_i}$ is the $q$-shift operator: $\tau_{q,z_i} f(z_1, \ldots, z_n) := f(z_1, \ldots, qz_i, \ldots, z_n)$. See (Macdonald 1995, ch. VI, §3) for the full system of $q$-difference equations.

**Special value**

$$P_\lambda(1, t, \ldots, t^{n-1}; q, t) = \prod_{i=1}^{n} t^{(i-1)\lambda_i} \times \prod_{i<j} \frac{(tq^{j-i}; q)_{\lambda_i - \lambda_j}}{(q^{j-i}; q)_{\lambda_i - \lambda_j}} \quad [109]$$

**Restriction of number of variables**

$$P_{\lambda_1, \lambda_2, \ldots, \lambda_{n-1}, 0}(z_1, \ldots, z_{n-1}, 0; q, t) = P_{\lambda_1, \lambda_2, \ldots, \lambda_{n-1}}(z_1, \ldots, z_{n-1}; q, t) \quad [110]$$

**Homogeneity**

$$P_{\lambda_1, \ldots, \lambda_n}(z; q, t) = z_1 \ldots z_n P_{\lambda_1 - 1, \ldots, \lambda_n - 1}(z; q, t) \quad (\lambda_n > 0) \quad [111]$$

**Self-duality** Let $\lambda, \mu$ be partitions.

$$\frac{P_\lambda(q^{\mu_1}t^{n-1}, q^{\mu_2}t^{n-2}, \ldots, q^{\mu_n}; q, t)}{P_\lambda(t^{n-1}, t^{n-2}, \ldots, 1; q, t)} = \frac{P_\mu(q^{\lambda_1}t^{n-1}, q^{\lambda_2}t^{n-2}, \ldots, q^{\lambda_n}; q, t)}{P_\mu(t^{n-1}, t^{n-2}, \ldots, 1; q, t)} \quad [112]$$

**Special cases and limit relations**
*Continuous q-ultraspherical polynomials* (see [72]):

$$P_{m,n}(re^{i\theta}, re^{-i\theta}; q, t) = \frac{(q;q)_{m-n}}{(t;q)_{m-n}} r^{m+n} \times C_{m-n}(\cos\theta; t \mid q) \quad [113]$$

*Symmetrized monomials* (see [103]):

$$P_\lambda(z; q, 1) = m_\lambda(z) \quad [114]$$

*Schur functions* (see [104]):

$$P_\lambda(z; q, q) = s_\lambda(z) \quad [115]$$

*Hall–Littlewood polynomials* (see Macdonald (1995), ch. III):

$$P_\lambda(z; 0, t) = P_\lambda(z; t) \quad [116]$$

*Jack polynomials* (see Macdonald (1995), §VI.10):

$$\lim_{q\uparrow 1} P_\lambda(z; q, q^a) = P_\lambda^{(1/a)}(z) \quad [117]$$

**Algebraic definition of Macdonald polynomials** Macdonald polynomials can also be defined algebraically. We work now with partitions $\lambda$ $(\lambda_1 \geq \lambda_2 \geq \cdots \geq 0)$ of arbitrary length $l(\lambda)$, and with symmetric polynomials in arbitrarily many variables $x_1, x_2, \ldots,$ which can be canonically extended to symmetric functions in infinitely many variables $x_1, x_2, \ldots$. The $r$th power sum $p_r$ and the symmetric functions $p_\lambda$ are formally defined by

$$p_r = \sum_{i\geq 1} x_i^r, \quad p_\lambda = p_{\lambda_1} p_{\lambda_2} \ldots \quad [118]$$

Put

$$z_\lambda := \prod_{i\geq 1} i^{m_i} m_i! \quad \text{where } m_i = m_i(\lambda) \text{ is the number of parts of } \lambda \text{ equal to } i. \quad [119]$$

Define an inner product $\langle\,,\rangle_{q,t}$ on the space of symmetric functions such that

$$\langle p_\lambda, p_\mu \rangle_{q,t} = \delta_{\lambda,\mu} z_\lambda \prod_{i=1}^{l(\lambda)} \frac{1 - q^{\lambda_i}}{1 - t^{\lambda_i}} \quad [120]$$

For partitions $\lambda, \mu$ the partial ordering $\lambda \geq \mu$ means now that $\sum_{j\geq 1} \lambda_j = \sum_{j\geq 1} \mu_j$ and $\lambda_1 + \cdots + \lambda_i \geq \mu_1 + \cdots + \mu_i$ for all $i$. The Macdonald polynomial $P_\lambda(x; q, t)$ can now be algebraically defined as the unique symmetric function $P_\lambda$ of the form $P_\lambda = \sum_{\mu\leq\lambda} u_{\lambda,\mu} m_\mu$ $(u_{\lambda,\mu} \in \mathbb{C}, u_{\lambda,\lambda} = 1)$ such that

$$\langle P_\lambda, P_\mu \rangle_{q.t} = 0 \quad \text{if } \lambda \neq \mu \quad [121]$$

If $l(\lambda) \leq n$, then the newly defined $P_\lambda(x)$ with $x_{n+1} = x_{n+2} = \cdots = 0$ coincides with $P_\lambda(x; q, t)$ defined analytically, and the new inner product is a constant multiple (depending on $n$) of the old inner product.

**Bilinear sum**

$$\sum_\lambda \frac{1}{\langle P_\lambda, P_\lambda \rangle_{q,t}} P_\lambda(x; q, t) P_\lambda(y; q, t) = \prod_{i,j\geq 1} \frac{(tx_i y_j; q)_\infty}{(x_i y_j; q)_\infty} \quad [122]$$

**Generalized Kostka numbers** The Kostka numbers $K_{\lambda,\mu}$ occurring as expansion coefficients in $s_\lambda = \sum_\mu K_{\lambda,\mu} m_\mu$ were generalized by Macdonald to coefficients $K_{\lambda,\mu}(q,t)$ occurring in connection with Macdonald polynomials, see Macdonald (1995, §VI.8). Macdonald's conjecture that $K_{\lambda,\mu}(q,t)$ is a polynomial in $q$ and $t$ with coefficients in $\mathbb{Z}_{\geq 0}$ was fully proved in Haiman (2001).

### Macdonald–Koornwinder Polynomials

Macdonald (2000, 2001) also introduced Macdonald polynomials associated with an arbitrary root system. For root system $BC_n$ this yields a three-parameter family which can be extended to the five-parameter Macdonald–Koornwinder (M–K) polynomials (Koornwinder 1992). They are orthogonal with respect to the measure occurring in [101] with $\Delta(z)$ given by [102]. The M–K polynomials are $n$-variable analogs of the Askey–Wilson polynomials. All polynomials just discussed tend, for $q \uparrow 1$, to Jacobi polynomials associated with root systems.

Macdonald conjectured explicit expressions for the quadratic norms of the Macdonald polynomials associated with root systems and of the M–K polynomials. These were proved by Cherednik by considering these polynomials as Weyl group symmetrizations of non-invariant polynomials

which are related to double affine Hecke algebras (see Macdonald (2003)).

## Elliptic Hypergeometric Series

Let $p, q \in \mathbb{C}, |p|, |q| < 1$. Define a modified Jacobi theta function by

$$\theta(x;p) := (x, p/x; p)_\infty \ (x \neq 0) \qquad [123]$$

and the elliptic shifted factorial by

$$(a;q,p)_k := \theta(a;p)\theta(aq;p)\ldots\theta(aq^{k-1};p) \quad (k \in \mathbb{Z}_{>0}),\ (a;q,p)_0 := 1 \qquad [124]$$

$$(a_1,\ldots,a_r;q,p)_k := (a_1;q,p)_k \ldots (a_r;q,p)_k \qquad [125]$$

where $a, a_1, \ldots, a_r \neq 0$. For $q = e^{2\pi i\sigma}$, $p = e^{2\pi i\tau}$ ($\Im\tau > 0$), and $a \in \mathbb{C}$ we have

$$\frac{\theta(ae^{2\pi i\sigma(x+\sigma^{-1})}; e^{2\pi i\tau})}{\theta(ae^{2\pi i\sigma x}; e^{2\pi i\tau})} = 1$$
$$\frac{\theta(ae^{2\pi i\sigma(x+\tau\sigma^{-1})}; e^{2\pi i\tau})}{\theta(ae^{2\pi i\sigma x}; e^{2\pi i\tau})} = -a^{-1}q^{-x} \qquad [126]$$

A series $\sum_{k=0}^{\infty} c_k$ with $c_{k+1}/c_k$ being an elliptic (i.e., doubly periodic meromorphic) function of $k$ considered as a complex variable is called an elliptic hypergeometric series. In particular, define the ${}_rE_{r-1}$ theta hypergeometric series as the formal series

$${}_rE_{r-1}(a_1,\ldots,a_r;b_1,\ldots,b_{r-1};q,p;z) := \sum_{k=0}^{\infty} \frac{(a_1,\ldots,a_r;q,p)_k}{(b_1,\ldots,b_{r-1};q,p)_k} \frac{z^k}{(q;q,p)_k} \qquad [127]$$

It has $g(k) := c_{k+1}/c_k$ with

$$g(x) = \frac{z\theta(a_1q^x;p)\ldots\theta(a_rq^x;p)}{\theta(q^{x+1};p)\,\theta(b_1q^x;p)\ldots\theta(b_{r-1}q^x;p)}$$

By [126], $g(x)$ is an elliptic function with periods $\sigma^{-1}$ and $\tau\sigma^{-1}$ ($q = e^{2\pi i\sigma}, p = e^{2\pi i\tau}$) if the balancing condition $a_1 \ldots a_r = qb_1 \ldots b_{r-1}$ is satisfied.

The ${}_rV_{r-1}$ very well-poised theta hypergeometric series (a special ${}_rE_{r-1}$) is defined, in case of argument 1, as:

$${}_rV_{r-1}(a_1;a_6,\ldots,a_r;q,p) := \sum_{k=0}^{\infty} \frac{\theta(a_1q^{2k};p)}{\theta(a_1;p)} \frac{(a_1,a_6,\ldots,a_r;q,p)_k}{(qa_1/a_6,\ldots,qa_1/a_r;q,p)_k} \times \frac{q^k}{(q;q,p)_k} \qquad [128]$$

The series is called balanced if $a_6^2 \ldots a_r^2 = a_1^{r-6}q^{r-4}$. The series terminates if, for instance, $a_r = q^{-n}$.

#### Elliptic Analog of Jackson's ${}_8W_7$ Summation

$${}_{10}V_9(a;b,c,d,q^{n+1}a^2/(bcd),q^{-n};q,p) = \frac{(qa,qa/(bc),qa/(bd),qa/(cd);q,p)_n}{(qa/b,qa/c,qa/d,qa/(bcd);q,p)_n} \qquad [129]$$

#### Elliptic Analog of Bailey's ${}_{10}W_9$ Transformation

$${}_{12}V_{11}\left(a;b,c,d,e,f,\frac{q^{n+2}a^3}{bcdef},q^{-n};q,p\right) = \frac{(qa,qa/(ef),(qa)^2/(bcde),(qa)^2/(bcdf);q,p)_n}{(qa/e,qa/f,(qa)^2/(bcdef),(qa)^2/(bcd);q,p)_n} \times {}_{12}V_{11}\left(\frac{qa^2}{bcd};\frac{qa}{cd},\frac{qa}{bd},\frac{qa}{bc},e,f,\frac{q^{n+2}a^3}{bcdef},q^{-n};q,p\right) \qquad [130]$$

Suitable ${}_{12}V_{11}$ functions satisfy a discrete biorthogonality relation which is an elliptic analog of [99].

#### Ruijsenaars' elliptic gamma function

$$\Gamma(z;q,p) := \prod_{j,k=0}^{\infty} \frac{1-z^{-1}q^{j+1}p^{k+1}}{1-zq^jp^k} \qquad [131]$$

which is symmetric in $p$ and $q$. Then

$$\Gamma(qz;q,p) = \theta(z;p)\Gamma(z;q,p)$$
$$\Gamma(q^nz;q,p) = (z;q,p)_n\Gamma(z;q,p) \qquad [132]$$

## Applications

#### Quantum Groups

A specific quantum group is usually a Hopf algebra which is a $q$-deformation of the Hopf algebra of functions on a specific Lie group or, dually, of a universal enveloping algebra (viewed as Hopf algebra) of a Lie algebra. The general philosophy is that representations of the Lie group or Lie algebra also deform to representations of the quantum group, and that special functions associated with the representations in the classical case deform to $q$-special functions associated with the representations in the quantum case. Sometimes this is straightforward, but often new subtle phenomena occur.

The representation-theoretic objects which may be explicitly written in terms of $q$-special functions include matrix elements of representations with respect to specific bases (in particular spherical elements), Clebsch–Gordan coefficients and Racah coefficients. Many one-variable $q$-hypergeometric functions have found interpretation in some way in connection with a quantum analog of a three-dimensional Lie group (generically the Lie group

SL(2, $\mathbb{C}$) and its real forms). Classical by now are: little $q$-Jacobi polynomials interpreted as matrix elements of irreducible representations of $SU_q(2)$ with respect to the standard basis; Askey–Wilson polynomials similarly interpreted with respect to a certain basis not coming from a quantum subgroup; Jackson's third $q$-Bessel functions as matrix elements of irreducible representations of $E_q(2)$; $q$-Hahn polynomials and $q$-Racah polynomials interpreted as Clebsch–Gordan coefficients and Racah coefficients, respectively, for $SU_q(2)$.

Further developments include: Macdonald polynomials as spherical elements on quantum analogs of compact Riemannian symmetric spaces; $q$-analogs of Jacobi functions as matrix elements of irreducible unitary representations of $SU_q(1,1)$; Askey–Wilson polynomials as matrix elements of representations of the SU(2) dynamical quantum group; an interpretation of discrete ${}_{12}V_{11}$ biorthogonality relations on the elliptic U(2) quantum group.

Since the $q$-deformed Hopf algebras are usually presented by generators and relations, identities for $q$-special functions involving noncommuting variables satisfying simple relations are important for further interpretations of $q$-special functions in quantum groups, for instance:

**$q$-Binomial formula with $q$-commuting variables**

$$(x+y)^n = \sum_{k=0}^{n} \begin{bmatrix} n \\ k \end{bmatrix}_q y^{n-k} x^k \quad (xy = qyx) \qquad [133]$$

**Functional equations for $q$-exponentials with $xy = qyx$**

$$\begin{aligned} e_q(x+y) &= e_q(y) e_q(x) \\ E_q(x+y) &= E_q(x) E_q(y) \end{aligned} \qquad [134]$$

$$\begin{aligned} e_q(x+y-yx) &= e_q(x) e_q(y) \\ E_q(x+y+yx) &= E_q(y) E_q(x) \end{aligned} \qquad [135]$$

### Various Algebraic Settings

**Classical groups over finite fields (Chevalley groups)** $q$-Hahn polynomials and various kinds of $q$-Krawtchouk polynomials have interpretations as spherical and intertwining functions on classical groups ($GL_n, SO_n, Sp_n$) over a finite field $F_q$ with respect to suitable subgroups, see Stanton (1984).

**Affine Kac–Moody algebras (see Lepowsky (1982))** The Rogers–Ramanujan identities [57], [58] and some of their generalizations were interpreted in the context of characters of representations of the simplest affine Kac–Moody algebra $A_1^{(1)}$. Macdonald's generalization of Weyl's denominator formula to affine root systems has an interpretation as an identity for the denominator of the character of a representation of an affine Kac–Moody algebra.

### Partitions of Positive Integers

Let $n$ be a positive integer, $p(n)$ the number of partitions of $n$, $p_N(n)$ the number of partitions of $n$ into parts $\le N$, $p_{\text{dist}}(n)$ the number of partitions of $n$ into distinct parts, and $p_{\text{odd}}(n)$ the number of partitions of $n$ into odd parts. Then, Euler observed:

$$\frac{1}{(q;q)_\infty} = \sum_{n=0}^{\infty} p(n) q^n \quad \frac{1}{(q;q)_N} = \sum_{n=0}^{\infty} p_N(n) q^n \qquad [136]$$

$$\begin{aligned} (-q;q)_\infty &= \sum_{n=0}^{\infty} p_{\text{dist}}(n) q^n \\ \frac{1}{(q;q^2)_\infty} &= \sum_{n=0}^{\infty} p_{\text{odd}}(n) q^n \end{aligned} \qquad [137]$$

and

$$(-q;q)_\infty = \frac{1}{(q;q^2)_\infty}, \qquad p_{\text{dist}}(n) = p_{\text{odd}}(n) \qquad [138]$$

The Rogers–Ramanujan identity [57] has the following partition-theoretic interpretation: the number of partitions of $n$ with parts differing at least 2 equals the number of partitions of $n$ into parts congruent to 1 or 4 (mod 5). Similarly, [58] yields: the number of partitions of $n$ with parts larger than 1 and differing at least 2 equals the number of partitions of $n$ into parts congruent to 2 or 3 (mod 5).

The left-hand sides of the Rogers–Ramanujan identities [57] and [58] have interpretations in the "hard hexagon model," see Baxter (1982). Much further work has been done on Rogers–Ramanujan-type identities in connection with more general models in statistical mechanics. The so-called "fermionic expressions" do occur.

# Quantum 3-Manifold Invariants

**C Blanchet**, Université de Bretagne-Sud, Vannes, France
**V Turaev**, IRMA, Strasbourg, France

## Introduction

The idea to derive topological invariants of smooth manifolds from partition functions of certain action functionals was suggested by A Schwarz (1978) and highlighted by E Witten (1988). Witten interpreted the Jones polynomial of links in the 3-sphere $S^3$ as a partition function of the Chern–Simons field theory. Witten conjectured the existence of mathematically defined topological invariants of 3-manifolds, generalizing the Jones polynomial (or rather its values in complex roots of unity) to links in arbitrary closed oriented 3-manifolds. A rigorous construction of such invariants was given by N Reshetikhin and V Turaev (1989) using the theory of quantum groups. The Witten–Reshetikhin–Turaev invariants of 3-manifolds, also called the "quantum invariants," extend to a topological quantum field theory (TQFT) in dimension 3.

## Ribbon and Modular Categories

The Reshetikhin–Turaev approach begins with fixing suitable algebraic data, which are best described in terms of monoidal categories. Let $\mathcal{C}$ be a monoidal category (i.e., a category with an associative tensor product and unit object $\mathbb{1}$). A "braiding" in $\mathcal{C}$ assigns to any objects $V, W \in \mathcal{C}$ an invertible morphism $c_{V,W} : V \otimes W \to W \otimes V$ such that, for any $U, V, W \in \mathcal{C}$,

$$c_{U,V\otimes W} = (\mathrm{id}_V \otimes c_{U,W})(c_{U,V} \otimes \mathrm{id}_W)$$
$$c_{U\otimes V,W} = (c_{U,W} \otimes \mathrm{id}_V)(\mathrm{id}_U \otimes c_{V,W})$$

A "twist" in $\mathcal{C}$ assigns to any object $V \in \mathcal{C}$ an invertible morphism $\theta_V : V \to V$ such that, for any $V, W \in \mathcal{C}$,

$$\theta_{V\otimes W} = c_{W,V}\, c_{V,W}(\theta_V \otimes \theta_W)$$

A "duality" in $\mathcal{C}$ assigns to any object $V \in \mathcal{C}$ a "dual" object $V^* \in \mathcal{C}$, and evaluation and co-evaluation morphisms $d_V : V^* \otimes V \to \mathbb{1}$, $b_V : \mathbb{1} \to V \otimes V^*$ such that

$$(\mathrm{id}_V \otimes d_V)(b_V \otimes \mathrm{id}_V) = \mathrm{id}_V$$
$$(d_V \otimes \mathrm{id}_{V^*})(\mathrm{id}_{V^*} \otimes b_V) = \mathrm{id}_{V^*}$$

The category $\mathcal{C}$ with duality, braiding, and twist is ribbon, if for any $V \in \mathcal{C}$,

$$(\theta_V \otimes \mathrm{id}_{V^*})b_V = (\mathrm{id}_V \otimes \theta_{V^*})b_V$$

For an endomorphism $f: V \to V$ of an object $V \in \mathcal{C}$, its trace "$\mathrm{tr}(f) \in \mathrm{End}_{\mathcal{C}}(\mathbb{1})$" is defined as

$$\mathrm{tr}(f) = d_V c_{V,V^*}((\theta_V f) \otimes \mathrm{id}_{V^*})b_V : \mathbb{1} \to \mathbb{1}$$

This trace shares a number of properties of the standard trace of matrices, in particular, $\mathrm{tr}(fg) = \mathrm{tr}(gf)$ and $\mathrm{tr}(f \otimes g) = \mathrm{tr}(f)\mathrm{tr}(g)$. For an object $V \in \mathcal{C}$, set

$$\dim(V) = \mathrm{tr}(\mathrm{id}_V) = d_V c_{V,V^*}(\theta_V \otimes \mathrm{id}_{V^*})b_V$$

Ribbon categories nicely fit the theory of knots and links in $S^3$. A link $L \subset S^3$ is a closed one-dimensional submanifold of $S^3$. (A manifold is closed if it is compact and has no boundary.) A link is oriented (resp. framed) if all its components are oriented (resp. provided with a homotopy class of nonsingular normal vector fields). Given a framed oriented link $L \subset S^3$ whose components are labeled with objects of a ribbon category $\mathcal{C}$, one defines a tensor $\langle L \rangle \in \mathrm{End}_{\mathcal{C}}(\mathbb{1})$. To compute $\langle L \rangle$, present $L$ by a plane diagram with only double transversal crossings such that the framing of $L$ is orthogonal to the plane. Each double point of the diagram is an intersection of two branches of $L$, going over and under, respectively. Associate with such a crossing the tensor $(c_{V,W})^{\pm 1}$ where $V, W \in \mathcal{C}$ are the labels of these two branches and $\pm 1$ is the sign of the crossing determined by the orientation of $L$. We also associate certain tensors with the points of the diagram where the tangent line is parallel to a fixed axis on the plane. These tensors are derived from the evaluation and co-evaluation morphisms and the twists. Finally, all these tensors are contracted into a single element $\langle L \rangle \in \mathrm{End}_{\mathcal{C}}(\mathbb{1})$. It does not depend on the intermediate choices and is preserved under isotopy of $L$ in $S^3$. For the trivial knot $O(V)$ with framing 0 and label $V \in \mathcal{C}$, we have $\langle O(V) \rangle = \dim(V)$.

Further constructions need the notion of a tangle. An (oriented) tangle is a compact (oriented) one-dimensional submanifold of $\boldsymbol{R}^2 \times [0,1]$ with endpoints on $\boldsymbol{R} \times 0 \times \{0,1\}$. Near each of its endpoints, an oriented tangle $T$ is directed either down or up, and thus acquires a sign $\pm 1$. One can view $T$ as a morphism from the sequence of $\pm 1$'s associated with its bottom ends to the sequence of $\pm 1$'s associated with its top ends. Tangles can be composed by putting one on top of the other. This defines a category of tangles $\mathcal{T}$ whose objects are finite sequences of $\pm 1$'s and whose morphisms are isotopy classes of framed oriented tangles. Given a ribbon category $\mathcal{C}$, we can consider $\mathcal{C}$-labeled tangles, that is, (framed oriented) tangles whose components are labeled with objects of $\mathcal{C}$. They form a category $\mathcal{T}_{\mathcal{C}}$. Links appear here as tangles without endpoints, that is, as morphisms $\emptyset \to \emptyset$. The link invariant $\langle L \rangle$ generalizes to a functor $\langle \cdot \rangle : \mathcal{T}_{\mathcal{C}} \to \mathcal{C}$.

To define 3-manifold invariants, we need modular categories (Turaev 1994). Let $\boldsymbol{k}$ be a field. A monoidal category $\mathcal{C}$ is $\boldsymbol{k}$-additive if its Hom sets are $\boldsymbol{k}$-vector spaces, the composition and tensor product of the morphisms are bilinear, and $\mathrm{End}_{\mathcal{C}}(\mathbb{1}) = \boldsymbol{k}$. An object $V \in \mathcal{C}$ is simple if $\mathrm{End}_{\mathcal{C}}(V) = \boldsymbol{k}$. A modular category is a $\boldsymbol{k}$-additive ribbon category $\mathcal{C}$ with a finite family of simple objects $\{V_\lambda\}_\lambda$ such that (1) for any object $V \in \mathcal{C}$ there is a finite expansion $\mathrm{id}_V = \sum_i f_i g_i$ for certain morphisms $g_i : V \to V_{\lambda_i}$, $f_i : V_{\lambda_i} \to V$ and (2) the $S$-matrix $(S_{\lambda,\mu})$ is invertible over $\boldsymbol{k}$ where $S_{\lambda,\mu} = \mathrm{tr}(c_{V_\lambda,V_\mu} c_{V_\mu,V_\lambda})$. Note that $S_{\lambda,\mu} = \langle H(\lambda,\mu) \rangle$ where $H(\lambda,\mu)$ is the oriented Hopf link with framing 0, linking number +1, and labels $V_\lambda$, $V_\mu$.

Axiom (1) implies that every simple object in $\mathcal{C}$ is isomorphic to exactly one of $V_\lambda$. In most interesting cases (when there is a well-defined direct summation in $\mathcal{C}$), this axiom may be rephrased by saying that $\mathcal{C}$ is finite semisimple, that is, $\mathcal{C}$ has a finite set of isomorphism classes of simple objects and all objects of $\mathcal{C}$ are direct sums of simple objects. A weaker version of the axiom (2) yields premodular categories.

The invariant $\langle \cdot \rangle$ of links and tangles extends by linearity to the case where labels are finite linear combinations of objects of $\mathcal{C}$ with coefficients in $\boldsymbol{k}$. Such a linear combination $\Omega = \sum_\lambda \dim(V_\lambda) V_\lambda$ is called the Kirby color. It has the following sliding property: for any object $V \in \mathcal{C}$, the two tangles in Figure 1 yield the same morphism $V \to V$. Here, the dashed line represents an arc on the closed component labeled by $\Omega$. This arc can be knotted or linked with other components of the tangle (not shown in the figure).

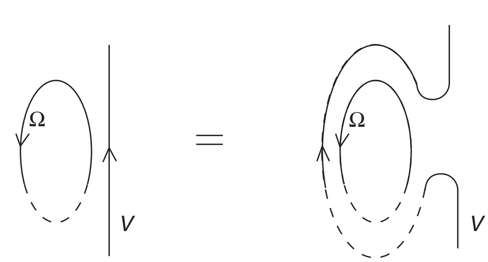

**Figure 1** Sliding property.

## Invariants of Closed 3-Manifolds

Given an embedded solid torus $g: S^1 \times D^2 \hookrightarrow S^3$, where $D^2$ is a 2-disk and $S^1 = \partial D^2$, a 3-manifold can be built as follows. Remove from $S^3$ the interior of $g(S^1 \times D^2)$ and glue back the solid torus $D^2 \times S^1$ along $g|_{S^1 \times S^1}$. This process is known as "surgery." The resulting 3-manifold depends only on the isotopy class of the framed knot represented by $g$. More generally, a surgery on a framed link $L = \cup_{i=1}^m L_i$ in $S^3$ with $m$ components yields a closed oriented 3-manifold $M_L$. A theorem of W Lickorish and A Wallace asserts that any closed connected oriented 3-manifold is homeomorphic to $M_L$ for some $L$. R Kirby proved that two framed links give rise to homeomorphic 3-manifolds if and only if these links are related by isotopy and a finite sequence of geometric transformations called Kirby moves. There are two Kirby moves: adjoining a distant unknot $O^\varepsilon$ with framing $\varepsilon = \pm 1$, and sliding a link component over another one as in Figure 1.

Let $L = \cup_{i=1}^m L_i \subset S^3$ be a framed link and let $(b_{i,j})_{i,j=1,\ldots,m}$ be its linking matrix: for $i \neq j, b_{i,j}$ is the linking number of $L_i, L_j$, and $b_{i,i}$ is the framing number of $L_i$. Denote by $e_+$ (resp. $e_-$) the number of positive (resp. negative) eigenvalues of this matrix. The sliding property of modular categories implies the following theorem. In its statement, a knot $K$ with label $\Omega$ is denoted by $K(\Omega)$.

**Theorem 1** *Let $\mathcal{C}$ be a modular category with Kirby color $\Omega$. Then $\langle O^1(\Omega)\rangle \neq 0, \langle O^{-1}(\Omega)\rangle \neq 0$ and the expression*

$$\tau_{\mathcal{C}}(M_L) = \langle O^1(\Omega)\rangle^{-e_+} \langle O^{-1}(\Omega)\rangle^{-e_-} \langle L_1(\Omega), \ldots, L_m(\Omega)\rangle$$

*is invariant under the Kirby moves on L. This expression yields, therefore, a well-defined topological invariant $\tau_{\mathcal{C}}$ of closed connected oriented 3-manifolds.*

Several competing normalizations of $\tau_{\mathcal{C}}$ exist in the literature. Here, the normalization used is such that $\tau_{\mathcal{C}}(S^3) = 1$ and $\tau_{\mathcal{C}}(S^1 \times S^2) = \sum_\lambda (\dim(V_\lambda))^2$. The invariant $\tau_{\mathcal{C}}$ extends to 3-manifolds with a framed oriented $\mathcal{C}$-labeled link $K$ inside by

$$\begin{aligned}\tau_{\mathcal{C}}&(M_L, K) \\ &= \langle O^1(\Omega)\rangle^{-e_+} \langle O^{-1}(\Omega)\rangle^{-e_-} \langle L_1(\Omega), \ldots, L_m(\Omega), K\rangle\end{aligned}$$

## Three-Dimensional TQFTs

A three-dimensional TQFT $\boldsymbol{V}$ assigns to every closed oriented surface $X$ a finite-dimensional vector space $\boldsymbol{V}(X)$ over a field $\boldsymbol{k}$ and assigns to every cobordism $(M, X, Y)$ a linear map $\boldsymbol{V}(M) = \boldsymbol{V}(M, X, Y): \boldsymbol{V}(X) \to \boldsymbol{V}(Y)$. Here, a "cobordism" $(M, X, Y)$ between surfaces $X$ and $Y$ is a compact oriented 3-manifold $M$ with $\partial M = (-X) \amalg Y$ (the minus sign indicates the orientation reversal). A TQFT has to satisfy axioms which can be expressed by saying that $\boldsymbol{V}$ is a monoidal functor from the category of surfaces and cobordisms to the category of vector spaces over $\boldsymbol{k}$. Homeomorphisms of surfaces should induce isomorphisms of the corresponding vector spaces compatible with the action of cobordisms. From the definition, $\boldsymbol{V}(\emptyset) = \boldsymbol{k}$. Every compact oriented 3-manifold $M$ is a cobordism between $\emptyset$ and $\partial M$ so that $\boldsymbol{V}$ yields a "vacuum" vector $\boldsymbol{V}(M) \in \mathrm{Hom}(\boldsymbol{V}(\emptyset), \boldsymbol{V}(\partial M)) = \boldsymbol{V}(\partial M)$. If $\partial M = \emptyset$, then this gives a numerical invariant $\boldsymbol{V}(M) \in \boldsymbol{V}(\emptyset) = \boldsymbol{k}$.

Interestingly, TQFTs are often defined for surfaces and 3-cobordisms with additional structure. The surfaces $X$ are normally endowed with Lagrangians, that is, with maximal isotropic subspaces in $H_1(X; \boldsymbol{R})$. For 3-cobordisms, several additional structures are considered in the literature: for example, 2-framings, $p_1$-structures, and numerical weights. All these choices are equivalent. The TQFTs requiring such additional structures are said to be "projective" since they provide projective linear representations of the mapping class groups of surfaces.

Every modular category $\mathcal{C}$ with ground field $\boldsymbol{k}$ and simple objects $\{V_\lambda\}_\lambda$ gives rise to a projective three-dimensional TQFT $\boldsymbol{V}_{\mathcal{C}}$. It depends on the choice of a square root $\mathcal{D}$ of $\sum_\lambda (\dim(V_\lambda))^2 \in \boldsymbol{k}$. For a connected surface $X$ of genus $g$,

$$\boldsymbol{V}_{\mathcal{C}}(X) = \mathrm{Hom}_{\mathcal{C}}\left(\mathbb{1}, \bigoplus_{\lambda_1,\ldots,\lambda_g} \bigotimes_{r=1}^{g} (V_{\lambda_r} \otimes V_{\lambda_r}^*)\right)$$

The dimension of this vector space enters the Verlinde formula

$$\dim_{\boldsymbol{k}}(\boldsymbol{V}_{\mathcal{C}}(X)) \cdot 1_{\boldsymbol{k}} = \mathcal{D}^{2g-2} \sum_\lambda (\dim(V_\lambda))^{2-2g}$$

where $1_{\boldsymbol{k}} \in \boldsymbol{k}$ is the unit of the field $\boldsymbol{k}$. If $\mathrm{char}(\boldsymbol{k}) = 0$, then this formula computes $\dim_{\boldsymbol{k}}(\boldsymbol{V}_{\mathcal{C}}(X))$. For a closed connected oriented 3-manifold $M$ with numerical weight zero, $\boldsymbol{V}_{\mathcal{C}}(M) = \mathcal{D}^{-b_1(M)-1} \tau_{\mathcal{C}}(M)$, where $b_1(M)$ is the first Betti number of $M$.

The TQFT $\boldsymbol{V}_{\mathcal{C}}$ extends to a vaster class of surfaces and cobordisms. Surfaces may be enriched with a finite set of marked points, each labeled with an object of $\mathcal{C}$ and endowed with a tangent direction. Cobordisms may be enriched with ribbon (or fat) graphs whose edges are labeled with objects of $\mathcal{C}$ and whose vertices are labeled with appropriate intertwiners. The resulting TQFT, also denoted $\boldsymbol{V}_{\mathcal{C}}$, is nondegenerate in the sense that, for any surface $X$, the vacuum vectors in $\boldsymbol{V}(X)$ determined by all $M$

with $\partial M = X$ span $\mathbf{V}(X)$. A detailed construction of $\mathbf{V}_{\mathcal{C}}$ is given in Turaev (1994).

The two-dimensional part of $\mathbf{V}_{\mathcal{C}}$ determines a "modular functor" in the sense of G Segal, G Moore, and N Seiberg.

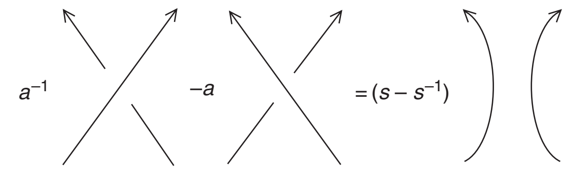

**Figure 2** The Homfly relation.

## Constructions of Modular Categories

The universal enveloping algebra $U\mathfrak{g}$ of a (finite-dimensional complex) simple Lie algebra $\mathfrak{g}$ admits a deformation $U_q\mathfrak{g}$, which is a quasitriangular Hopf algebra. The representation category $\mathrm{Rep}(U_q\mathfrak{g})$ is $\mathbf{C}$-linear and ribbon. For generic $q \in \mathbf{C}$, this category is semisimple. (The irreducible representations of $\mathfrak{g}$ can be deformed to irreducible representations of $U_q\mathfrak{g}$.) For $q$, an appropriate root of unity, a certain subquotient of $\mathrm{Rep}(U_q\mathfrak{g})$ is a modular category with ground field $\boldsymbol{k} = \mathbf{C}$. For $\mathfrak{g} = \mathrm{sl}_2(\mathbf{C})$, it was pointed out by Reshetikhin and Turaev; the general case involves the theory of tilting modules. The corresponding 3-manifold invariant $\tau$ is denoted $\tau_q^{\mathfrak{g}}$. For example, if $\mathfrak{g} = \mathrm{sl}_2(\mathbf{C})$ and $M$ is the Poincaré homology sphere (obtained by surgery on a left-hand trefoil with framing –1), then (Le 2003)

$$\tau_q^{\mathfrak{g}}(M) = (1-q)^{-1} \sum_{n \geq 0} q^n (1 - q^{n+1}) \times (1 - q^{n+2}) \cdots (1 - q^{2n+1})$$

The sum here is finite since $q$ is a root of unity.

There is another construction (Le 2003) of a modular category associated with a simple Lie algebra $\mathfrak{g}$ and certain roots of unity $q$. The corresponding quantum invariant of 3-manifolds is denoted $\tau_q^{P\mathfrak{g}}$. (Here, it is normalized so that $\tau_q^{P\mathfrak{g}}(S^3) = 1$.) Under mild assumptions on the order of $q$, we have $\tau_q^{\mathfrak{g}}(M) = \tau_q^{\mathfrak{g}}(M)\tau'(M)$ for all $M$, where $\tau'(M)$ is a certain Gauss sum determined by $\mathfrak{g}$, the homology group $H = H_1(M)$ and the linking form $\mathrm{Tors}\, H \times \mathrm{Tors}\, H \to \mathbf{Q}/\mathbf{Z}$.

A different construction derives modular categories from the category of framed oriented tangles $\mathcal{T}$. Given a ring $K$, a bigger category $K[\mathcal{T}]$ can be considered whose morphisms are linear combinations of tangles with coefficients in $K$. Both $\mathcal{T}$ and $K[\mathcal{T}]$ have a natural structure of a ribbon monoidal category.

The skein method builds ribbon categories by quotienting $K[\mathcal{T}]$ using local "skein" relations, which appear in the theory of knot polynomials (the Alexander–Conway polynomial, the Homfly polynomial, and the Kauffman polynomial). In order to obtain a semisimple category, one completes the quotient category with idempotents as objects (the Karoubi completion). Choosing appropriate skein relations, one can recover the modular categories derived from quantum groups of series $A$, $B$, $C$, $D$. In particular, the categories determined by the series $A$ arise from the Homfly skein relation shown in Figure 2 where $a, s \in K$. The categories determined by the series $B$, $C$, $D$ arise from the Kauffman skein relation.

The quantum invariants of 3-manifolds and the TQFTs associated with $\mathrm{sl}_N$ can be directly described in terms of the Homfly skein theory, avoiding the language of ribbon categories (W Lickorish, C Blanchet, N Habegger, G Masbaum, P Vogel for $\mathrm{sl}_2$ and Y Yokota for all $\mathrm{sl}_N$).

## Unitarity

From both physical and topological viewpoints, one is mainly interested in Hermitian and unitary TQFTs (over $\boldsymbol{k} = \mathbf{C}$). A TQFT $\mathbf{V}$ is Hermitian if the vector space $\mathbf{V}(X)$ is endowed with a nondegenerate Hermitian form $\langle .,. \rangle_X : \mathbf{V}(X) \otimes_{\mathbb{C}} \mathbf{V}(X) \to \mathbb{C}$ such that:

1. the form $\langle .,. \rangle_X$ is natural with respect to homeomorphisms and multiplicative with respect to disjoint union and
2. for any cobordism $(M, X, Y)$ and any $x \in \mathbf{V}(X)$, $y \in \mathbf{V}(Y)$,

$$\langle \mathbf{V}(M, X, Y)(x), y \rangle_Y = \langle x, \mathbf{V}(-M, Y, X)(y) \rangle_X$$

If $\langle .,. \rangle_X$ is positive definite for every $X$, then the Hermitian TQFT is "unitary." Note two features of Hermitian TQFTs. If $\partial M = \emptyset$, then $\mathbf{V}(-M) = \overline{\mathbf{V}(M)}$. The group of self-homeomorphisms of any $X$ acts in $\mathbf{V}(X)$ preserving the form $\langle .,. \rangle_X$. For a unitary TQFT, this gives an action by unitary matrices.

The three-dimensional TQFT derived from a modular category $\mathcal{V}$ is Hermitian (resp. unitary) under additional assumptions on $\mathcal{V}$ which are discussed briefly. A "conjugation" in $\mathcal{V}$ assigns to each morphism $f : V \to W$ in $\mathcal{V}$ a morphism $\bar{f} : W \to V$ so that

$$\bar{\bar{f}} = f, \quad \overline{f + g} = \bar{f} + \bar{g} \quad \text{for any } f, g : V \to W$$
$$\overline{f \otimes g} = \bar{f} \otimes \bar{g} \quad \text{for any morphisms } f, g \text{ in } \mathcal{C}$$
$$\overline{f \circ g} = \bar{g} \circ \bar{f} \quad \text{for any morphisms } f : V \to W,\ g : W \to V$$

One calls $\mathcal{V}$ Hermitian if it is endowed with conjugation such that

$$\overline{\theta_V} = (\theta_V)^{-1}, \quad \overline{c_{V,W}} = (c_{V,W})^{-1}$$
$$\overline{b_V} = d_V c_{V,V^*}(\theta_V \otimes \mathbf{1}_{V^*})$$
$$\overline{d_V} = (\mathbf{1}_{V^*} \otimes \theta_V^{-1}) c_{V^*,V}^{-1} b_V$$

for any objects $V$, $W$ of $\mathcal{V}$. A Hermitian modular category $\mathcal{V}$ is unitary if $\mathrm{tr}(f\bar{f}) \geq 0$ for any morphism $f$ in $\mathcal{V}$. The three-dimensional TQFT, derived from a Hermitian (resp. unitary) modular category, has a natural structure of a Hermitian (resp. unitary) TQFT.

The modular category derived from a simple Lie algebra $\mathfrak{g}$ and a root of unity $q$ is always Hermitian. It may be unitary for some $q$. For simply laced $\mathfrak{g}$, there are always such roots of unity $q$ of any given sufficiently big order. For non-simply-laced $\mathfrak{g}$, this holds under certain divisibility conditions on the order of $q$.

## Integral Structures in TQFTs

The quantum invariants of 3-manifolds have one fundamental property: up to an appropriate rescaling, they are algebraic integers. This was first observed by H Murakami, who proved that $\tau_q^{\mathrm{sl}_2}(M)$ is an algebraic integer, provided the order of $q$ is an odd prime and $M$ is a homology sphere. This extends to an arbitrary closed connected oriented 3-manifold $M$ and an arbitrary simple Lie algebra $\mathfrak{g}$ as follows (Le 2003): for any sufficiently big prime integer $r$ and any primitive $r$th root of unity $q$,

$$\tau_q^{P\mathfrak{g}}(M) \in \mathbf{Z}[q] = \mathbf{Z}[\exp(2\pi i/r)] \qquad [1]$$

This inclusion allows one to expand $\tau_q^{P\mathfrak{g}}(M)$ as a polynomial in $q$. A study of its coefficients leads to the Ohtsuki invariants of rational homology spheres and further to perturbative invariants of 3-manifolds due to T Le, J Murakami, and T Ohtsuki (see Ohtsuki (2002)). Conjecturally, the inclusion [1] holds for nonprime (sufficiently big) $r$ as well. Connections with the algebraic number theory (specifically modular forms) were studied by D Zagier and R Lawrence.

It is important to obtain similar integrality results for TQFTs. Following P Gilmer, fix a Dedekind domain $D \subset \mathbf{C}$ and call a TQFT $\mathbf{V}$ almost $D$-integral if it is nondegenerate and there is $d \in \mathbf{C}$ such that $d\mathbf{V}(M) \in D$ for all $M$ with $\partial M = \emptyset$. Given an almost-integral TQFT $\mathbf{V}$ and a surface $X$, we define $S(\hat{X})$ to be the $D$-submodule of $\mathbf{V}(X)$, generated by all vacuum vectors for $X$. This module is preserved under the action of self-homeomorphisms of $X$. It turns out that $S(X)$ is a finitely generated projective $D$-module and $\mathbf{V}(X) = S(X) \otimes_D \mathbf{C}$. A cobordism $(M, X, Y)$ is targeted if all its connected components meet $Y$ along a nonempty set. In this case, $\mathbf{V}(M)(S(X)) \subset S(Y)$. Thus, applying $S$ to surfaces and restricting $\tau$ to targetet cobordisms, we obtain an "integral version" of $\mathbf{V}$. In many interesting cases, the $D$-module $S(X)$ is free and its basis may be described explicitly. A simple Lie algebra $\mathfrak{g}$ and a primitive $r$th (in some cases 4$r$th) root of unity $q$ with sufficiently big prime $r$ give rise to an almost $D$-integral TQFT for $D = \mathbf{Z}[q]$.

## State-Sum Invariants

Another approach to three-dimensional TQFTs is based on the theory of 6$j$-symbols and state sums on triangulations of 3-manifolds. This approach introduced by V Turaev and O Viro is a quantum deformation of the Ponzano–Regge model for the three-dimensional lattice gravity. The quantum 6$j$-symbols derived from representations of $U_q(\mathrm{sl}_2\mathbf{C})$ are $\mathbf{C}$-valued rational functions of the variable $q_0 = q^{1/2}$

$$\begin{vmatrix} i & j & k \\ l & m & n \end{vmatrix} \qquad [2]$$

numerated by 6-tuples of non-negative integers $i$, $j$, $k$, $l$, $m$, $n$. One can think of these integers as labels sitting on the edges of a tetrahedron (see Figure 3). The 6$j$-symbol admits various equivalent normalizations and we choose the one which has full tetrahedral symmetry. Now, let $q_0 \in \mathbf{C}$ be a primitive 2$r$th root of unity with $r \geq 2$. Set $I = \{0, 1, \ldots, r-2\}$. Given a labeled tetrahedron $T$ as in Figure 3 with $i, j, k, l, m, n \in I$, the 6$j$-symbol [2] can be evaluated at $q_0$ and we can obtain a complex number denoted $|T|$. Consider a closed three-dimensional manifold $M$ with triangulation $t$. (Note that all 3-manifolds can be triangulated.) A coloring of $M$ is a mapping $\varphi$ from the set $\mathrm{Edg}(t)$ of the edges of $t$ to $I$. Set

$$|M| = (\sqrt{2r}/(q_0 - q_0^{-1}))^{-2a} \sum_{\varphi} \prod_{e \in \mathrm{Edg}(t)} \langle \varphi(e) \rangle \prod_T |T^{\varphi}|$$

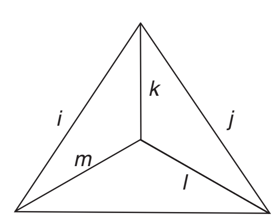

**Figure 3** Labeled tetrahedron.

where $a$ is the number of vertices of $t$, $\langle n \rangle = (-1)^n (q_0^n - q_0^{-n})/(q_0 - q_0^{-1})$ for any integer $n$, $T$ runs over all tetrahedra of $t$, and $T^\varphi$ is $T$ with the labeling induced by $\varphi$. It is important to note that $|M|$ *does not depend on the choice of t and thus yields a topological invariant of M*.

The invariant $|M|$ is closely related to the quantum invariant $\tau_q^{\mathfrak{g}}(M)$ for $\mathfrak{g} = \mathrm{sl}_2(\mathbf{C})$. Namely, $|M|$ is the square of the absolute value of $\tau_q^{\mathfrak{g}}(M)$, that is, $|M| = |\tau_q^{\mathfrak{g}}(M)|^2$. This computes $|\tau_q^{\mathfrak{g}}(M)|$ inside $M$ without appeal to surgery. No such computation of the phase of $\tau_q^{\mathfrak{g}}(M)$ is known.

These constructions generalize in two directions. First, they extend to manifolds with boundary. Second, instead of the representation category of $U_q(\mathrm{sl}_2\mathbf{C})$, one can use an arbitrary modular category $\mathcal{C}$. This yields a three-dimensional TQFT, which associates to a surface $X$ a vector space $|X|_\mathcal{C}$, and to a 3-cobordism $(M, X, Y)$ a homomorphism $|M|_\mathcal{C} : |X|_\mathcal{C} \to |Y|_\mathcal{C}$, (see Turaev (1994)). When $X = Y = \emptyset$, this homomorphism is multiplication $\mathbf{C} \to \mathbf{C}$ by a topological invariant $|M|_\mathcal{C} \in \mathbf{C}$. The latter is computed as a state sum on a triangulation of $M$ involving the 6*j*-symbols associated with $\mathcal{C}$. In general, these 6*j*-symbols are not numbers but tensors so that, instead of their product, one should use an appropriate contraction of tensors. The vectors in $V(X)$ are geometrically represented by trivalent graphs on $X$ such that every edge is labeled with a simple object of $\mathcal{C}$ and every vertex is labeled with an intertwiner between the three objects labeling the incident edges. The TQFT $|\cdot|_\mathcal{C}$ is related to the TQFT $\boldsymbol{V} = \boldsymbol{V}_\mathcal{C}$ by $|M|_\mathcal{C} = |\boldsymbol{V}(M)|^2$. Moreover, for any closed oriented surface $X$,

$$\begin{aligned}|X|_\mathcal{C} &= \mathrm{End}(\boldsymbol{V}(X)) = \boldsymbol{V}(X) \otimes (\boldsymbol{V}(X))^* \\ &= \boldsymbol{V}(X) \otimes \boldsymbol{V}(-X)\end{aligned}$$

and for any three-dimensional cobordism $(M, X, Y)$,

$$\begin{aligned}|M|_\mathcal{C} = \boldsymbol{V}(M) \otimes \boldsymbol{V}(-M) &: \boldsymbol{V}(X) \otimes \boldsymbol{V}(-X) \\ &\to \boldsymbol{V}(Y) \otimes \boldsymbol{V}(-Y)\end{aligned}$$

J Barrett and B Westbury introduced a generalization of $|M|_\mathcal{C}$ derived from the so-called spherical monoidal categories (which are assumed to be semisimple with a finite set of isomorphism classes of simple objects). This class includes modular categories and a most interesting family of (unitary monoidal) categories arising in the theory of subfactors (see Evans and Kawahigashi (1998) and Kodiyalam and Sunder (2001)). Every spherical category $\mathcal{C}$ gives rise to a topological invariant $|M|_\mathcal{C}$ of a closed oriented 3-manifold $M$. (It seems that this approach has not yet been extended to cobordisms.)

Every monoidal category $\mathcal{C}$ gives rise to a double (or a center) $Z(\mathcal{C})$, which is a braided monoidal category (see Majid (1995)). If $\mathcal{C}$ is spherical, then $Z(\mathcal{C})$ is modular. Conjecturally, $|M|_\mathcal{C} = \tau_{Z(\mathcal{C})}(M)$. In the case where $\mathcal{C}$ arises from a subfactor, this has been recently proved by Y Kawahigashi, N Sato, and M Wakui.

The state sum invariants above are closely related to spin networks, spin foam models, and other models of quantum gravity in dimension $2 + 1$ (see Baez (2000) and Carlip (1998)).

# Quantum Calogero–Moser Systems

**R Sasaki**, Kyoto University, Kyoto, Japan

## Introduction

Calogero–Moser (C–M) systems are multiparticle (i.e., finite degrees of freedom) dynamical systems with long-range interactions. They are integrable and solvable at both classical and quantum levels. These systems offer an ideal arena for interplay of many important concepts in mathematical/theoretical physics: to name a few, classical and quantum mechanics, classical and quantum integrability, exact and quasi-exact solvability, addition of discrete (spin) degrees of freedom, quantum Lax pair formalism, supersymmetric quantum mechanics, crystallographic root systems and associated Weyl groups and Lie algebras, noncrystallographic root systems, and Coxeter groups or finite reflection groups. The quantum integrability or solvability of C–M systems does not depend on such known solution mechanisms as Yang–Baxter equations, quantum *R*-matrix or Bethe ansatz for the quantum systems. In fact, quantum C–M systems provide a good material for pondering about quantum integrability.

## Quantum (Liouville) Integrability

The classical Liouville theorem for an integrable system consists of two parts. Let us consider Hamiltonian dynamics of finite degrees of freedom $N$ with coordinates $q=(q_1,\ldots,q_N)$ and conjugate momenta $p=(p_1,\ldots,p_N)$ equipped with Poisson brackets $\{q_j,p_k\}=\delta_{jk},\{q_j,q_k\}=\{p_j,p_k\}=0$. The first part is the existence of a set of independent and involutive $\{K_j,K_k\}=0$ conserved quantities $\{K_j\}$ as many as the degrees of freedom $(j=1,\ldots,N)$. The second part asserts that the generating function of the canonical transformation for the action-angle variables can be constructed from the conserved quantities via quadrature. In other words, the second part, that is, the reducibility to the action-angle variables is the integrability. The quantum counterpart of the first half is readily formulated: that is, the existence of a set of independent and mutually commuting (involutive) $[K_j,K_k]=0$ conserved quantities $\{K_j\}$ as many as the degrees of freedom. (This does not necessary imply, however, that they are well defined in a proper Hilbert space.) The definition of the quantum integrability should come as a second part, which is yet to be formulated. It is clear that the quantum Liouville integrability does not imply the complete determination of the eigenvalues and eigenfunctions. Such systems would be called exactly solvable. This can be readily understood by considering any (autonomous) degree-1 Hamiltonian system, which, by definition, is Liouville integrable at the classical and quantum levels. However, it is known that the number of excatly solvable degree-1 Hamiltonians are very limited. What would be the quantum counterpart of the "transformation to action-angle variables by quadrature"? Could it be better formulated in terms of a path integral? Many questions remain to be answered. The quantum C–M systems, an infinite family of exactly solvable multiparticle Hamiltonians, would shed some light on the problem of quantum integrability, in addition to their own beautiful structure explored below.

Throughout this article, the dependence on Planck's constant, $\hbar$, is shown explicitly to distinguish the quantum effects.

## Simplest Cases (Based on $A_{r-1}$ Root System)

The simplest example of a C–M system consists of $r$ particles of equal mass (normalized to unity) on a line with pairwise $1/(\text{distance})^2$ interactions described by the following Hamiltonian:

$$\hat{\mathcal{H}}=\frac{1}{2}\sum_{j=1}^{r}p_j^2+g(g-\hbar)\sum_{j<k}^{r}\frac{1}{(q_j-q_k)^2} \qquad [1]$$

in which $g$ is a real positive coupling constant. Here $q=(q_1,\ldots,q_r)$ are the coordinates and $p=(p_1,\ldots,p_r)$ are the conjugate canonical momenta obeying the canonical commutation relations: $[q_j,p_k]=i\hbar\delta_{jk},[q_j,q_k]=[p_j,p_k]=0,\quad j,k=1,\ldots,r$. The Heisenberg equations of motion are $\dot{q}_j=(i/\hbar)[\hat{\mathcal{H}},q_j]=p_j,\ \ddot{q}_j=\dot{p}_j=(i/\hbar)[\hat{\mathcal{H}},p_j]=2g(g-\hbar)\sum_{k\neq j}1/(q_j-q_k)^3$. The repulsive $1/(\text{distance})^2$ potential cannot be surmounted classically or quantum mechanically, and the relative position of the particles on the line is not changed during the time evolution. Classically, it means that if a motion starts at a configuration $q_1>q_2>\cdots>q_r$, then the inequalities remain valid throughout the time evolution. At the quantum level, the wave functions vanish at the boundaries, and the configuration space can be naturally limited to $q_1>q_2>\cdots>q_r$ (the principal Weyl chamber).

Similar integrable quantum many-particle dynamics are obtained by replacing the inverse square potential in [1] by the trigonometric

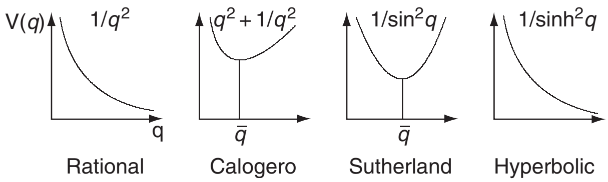

**Figure 1** Four different types of quantum C–M potentials.

(hyperbolic) counterpart (see Figure 1) $1/(q_j - q_k)^2 \to a^2/\sinh^2 a(q_j - q_k)$, in which $a > 0$ is a real parameter. The $1/\sin^2 q$ potential case (the Sutherland system) corresponds to the $1/(\text{distance})^2$ interaction on a circle of radius $1/2a$, see Figure 2. A harmonic confining potential $\omega^2 \sum_{j=1}^r q_j^2/2$ can be added to the rational Hamiltonian [1] without breaking the integrability (the Calogero system, see Figure 1). At the classical level, the trigonometric (hyperbolic) and rational C–M systems are obtained from the elliptic potential systems (with the Weierstrass $\wp$ function) as the degenerate limits: $\wp(q_1 - q_2) \to a^2/\sinh^2 a(q_1 - q_2) \to 1/(q_1 - q_2)^2$, namely as one (two) period(s) of the $\wp$ function tends to infinity.

It is remarkable that these equations of motion can be expressed in a matrix form (Lax pair): $\mathrm{i}/\hbar[\hat{\mathcal{H}}, L] = \mathrm{d}L/\mathrm{d}t = LM - ML = [L, M] \Leftrightarrow$ Heisenberg equation of motion, in which $L$ and $M$ are given by

$$L = \begin{pmatrix} p_1 & \frac{\mathrm{i}g}{q_1-q_2} & \cdots & \frac{\mathrm{i}g}{q_1-q_r} \\ \frac{\mathrm{i}g}{q_2-q_1} & p_2 & \cdots & \frac{\mathrm{i}g}{q_2-q_r} \\ \vdots & \vdots & \ddots & \vdots \\ \frac{\mathrm{i}g}{q_r-q_1} & \frac{\mathrm{i}g}{q_r-q_2} & \cdots & p_r \end{pmatrix}$$

$$M = \begin{pmatrix} m_1 & -\frac{\mathrm{i}g}{(q_1-q_2)^2} & \cdots & -\frac{\mathrm{i}g}{(q_1-q_r)^2} \\ -\frac{\mathrm{i}g}{(q_2-q_1)^2} & m_2 & \cdots & -\frac{\mathrm{i}g}{(q_2-q_r)^2} \\ \vdots & \vdots & \ddots & \vdots \\ -\frac{\mathrm{i}g}{(q_r-q_1)^2} & -\frac{\mathrm{i}g}{(q_r-q_2)^2} & \cdots & m_r \end{pmatrix} \quad [2]$$

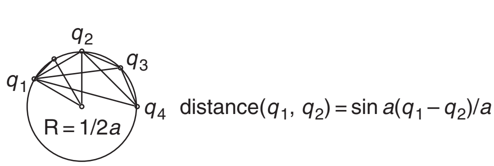

**Figure 2** Sutherland potential is $1/(\text{distance})^2$ interaction on a circle. The large-radius limit, $a \to 0$, gives the rational potential.

The diagonal element $m_j$ of $M$ is given by $m_j = \mathrm{i}g \sum_{k \neq j} 1/(q_j - q_k)^2$. The matrix $M$ has a special property $\sum_{j=1}^r M_{jk} = \sum_{k=1}^r M_{jk} = 0$, which ensures the quantum conserved quantities as the total sum of powers of Lax matrix $L$: $[\hat{\mathcal{H}}, K_n] = 0$, $K_n \equiv \mathrm{Ts}(L^n) = \sum_{j,k} (L^n)_{jk}$, $(n = 1, 2, 3, \ldots)$, $[K_n, K_m] = 0$. It should be stressed that the trace of $L^n$ is not conserved because of the noncommutativity of $q$ and $p$. The Hamiltonian is equivalent to $K_2, \hat{\mathcal{H}} \propto K_2 +$ const. In other words, the Lax matrix $L$ is like a "square root" of the Hamiltonian. The quantum equations of motion for the Sutherland and hyperbolic potentials are again expressed by Lax pairs if the following replacements are made: $1/(q_j - q_k) \to a \coth a(q_j - q_k)$ in $L$ and $1/(q_j - q_k)^2 \to a^2/\sinh^2 a(q_j - q_k)$ in $M$. The quantum conserved quantities are obtained in the same manner as above for the systems with the trigonometric and hyperbolic interactions.

The main goal here is to find all the eigenvalues $\{\mathcal{E}\}$ and eigenfunctions $\{\psi(q)\}$ of the Hamiltonians with the rational, Calogero, Sutherland, and hyperbolic potentials: $\hat{\mathcal{H}}\psi(q) = \mathcal{E}\psi(q)$. The momentum operator $p_j$ acts as differential operators $p_j = -\mathrm{i}\hbar\partial/\partial q_j$. For example, for the rational model Hamiltonian [1], the eigenvalue equation reads

$$\left[-\frac{\hbar^2}{2}\sum_{j=1}^{r}\frac{\partial^2}{\partial q_j^2} + g(g-\hbar)\sum_{j<k}^{r}\frac{1}{(q_j - q_k)^2}\right]\psi(q) = \mathcal{E}\psi(q) \quad [3]$$

which is a second-order Fuchsian differential equation for each variable $\{q_j\}$ with a regular singularity at each hyperplane $q_j = q_k$ whose exponents are $g/\hbar, 1 - g/\hbar$. Any solution $\psi$ of [3] is regular at all points, except for those on the union of hyperplanes $q_j = q_k$. Since the structure of the singularity is the same for the other three types of potentials, the same assertion for the regularity and singularity of the solution $\psi$ holds for these cases, too. For the trigonometric (Sutherland) case, there are other singularities at $q_j - q_k = l\pi/a$, $l \in \mathbf{Z}$, due to the periodicity of the potential. As is clear from the shape of the potentials, see Figure 1, the rational and hyperbolic Hamiltonians have only continuous spectra, whereas the Calogero and Sutherland Hamiltonians have only discrete spectra.

The integrability or more precisely the triangularity of the quantum C–M Hamiltonian was first discovered by Calogero for particles on a line with inverse square potential plus a confining harmonic force and by Sutherland for the particles on a circle

with the trigonometric potential. Later, classical integrability of the models in terms of Lax pairs was proved by Moser. Olshanetsky and Perelomov showed that these systems were based on $A_{r-1}$ root systems, that is, $q_j - q_k = \alpha \cdot q$, and $\alpha$ is one of the root vectors of $A_{r-1}$ root system [13]. They also introduced generalizations of the C–M systems based on any root system including the noncrystallographic ones.

As shown by Heckman–Opdam and Sasaki and collaborators, quantum C–M systems with degenerate potentials (i.e., the rational potentials with/without harmonic force, the hyperbolic, and the trigonometric potentials), based on any root system can be formulated and solved universally. To be more precise, the rational and Calogero systems are integrable for all root systems, the crystallographic and noncrystallographic. The hyperbolic and trigonometric (Sutherland) systems are integrable for any crystallographic root system. The universal formulas for the Hamiltonians, Lax pairs, ground state wave functions, conserved quantities, the triangularity, the discrete spectra for the Calogero and Sutherland systems, the creation and annihilation operators, etc., are equally valid for any root system. This will be shown in the next section. Some rudimentary facts of the root systems and reflections are summarized in the appendix.

## Universal Formalism

A C–M system is a Hamiltonian dynamical systems associated with a root system $\Delta$ of rank $r$, which is a set of vectors in $\mathbf{R}^r$ with its standard inner product. A brief review of the properties of the root systems and the associated reflections together with explicit realizations of all the classical root systems will be found in the appendix.

### Factorized Hamiltonian

The Hamiltonian for the quantum C–M system can be written in terms of a pre-potential $W(q)$ in a "factorized form":

$$\mathcal{H} = \frac{1}{2}\sum_{j=1}^{r}\left(p_j - \mathrm{i}\frac{\partial W(q)}{\partial q_j}\right)\left(p_j + \mathrm{i}\frac{\partial W(q)}{\partial q_j}\right) \qquad [4]$$

The pre-potential is a sum over positive roots:

$$W(q) = \sum_{\alpha\in\Delta_+} g_\alpha \ln|w(\alpha\cdot q)| + \left(-\frac{\omega}{2}q^2\right) \qquad [5]$$

The real positive coupling constants $g_\alpha$ are defined on orbits of the corresponding Coxeter group, that is, they are identical for roots in the same orbit. That is, for the simple Lie algebra cases, one coupling constant, $g_\alpha = g$, for all roots in simply laced models and two independent coupling constants, $g_\alpha = g_{\mathrm{L}}$ for long roots and $g_\alpha = g_{\mathrm{S}}$ for short roots, in non-simply laced models. The function $w(u)$ and the other functions $x(u)$ and $y(u)$ appearing in the Lax pair [10], [11] are listed in Table 1 for each type of degenerate potentials. The dynamics of the prepotentials $W(q)$ (eqn [5]) has been discussed by Dyson from a different point of view (random-matrix model). The above factorized Hamiltonian [4] consists of an operator part $\hat{\mathcal{H}}$, which is the Hamiltonian in the usual definition (see the Hamiltonians in the previous section, e.g., [1]), and a constant $\mathcal{E}_0$ which is the ground-state energy, $\mathcal{H} = \hat{\mathcal{H}} - \mathcal{E}_0$. The factorized Hamiltonian [4] also arises within the context of supersymmetric quantum mechanics.

**Table 1** Functions appearing in the prepotential and Lax pair

| *Potential* | $w(u)$ | $x(u)$ | $y(u)$ |
|---|---|---|---|
| Rational | $u$ | $1/u$ | $-1/u^2$ |
| Hyperbolic | $\sinh au$ | $a\coth au$ | $-a^2/\sinh^2 au$ |
| Trigonometric | $\sin au$ | $a\cot au$ | $-a^2/\sin^2 au$ |

The pre-potential and the Hamiltonian are invariant under reflection of the phase space variables in the hyperplane perpendicular to any root $W(s_\alpha(q)) = W(q), \mathcal{H}(s_\alpha(p), s_\alpha(q)) = \mathcal{H}(p,q), \forall\alpha\in\Delta$, with $s_\alpha$ defined by [12]. The above Coxeter (Weyl) invariance is the only (discrete) symmetry of the C–M systems. The main problem is, as in the $A_{r-1}$ case, to find all the eigenvalues $\{\mathcal{E}\}$ and eigenfunctions $\{\psi(q)\}$ of the above Hamiltonian $\mathcal{H}\psi(q) = \mathcal{E}\psi(q)$.

For any root system and for any choice of potential, the C–M system has a hard repulsive potential $\sim 1/(\alpha\cdot q)^2$ near the reflection hyperplane $H_\alpha = \{q\in\mathbf{R}^r, \alpha\cdot q = 0\}$. The C–M eigenvalue equation is a second-order Fuchsian differential equation with regular singularities at each reflection hyperplane $H_\alpha$ and those arising from the periodicity in the case of the Sutherland potential. Near the reflection hyperplane $H_\alpha$, the solution behaves as follows:

$$\psi \sim (\alpha\cdot q)^{g_\alpha/\hbar}(1 + \text{regular terms}), \quad \text{or}$$
$$\psi \sim (\alpha\cdot q)^{1-g_\alpha/\hbar}(1 + \text{regular terms})$$

The former solution is chosen for the square integrability. Because of the singularities, the configuration space is restricted to the principal Weyl chamber PW or the principal Weyl alcove $\mathrm{PW_T}$ for the trigonometric potential (see Figure 3): $\mathrm{PW} = \{q\in\mathbf{R}^r \mid \alpha\cdot q > 0, \alpha\in\Pi\}, \mathrm{PW_T} = \{q\in\mathbf{R}^r \mid \alpha\cdot q > 0,$

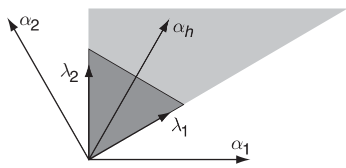

**Figure 3** Simple roots, the highest root, fundamental weights, and the principal Weyl alcove (grey) and the principal Weyl chamber (light grey, extending to infinity) in a two-dimensional root system.

$\alpha \in \Pi, \alpha_h \cdot q < \pi/a\}$, ($\Pi$: set of simple roots, see the appendix). Here $\alpha_h$ is the highest root.

### Ground-State Wave Function and Energy

One straightforward outcome of the factorized Hamiltonian [4] is the universal ground-state wave function, which is given by

$$\begin{aligned}\Phi_0(q) &= e^{W(q)/\hbar} \\ &= \prod_{\alpha\in\Delta_+} |w(\alpha\cdot q)|^{g_\alpha/\hbar}\left(\times e^{-(\omega/2\hbar)q^2}\right) \\ \mathcal{H}\Phi_0(q) &= 0\end{aligned} \qquad [6]$$

The exponential factor $e^{-(\omega/2\hbar)q^2}$ exists only for the Calogero systems. The ground-state energy, that is, the constant part of $\mathcal{H} = \hat{\mathcal{H}} - \mathcal{E}_0$, has a universal expression for each potential:

$$\mathcal{E}_0 = \begin{cases} 0 & \text{rational} \\ \omega\left(\hbar r/2 + \sum_{\alpha\in\Delta_+} g_\alpha\right) & \text{Calogero}\end{cases}$$
$$\mathcal{E}_0 = 2a^2\rho^2 \times \begin{cases} -1 & \text{hyperbolic} \\ 1 & \text{Sutherland}\end{cases} \qquad [7]$$

where $\rho = 1/2\sum_{\alpha\in\Delta_+} g_\alpha \alpha$ is called a "deformed Weyl vector." Obviously, $\Phi_0(q)$ is square integrable in the configuration spaces for the Calogero and Sutherland systems and not square integrable for the rational and hyperbolic potentials.

### Excited States, Triangularity, and Spectrum

Excited states of the C–M systems can be easily obtained as eigenfunctions of a differential operator $\tilde{\mathcal{H}}$ obtained from $\mathcal{H}$ by a similarity transformation:

$$\begin{aligned}\tilde{\mathcal{H}} &= e^{-W/\hbar}\mathcal{H}e^{W/\hbar} \\ &= \frac{-1}{2}\sum_{j=1}^{r}(\hbar^2\partial^2/\partial q_j^2 + 2\hbar\partial W/\partial q_j \partial/\partial q_j)\end{aligned}$$

The eigenvalue equation for $\tilde{\mathcal{H}}$, $\tilde{\mathcal{H}}\Psi_\mathcal{E} = \mathcal{E}\Psi_\mathcal{E}$, is then equivalent to that of the original Hamiltonian, $\mathcal{H}\Psi_\mathcal{E} e^W = \mathcal{E}\Psi_\mathcal{E} e^W$. Since all the singularities of the Fuchsian differential equation $\mathcal{H}\psi(q) = \mathcal{E}\psi(q)$ are contained in the ground-state wave function $e^W$, $\Psi_\mathcal{E}$ must be regular at finite $q$, including all the reflection boundaries. As for the rational and hyperbolic potentials, the energy eigenvalues are only continuous. For the rational case, the eigenfunctions are multivariable generalization of Bessel functions.

**Calogero systems** The similarity-transformed Hamiltonian $\tilde{\mathcal{H}}$ reads

$$\begin{aligned}\tilde{\mathcal{H}} &= \hbar\omega q\cdot\frac{\partial}{\partial q} - \frac{\hbar^2}{2}\sum_{j=1}^{r}\frac{\partial^2}{\partial q_j^2} \\ &\quad - \hbar\sum_{\alpha\in\Delta_+}\frac{g_\alpha}{\alpha\cdot q}\alpha\cdot\frac{\partial}{\partial q}\end{aligned} \qquad [8]$$

which maps a Coxeter-invariant polynomial in $q$ of degree $d$ to another of degree $d$. Thus, the Hamiltonian $\tilde{\mathcal{H}}$ (8) is lower-triangular in the basis of Coxeter-invariant polynomials and the diagonal elements have values as $\hbar\omega \times$ degree, as given by the first term. Independent Coxeter-invariant polynomials exist at the degrees $f_j$ listed in Table 2: $f_j = 1 + e_j$, $j = 1, \ldots, r$, where $\{e_j\}$, $j = 1, \ldots, r$, are the exponents of $\Delta$.

The eigenvalues of the Hamiltonian $\mathcal{H}$ are $\hbar\omega N$ with $N$ a non-negative integer. $N$ can be expressed as $N = \sum_{j=1}^r n_j f_j$, $n_j \in \mathbf{Z}_+$, and the degeneracy of the eigenvalue $\hbar\omega N$ is the number of partitions of $N$. It is remarkable that the coupling constant dependence appears only in the ground-state energy $\mathcal{E}_0$. This is a deformation of the isotropic harmonic oscillator confined in the principal Weyl chamber. The eigenpolynomials are generalization of multivariable Laguerre (Hermite) polynomials. One immediate consequence of this spectrum is the periodicity of the quantum motion. If a system has a wave function $\psi(0)$ at $t = 0$, then at $t = T = 2\pi/\omega$ the system has physically the same wave function as $\psi(0)$, that is, $\psi(T) = e^{-i\mathcal{E}_0 T/\hbar}\psi(0)$. The same assertion holds at the classical level, too.

**Table 2** The degrees $f_j$ in which independent Coxeter-invariant polynomials exist

| $\Delta$ | $f_j = 1 + e_j$ | $\Delta$ | $f_j = 1 + e_j$ |
|---|---|---|---|
| $A_r$ | $2, 3, 4, \ldots, r+1$ | $E_8$ | 2, 8, 12, 14, 18, 20, 24, 30 |
| $B_r$ | $2, 4, 6, \ldots, 2r$ | $F_4$ | 2, 6, 8, 12 |
| $C_r$ | $2, 4, 6, \ldots, 2r$ | $G_2$ | 2, 6 |
| $D_r$ | $2, 4, \ldots, 2r-2, r$ | $I_2(m)$ | 2, $m$ |
| $E_6$ | 2, 5, 6, 8, 9, 12 | $H_3$ | 2, 6, 10 |
| $E_7$ | 2, 6, 8, 10, 12, 14, 18 | $H_4$ | 2, 12, 20, 30 |

**Sutherland Systems** The periodicity of the trigonometric potential dictates that the wave function should be a Bloch factor $e^{2ia\mu\cdot q}$ (where $\mu$ is a weight) multiplied by a Fourier series in terms of simple roots. The basis of the Weyl invariant wave functions is specified by a dominant weight $\lambda=\sum_{j=1}^{r} m_j\lambda_j$, $m_j\in\mathbf{Z}_+$, $\phi_\lambda(q)\equiv\sum_{\mu\in O_\lambda} e^{2ia\mu\cdot q}$, where $O_\lambda$ is the orbit of $\lambda$ by the action of the Weyl group: $O_\lambda=\{g(\lambda)\,|\,g\in G_\Delta\}$. The set of functions $\{\phi_\lambda\}$ has an order $\succ$, $|\lambda|^2>|\lambda'|^2\Rightarrow\phi_\lambda\succ\phi_{\lambda'}$. The similarity-transformed Hamiltonian $\tilde{\mathcal{H}}$ given by

$$\tilde{\mathcal{H}}=-\frac{\hbar^2}{2}\sum_{j=1}^{r}\frac{\partial^2}{\partial q_j^2}-a\hbar\sum_{\alpha\in\Delta_+}g_\alpha\cot(a\alpha\cdot q)\alpha\cdot\frac{\partial}{\partial q}\quad[9]$$

is lower-triangular in this basis: $\tilde{\mathcal{H}}\phi_\lambda=2a^2(\hbar^2\lambda^2+2\hbar\rho\cdot\lambda)\phi_\lambda+\sum_{|\lambda'|<|\lambda|}c_{\lambda'}\phi_{\lambda'}$. That is, the eigenvalue is $\mathcal{E}=2a^2(\hbar^2\lambda^2+2\hbar\rho\cdot\lambda)$ or $\mathcal{E}+\mathcal{E}_0=2a^2(\hbar\lambda+\rho)^2$. Again, the coupling constant dependence comes solely from the deformed Weyl vector $\rho$. This spectrum is a deformation of the spectrum corresponding to the free motion with momentum $2\hbar a\lambda$ in the principal Weyl alcove. The corresponding eigenfunction is called a generalized Jack polynomial or Heckman–Opdam's Jacobi polynomial. For the rank-2 $(r=2)$ root systems, $A_2$, $B_2\cong C_2$ and $I_2(m)$ (the dihedral group), the complete set of eigenfunctions are known explicitly.

### Quantum Lax Pair and Quantum Conserved Quantities

The universal Lax pair for C–M systems is given in terms of the representations of the Coxeter (Weyl) group in stead of the Lie algebra. The Lax operators without spectral parameter for the rational, trigonometric, and hyperbolic potentials are

$$L(p,q)=p\cdot\hat{H}+X(q)$$
$$X(q)=\mathrm{i}\sum_{\alpha\in\Delta_+}g_\alpha(\alpha\cdot\hat{H})x(\alpha\cdot q)\hat{s}_\alpha\quad[10]$$

$$M(q)=\frac{\mathrm{i}}{2}\sum_{\alpha\in\Delta_+}g_\alpha\alpha^2y(\alpha\cdot q)(\hat{s}_\alpha-I)\quad[11]$$

where $I$ is the identity operator and $\{\hat{s}_\alpha|\alpha\in\Delta\}$ are the reflection operators of the root system. They act on a set of $\mathbf{R}^r$ vectors, $\mathcal{R}=\{\mu^{(k)}\in\mathbf{R}^r\,|\,k=1,\ldots,d\}$, permuting them under the action of the reflection group. The vectors in $\mathcal{R}$ form a basis for the representation space $\mathbf{V}$ of dimension $d$. The matrix elements of the operators $\{\hat{s}_\alpha\,|\,\alpha\in\Delta\}$ and $\{\hat{H}_j\,|\,j=1,\ldots,r\}$ are defined as follows: $(\hat{s}_\alpha)_{\mu\nu}=\delta_{\mu,s_\alpha(\nu)}=\delta_{\nu,s_\alpha(\mu)}$, $(\hat{H}_j)_{\mu\nu}=\mu_j\delta_{\mu\nu}$, $\alpha\in\Delta$, $\mu$, $\nu\in\mathcal{R}$. The form of the functions $x,y$ depends on the chosen potential as given in Table 1. Then the equations of motion can be expressed in a matrix form $\mathrm{d}L/\mathrm{d}t=\mathrm{i}/\hbar[\mathcal{H},L]=[L,M]$. The operator $M$ satisfies the relation $\sum_{\mu\in\mathcal{R}}M_{\mu\nu}=\sum_{\nu\in\mathcal{R}}M_{\mu\nu}=0$, which is essential for deriving quantum conserved quantities as the total sum (Ts) of all the matrix elements of $L^n$: $K_n=\mathrm{Ts}(L^n)\equiv\sum_{\mu,\nu\in\mathcal{R}}(L^n)_{\mu\nu}$, $[\mathcal{H},K_n]=0$, $[K_m,K_n]=0$, $n,m=1,\ldots$ In particular, the power 2 is universal to all the root systems, and the quantum Hamiltonian is given by $\mathcal{H}\propto K_2+$ const. As in the affine Toda molecule systems, a Lax pair with a spectral parameter can also be introduced universally for all the above potentials. The Dunkl operators, or the commuting differential–difference operators are also used to construct quantum conserved quantities for some root systems. This method is essentially equivalent to the universal Lax operator formalism. As the Lax operators do not contain the Planck's constant, the quantum Lax pair is essentially of the same form as the classical Lax pair. The difference between the trace (tr) and the total sum (Ts) vanishes as $\hbar\to 0$.

**Lax pair for Calogero systems** The quantum Lax pair for the Calogero systems is obtained from the universal Lax pair [10] by replacement $L\to L^\pm=L\pm\mathrm{i}\omega Q$, $Q\equiv q\cdot\hat{H}$, which correspond to the creation and annihilation operators of a harmonic oscillator. The equations of motion are rewritten as $\mathrm{d}L^\pm/\mathrm{d}t=\mathrm{i}/\hbar[\mathcal{H},L^\pm]=[L^\pm,M]\pm\mathrm{i}\omega L^\pm$. Then $\mathcal{L}^\pm=L^\pm L^\mp$ satisfy the Lax type equation $\mathrm{d}\mathcal{L}^\pm/\mathrm{d}t=\mathrm{i}/\hbar[\mathcal{H},\mathcal{L}^\pm]$, giving rise to conserved quantities $\mathrm{Ts}(\mathcal{L}^\pm)^n$, $n=1,2,\ldots$ The Calogero Hamiltonian is given by $\mathcal{H}\propto\mathrm{Ts}(\mathcal{L}^\pm)$.

All the eigenstates of the Calogero Hamiltonian $\mathcal{H}$ with eigenvalues $\hbar\omega N$, $N=\sum_{j=1}^{r}n_jf_j$, $n_j\in\mathbf{Z}_+$, are simply constructed in terms of $L^\pm$: $\prod_{j=1}^{r}(B_{f_j}^+)^{n_j}e^W$. Here the integers $\{f_j\}$, $j=1,\ldots,r$, are listed in Table 2. The creation operators $B_{f_j}^+$ and the corresponding annihilation operators $B_{f_j}^-$ are defined by $B_{f_j}^\pm=\mathrm{Ts}(L^\pm)^{f_j}$, $j=1,\ldots,r$. They are Hermitian conjugate to each other $(B_{f_j}^\pm)^\dagger=B_{f_j}^\mp$ with respect to the standard Hermitian inner product of the states defined in PW. They satisfy commutation relations $[\mathcal{H},B_k^\pm]=\pm\hbar k\omega B_k^\pm$, $[B_k^+,B_l^+]=[B_k^-,B_l^-]=0$, $k,l\in\{f_j\,|\,j=1,\ldots,r\}$. The ground state is annihilated by all the annihilation operators $B_{f_j}^-e^W=0$, $j=1,\ldots,r$.

## Further Developments

### Rational Potentials: Superintegrability

The systems with the rational potential have a remarkable property: superintegrability. A rational C–M system based on a rank-$r$ root system has $2r-1$

independent conserved quantities. Roughly speaking, they are of the form $K_n = \mathrm{Ts}(L^n), J_m = \mathrm{Ts}(QL^m), Q \equiv q \cdot \hat{H}$, among which only $r$ are involutive. At the classical level, superintegrability can be characterized as algebraic linearizability. Since a commutator of any conserved quantities is again a conserved quantity, these conserved quantities form a nonlinear algebra called a quadratic algebra. It can be considered as a finite-dimensional analog of the W-algebra appearing in certain conformal field theory.

#### Quantum vs Classical Integrability

In C–M systems, the classical and quantum integrability are very closely related. The quantum discrete spectra of the Calogero and the Sutherland systems are, as shown above, expressed in terms of the coupling constant $(\omega, g)$ and the exponents or the weights of the corresponding root systems. Namely, they are integral multiples of coupling constants. The corresponding classical systems with the potential $V(q) = (1/2)\sum_{j=1}^{r}(\partial W(q)/\partial q_j)^2$ share many remarkable properties. As is clear from Figure 1, they always have an equilibrium position. The equilibrium positions $(\bar{q})$ are described by the zeros of a classical orthogonal polynomial; the Hermite polynomial ($A$-type Calogero), the Laguerre polynomial ($B, C, D$-type Calogero), the Chebyshev polynomial ($A$-type Sutherland) and the Jacobi polynomial ($B, C, D$-type Sutherland). For the exceptional root systems, the corresponding polynomials were not known for a long time. The minimum energy of the classical potential $V(q)$ at the equilibrium is the quantum ground-state energy $\lim_{\hbar\to 0}\mathcal{E}_0$ itself. It is also an integral multiple of coupling constants for both Calogero and Sutherland cases. Near a classical equilibrium, a multiparticle dynamical system is always reduced to a system of coupled harmonic oscillators. For Calogero systems, the eigenfrequencies of these small oscillations are, in fact, exactly the same as the quantum eigenfrequencies, $\omega f_j = \omega(1 + e_j)$. For Sutherland systems, the classical eigenfrequencies are the same as the $o(\hbar)$ part of the quantum spectra corresponding to all the fundamental weights $\lambda_j$: $2a^2\lambda_j \cdot \rho$. Moreover, the eigenvalues of various Lax matrices $L$ and $M$ at the equilibrium take many "interesting values." These results provide ample explicit examples of the general theorem on the quantum–classical correspondence formulated by Loris–Sasaki.

#### Spin Models

For any root system $\Delta$ and an irreducible representation $\mathcal{R}$ of the Coxeter (Weyl) group $G_\Delta$, a spin C–M system can be defined for each of the potentials: rational, Calogero, hyperbolic and Sutherland. For each member $\mu$ of $\mathcal{R}$, to be called a "site," a vector space $\mathbf{V}_\mu$ is associated whose element is called a "spin." The dynamical variables are those of the particles $\{q_j, p_j\}$ and the spin exchange operators $\{\hat{\mathcal{P}}_\alpha\}$ $(\alpha \in \Delta)$ which exchange the spins at the sites $\mu$ and $s_\alpha(\mu)$. For each $\Delta$ and $\mathcal{R}$ a spin exchange model can be defined by "freezing" the particle degrees of freedom at the equilibrium point of the corresponding classical potential $\{q, p\} \to \{\bar{q}, 0\}$. These are generalization of Haldane–Shastry model for Sutherland potentials and that of Polychronakos for the Calogero potentials. Universal Lax pair operators for both spin C–M systems and spin exchange models are known and conserved quantities are constructed.

#### Integrable Deformations

C–M systems allow various integrable deformations at the classical and/or quantum levels. One of the well-known deformations is the so-called "relativistic" C–M system or the Ruijsenaars–Schneider (R–S) system. For degenerate potentials, they are integrable both at the classical and quantum levels. The classical quantities of the R–S systems at equilibrium exhibit many interesting properties, too. The equilibrium positions are described by the zeros of certain deformation of the above-mentioned classical polynomials. The frequencies of small oscillations are also related to the exact quantum spectrum, and they can be expressed as coupling constant times the ($q$-) integers.

Inozemtsev models are classically integrable multiparticle dynamical systems related to C–M systems based on classical root systems $(A, B, C, D)$ with additional $q^6$ (rational) or $\sin^2 2q$ (trigonometric) potentials. Their quantum versions are not exactly solvable in contrast to the C–M or R–S systems, although there is some evidence of their Liouville integrability (without a proper Hilbert space). Quantum Inozemtsev systems can be deformed to be a widest class of quasi-exactly solvable multiparticle dynamical systems. They possess a form of higher-order supersymmetry for which the method of prepotential is also useful.

### Appendix: Root Systems

Some rudimentary facts of the root systems and reflections are recapitulated here. The set of roots $\Delta$ is invariant under reflections in the hyperplane perpendicular to each vector in $\Delta$. In other words, $s_\alpha(\beta) \in \Delta, \forall \alpha, \beta \in \Delta$, where

$$s_\alpha(\beta) = \beta - (\alpha^\vee \cdot \beta)\alpha, \quad \alpha^\vee \equiv 2\alpha/|\alpha|^2 \qquad [12]$$

The set of reflections $\{s_\alpha \mid \alpha \in \Delta\}$ generates a group $G_\Delta$, known as a Coxeter group, or finite reflection group. The orbit of $\beta \in \Delta$ is the set of root vectors resulting from the action of the Coxeter group on it. The set of positive roots $\Delta_+$ may be defined in terms of a vector $U \in \mathbf{R}^r$, with $\alpha \cdot U \neq 0, \forall \alpha \in \Delta$, as the roots $\alpha \in \Delta$ such that $\alpha \cdot U > 0$. Given $\Delta_+$, there is a unique set of $r$ simple roots $\Pi = \{\alpha_j \mid j = 1, \ldots, r\}$ defined such that they span the root space and the coefficients $\{a_j\}$ in $\beta = \sum_{j=1}^r a_j \alpha_j$ for $\beta \in \Delta_+$ are all non-negative. The highest root $\alpha_h$, for which $\sum_{j=1}^r a_j$ is maximal, is then also determined uniquely. The subset of reflections $\{s_\alpha \mid \alpha \in \Pi\}$ in fact generates the Coxeter group $G_\Delta$. The products of $s_\alpha$, with $\alpha \in \Pi$, are subject solely to the relations $(s_\alpha s_\beta)^{m(\alpha,\beta)} = 1$, $\alpha, \beta \in \Pi$. The interpretation is that $s_\alpha s_\beta$ is a rotation in some plane by $2\pi/m(\alpha, \beta)$. The set of positive integers $m(\alpha, \beta)$ (with $m(\alpha, \alpha) = 1, \forall \alpha \in \Pi$) uniquely specifies the Coxeter group. The weight lattice $P(\Delta)$ is defined as the $\mathbf{Z}$-span of the fundamental weights $\{\lambda_j\}$, defined by $\alpha_j^\vee \cdot \lambda_k = \delta_{jk}, \forall \alpha_j \in \Pi$.

The root systems for finite reflection groups may be divided into two types: crystallographic and noncrystallographic. Crystallographic root systems satisfy the additional condition $\alpha^\vee \cdot \beta \in \mathbf{Z}, \forall \alpha, \beta \in \Delta$. The remaining noncrystallographic root systems are $H_3, H_4$, whose Coxeter groups are the symmetry groups of the icosahedron and four-dimensional 600-cell, respectively, and the dihedral group of order $2m, \{I_2(m) | m \geq 4\}$.

The explicit examples of the classical root systems, that is, $A, B, C$, and $D$ are given below. For the exceptional and noncrystallographic root systems, the reader is referred to Humphrey's book. In all cases, $\{\boldsymbol{e}_j\}$ denotes an orthonormal basis in $\mathbf{R}^r$.

1. $A_{r-1}$: This root system is related with the Lie algebra $su(r)$.

$$\Delta = \bigcup_{1 \leq j \leq k \leq r} \{\pm(\boldsymbol{e}_j - \boldsymbol{e}_k)\}, \qquad \prod = \bigcup_{j=1}^{r-1} \{\boldsymbol{e}_j - \boldsymbol{e}_{j+1}\} \tag{13}$$

2. $B_r$: This root system is associated with Lie algebra $so(2r+1)$. The long roots have $(\text{length})^2 = 2$ and short roots have $(\text{length})^2 = 1$:

$$\Delta = \bigcup_{1 \leq j \leq k \leq r} \{\pm \boldsymbol{e}_j \pm \boldsymbol{e}_k\} \cup_{j=1}^r \{\pm \boldsymbol{e}_j\}, \qquad \prod = \bigcup_{j=1}^{r-1} \{\boldsymbol{e}_j - \boldsymbol{e}_{j+1}\} \cup \{\boldsymbol{e}_r\} \tag{14}$$

3. $C_r$: This root system is associated with Lie algebra $sp(2r)$. The long roots have $(\text{length})^2 = 4$ and short roots have $(\text{length})^2 = 2$:

$$\Delta = \bigcup_{1 \leq j \leq k \leq r} \{\pm \boldsymbol{e}_j \pm \boldsymbol{e}_k\} \cup_{j=1}^r \{\pm 2\boldsymbol{e}_j\}, \qquad \prod = \bigcup_{j=1}^{r-1} \{\boldsymbol{e}_j - \boldsymbol{e}_{j+1}\} \cup \{2\boldsymbol{e}_r\} \tag{15}$$

4. $D_r$: This root system is associated with Lie algebra $so(2r)$:

$$\Delta = \bigcup_{1 \leq j \leq k \leq r} \{\pm \boldsymbol{e}_j \pm \boldsymbol{e}_k\}, \qquad \prod = \bigcup_{j=1}^{r-1} \{\boldsymbol{e}_j - \boldsymbol{e}_{j+1}\} \cup \{\boldsymbol{e}_{r-1} + \boldsymbol{e}_r\} \tag{16}$$

## Introduction

Statistical physics deals with systems with many degrees of freedom and the problems concern finding procedures for the extraction of relevant physical quantities for these extremely complex systems. The idea is to find relevant reduction procedures which map the complex systems onto simpler, tractable models at the price of introducing elements of uncertainty. Therefore, probability theory is a natural mathematical tool in statistical physics. Since the early days of statistical physics, in classical (Newtonian) physical systems, it is natural to model the observables by a collection of random variables acting on a probability space. Kolmogorovian probability techniques and results are the main tools in the development of classical statistical physics. A random variable is usually considered as a measurable function with expectation given as its integral with respect to a probability measure. Alternatively, a random variable can also be viewed as a multiplication operator by the associated function. Different random variables commute as multiplication operators, and one speaks of a commutative probabilistic model.

Now, looking at genuine quantum systems, in many cases the procedure mentioned above leads to commutative probabilistic models, but there exist the realms of physics where quantum noncommutative probabilistic concepts are unavoidable. Typical examples of such areas are quantum optics, low-temperature solid-state physics and ground-state physics such as quantum field theory. During the last 50 years physicists have developed more or less heuristic methods to deal with, for example, manifestations of fluctuations of typical quantum nature. In the last 30 years, mathematical foundations of such theories were also formulated, and a notion of quantum probability was launched as a branch of mathematical physics and mathematics (Cushen and Hudson 1971, Fannes and Quaegebeur 1983, Quaegebeur 1984, Hudson 1973, Giri and von Waldenfels 1978).

The aim of this article is to review briefly a few selected rigorous results concerning noncommutative limit theorems. This choice is made not only because of the author's interest but also for its close relation to concrete problems in statistical physics where one aims at understanding the macroscopic phenomena on the basis of the microscopic structure. A precise definition or formulation of a microscopic and a macroscopic system is of prime importance. The so-called algebraic approach of dynamical systems (Brattelli and Robinson 1979 and 2002) offers the necessary generality and mathematical framework to deal with classical and quantum, microscopic and macroscopic, finite and infinite systems. The observables of any system are assumed to be elements of an ($C^*$- or von Neumann) algebra $\mathcal{A}$, and the physical states are given by positive linear normalized functionals $\omega$ of $\mathcal{A}$, mapping the observables on their expectation values.

A common physicist's belief is that the macroscopic behavior of an idealized infinite system is described by a reduced set of macroscopic quantities (Sewell 1986). Some examples of these are the average densities of particles, energy, momentum, magnetic moment, etc. Analogously as the microscopic quantities, the macroscopic observables should be elements of an algebra, and macroscopic states of the system should be states on this algebra. The main problem is to construct the precise mathematical procedures to go from a given microscopic system to its macroscopic systems.

A well-known macroscopic system is the one given by the algebra of the observables at infinity (Lanford and Ruelle 1969) containing the spacial averages of local micro-observables, that is, for any local observable $A$ one considers the observable

$$A_\omega = \omega_\lim_{V\to\infty} \frac{1}{V}\int_V \mathrm{d}x\, \tau_x A$$

where $V$ is any finite volume in $\mathbb{R}^\nu$ and $\tau_x$ the translation over $x \in \mathbb{R}^\nu$, and where $\omega_\lim$ is the weak operator limit in the microstate $\omega$. The limits $A_\omega$ obtained correspond to the law of large numbers in probability. The algebra generated by these limit observables $\mathcal{A}_\omega = \{A_\omega \mid A \in \mathcal{A}\}$ is an abelian algebra of observables of a macroscopic system. This algebra can be identified with an algebra with pointwise product of measurable functions for some measure or macroscopic state.

The content of this review is to describe an analogous mapping from micro to macro but for a different type of scaling, namely the scaling of fluctuations. For any local observable $A \in \mathcal{A}$, one considers the limit

$$\lim_V \frac{1}{V^{1/2}}\int_V \mathrm{d}x(\tau_x A - \omega(\tau_x A)) \equiv F(A)$$

The problem consists in characterizing the $F(A)$ as an operator on a Hilbert space, called fluctuation

operator, and to specify the algebraic character of the set of all of these.

Based on this quantum central-limit theorem, one notes that not all locally different microscopic observables always yield different fluctuation operators. Hence the central-limit theorem realizes a well-defined procedure of coarse graining or reduction procedure which is handled by the mathematical notion of an equivalence relation on the microscopic observables yielding the same fluctuation operator.

In the following sections we discuss the preliminaries, the basic results about normal and abnormal fluctuations. Three model-independent applications are also discussed. In this review, we omit the properties of the so-called modulated fluctuations.

One should remark that we discuss only fluctuations in space. One can also consider timelike fluctuations. The theory of fluctuation operators for these has not been explicitly worked out so far. However, it is clear that for normal fluctuations the clustering properties of the time correlation functions will play a crucial role. On the other hand, typical properties of the structure of this fluctuation algebra may come up.

Another point which one has to stress is that all systems, which are treated in this review, are quasilocal systems. Other systems, for example, fermion systems, are note treated. But, in particular, fermion systems share many properties of quasilocality, and many of the results mentioned hold true also for fermion systems.

## Preliminaries

### Quantum Lattice Systems

Although all results we review can be extented to continuous or more general systems, modulo some technicalities, we limit ourself to quasilocal quantum dynamical lattice systems.

We consider the quasilocal algebra built on a $\nu$-dimensional lattice $\mathbb{Z}^\nu$. Let $\mathcal{D}(\mathbb{Z}^\nu)$ be the directed set of finite subsets of $\mathbb{Z}^\nu$ where the direction is the inclusion. With each point $x \in \mathbb{Z}^\nu$ we associate an algebra ($C^*$- or von Neumann algebra) $\mathcal{A}_x$, all copies of an algebra $\mathcal{A}$. For all $\Lambda \in \mathcal{D}(\mathbb{Z}^\nu)$, the tensor product $\otimes_{x\in\Lambda}\mathcal{A}_x$ is denoted by $\mathcal{A}_\Lambda$. We take $\mathcal{A}$ to be nuclear, then there exists a unique $C^*$-norm on $\mathcal{A}_\Lambda$. Every copy $\mathcal{A}_x$ is naturally embedded in $\mathcal{A}_\Lambda$. The family $\{\mathcal{A}_\Lambda\}_{\Lambda\in\mathcal{D}(\mathbb{Z}^\nu)}$ has the usual relations of locality and isotony:

$$[\mathcal{A}_{\Lambda_1}, \mathcal{A}_{\Lambda_2}] = 0 \quad \text{if } \Lambda_1 \cap \Lambda_2 = \emptyset \qquad [1]$$

$$\mathcal{A}_{\Lambda_1} \subseteq \mathcal{A}_{\Lambda_2} \quad \text{if } \Lambda_1 \subseteq \Lambda_2 \qquad [2]$$

Denote by $\mathcal{A}_\mathrm{L}$ all local observables, that is,

$$\mathcal{A}_\mathrm{L} = \bigcup_\Lambda \mathcal{A}_\Lambda$$

This algebra is naturally equipped with a $C^*$-norm $\|\cdot\|$ and its closure

$$\mathcal{B} = \overline{\mathcal{A}_\mathrm{L}}$$

is called a quasilocal $C^*$-algebra and considered as the microscopic algebra of observables of the system. Typical examples are spin systems where $\mathcal{A} = M_n$ is the $n \times n$ complex matrix algebra. In this case, every state $\omega$ of $\mathcal{B}$ is then locally normal, that is, there exists a family of density matrices $\{\rho_\Lambda \mid \Lambda \in \mathcal{D}(\mathbb{Z}^\nu)\}$ such that

$$\omega(A) = \mathrm{tr}\,\rho_\Lambda A \quad \text{for all } A \in \mathcal{A}_\Lambda$$

An important group of $*$-automorphisms of $\mathcal{B}$ is the group of space translations $\{\tau_x, x \in \mathbb{Z}^\nu\}$:

$$\tau_x : A_y \in \mathcal{A}_y \to \tau_x A_y = A_{x+y} \in \mathcal{A}_{y+x}$$

for all $A \in \mathcal{A}$.

Note that the quasilocal algebra $\mathcal{B}$ is asymptotically abelian for space translations: that is, for all $A, B \in \mathcal{B}$

$$\lim_{|x|\to\infty} \|[A, \tau_x B]\| = 0$$

A state $\omega$ of $\mathcal{B}$ represents a physical state of the system, assigning to every observable $A$ its expectation value $\omega(A)$. Therefore, this setting can be viewed as the quantum analog of the classical probabilistic setting. Sequences of random variables or observables can be constructed by considering an observable and its translates, that is, $\tau_x(A)_{x\in\mathbb{Z}^\nu}$ is a noncommutative random field. If a state $\omega$ is translation invariant, that is, $\omega \circ \tau_x = \omega$ for all $x$, then all $\tau_x(A)$ are identically distributed random variables. The mixing property of the random field is then expressed by the spatial correlations tending to zero:

$$\omega\big(\tau_x(A)\tau_y(B)\big) - \omega(\tau_x(A))\omega\big(\tau_y(B)\big) \to 0 \qquad [3]$$

if $|x - y| \to \infty$.

One of the basic limit theorems of probability theory is the weak law of large numbers. In this noncommutative setting the law of large numbers is translated into the problem of the convergence of space averages of an observable $A \in \mathcal{B}$. A first result was given by the mean ergodic theorem of von Neumann (1929). In Brattelli and Robinson (1979, 2002) one finds the following theorem: if the state $\omega$ is space translation invariant and mixing (see [3]) then for all $A, B$, and $C$ in $\mathcal{B}$

$$\lim_{\Lambda\to\mathbb{Z}^\nu} \omega\left(A \frac{1}{|\Lambda|}\left(\sum_{x\in\Lambda} \tau_x(B)\right) C\right) = \omega(AC)\omega(B) \qquad [4]$$

That is, in the GNS (Gelfand–Naimark–Segal) representation of the state $\omega$, the sequence $S_\Lambda(B) = 1/|\Lambda| \sum_{x\in\Lambda} \tau_x B$ converges weakly to a multiple of the identity: $S(B) \equiv \omega(B)\mathbb{1}$. This theorem, called the mean ergodic theorem, characterizes the class of states yielding a weak law of large numbers. Clearly, these limits $\{S(A)|A \in \mathcal{B}\}$ form a trivial abelian algebra of macroscopic observables.

Now we go a step further and consider space fluctuations. Define the local fluctuation of an observable $A$ in a homogeneous (spatial invariant) state $\omega$ by

$$F_\Lambda(A) = \frac{1}{|\Lambda|^{1/2}} \sum_{x\in\Lambda} (\tau_x A - \omega(A)) \qquad [5]$$

The problem is to give a rigorous meaning to $\lim F_\Lambda(A)$ for $\Lambda$ tending to $\mathbb{Z}^\nu$ in the sense of extending boxes. When does such a limit exist? What are the properties of the fluctuations or the limits $F(A) = \lim F_\Lambda(A)$, etc.? Again, the $F(A)$ are macroscopic variables of the microsystem.

Already we remark the following: if $A, B$ are strictly local elements, $A, B \in \mathcal{A}_\mathrm{L}$, then

$$\sum_{y\in\mathbb{Z}^\nu} [A, \tau_y B] \in \mathcal{A}_\mathrm{L}$$

and an easy computation yields, by [4],

$$\begin{aligned} &\text{weak}\lim_\Lambda [F_\Lambda(A), F_\Lambda(B)] \\ &= \text{weak}\lim_\Lambda \frac{1}{|\Lambda|} \sum_{x\in\Lambda} \tau_x \left( \sum_{y\in\Lambda} [A, \tau_{y-x} B] \right) \\ &= \text{weak}\lim_\Lambda \frac{1}{|\Lambda|} \sum_{x\in\Lambda} \tau_x \left( \sum_{y\in\mathbb{Z}^\nu} [A, \tau_y B] \right) \\ &= \sum_{y\in\mathbb{Z}^\nu} \omega([A, \tau_y B]) \equiv \mathrm{i}\sigma(A, B)\mathbb{1} \end{aligned}$$

that is, if the $F(A)$ and $F(B)$ limits do exist, then

$$[F(A), F(B)] = \mathrm{i}\sigma(A, B)\mathbb{1} \qquad [6]$$

This property indicates that fluctuations should have the same commutation relations as boson fields. If fluctuations can be characterized as macroscopic observables, they must satisfy the canonical commutation relations (CCRs). Therefore, in the next section we introduce the essentials on CCR representations.

### CCR Representations

We present the abstract Weyl CCR $C^*$-algebra. More details can be found in Brattelli and Robinson (1979, 2002) and in particular in Manuceau *et al.* (1973), where the case of a real test function space $(H, \sigma)$ with a possibly degenerate symplectic form $\sigma$ is treated. Hence, $H$ is a real vector space and $\sigma$ a bilinear, antisymmetric form on $H$.

Denote by $W(H, \sigma)$ the complex vector space generated by the functions $W(f)$, $f \in H$, defined by

$$W(f) : H \to \mathbb{C} : g \to W(f)g = \begin{cases} 0 & \text{if } f \neq g \\ 1 & \text{if } f = g \end{cases}$$

$W(H, \sigma)$ becomes an algebra with unit $W(0)$ for the product

$$W(f)W(g) = W(f+g)\mathrm{e}^{-(\mathrm{i}/2)\sigma(f,g)}; \quad f, g \in H$$

and a $^*$-algebra for the involution

$$W(f) \to W(f)^* = W(-f)$$

It becomes a $C^*$-algebra $C^*(H, \sigma)$ following the construction of Verbeure and Zagrebnov (1992). A linear functional $\omega$ of a $C^*$-algebra $C^*(H, \sigma)$ is called a state if $\omega(I) = 1$ and $\omega(A^*A) \geq 0$ for all $A \in C^*(H, \sigma)$ and $I = W(0)$. Every state gives rise to a representation through the GNS construction (Brattelli and Robinson 1979, 2002). In particular, $\omega$ is a state if for any choice of $A = \sum_j c_j W(f_j)$ we have

$$\sum_{j^k} c_j \bar{c}_k \omega\big(W(f_j - f_j)\big)\mathrm{e}^{-\mathrm{i}\sigma(f_j, f_k)} \geq 0$$

$$\omega(W(0)) = 1$$

A remark about the special case that $\sigma$ is degenerate is in order. Denote by $H_0$ the kernel of $\sigma$:

$$H_0 = \{f \in H | \sigma(f, g) = 0 \text{ for all } g \in H\}$$

If $H = H_0 \oplus H_1$ with $\sigma_1$ a nondegenerate symplectic form on $H_1$ and $\sigma_1$ equal to the restriction of $\sigma$ to $H_1$, we have that $C^*(H, \sigma)$ is a tensor product:

$$C^*(H, \sigma) = C^*(H_0, 0) \otimes C^*(H_1, \sigma_1)$$

Note that $C^*(H_0, 0)$ is abelian and that each positive-definite normalized functional $\varphi$,

$$\varphi : h \in H_0 \to \varphi(W(h))$$

defines a state $\omega(W(h)) = \varphi(W(h))$ on $C^*(H_0, 0)$.

Let $\xi$ be any character of the abelian additive group $H$, then the map $\tau_\xi$,

$$\tau_\xi W(f) = \xi(f) W(f)$$

extends to a $^*$-automorphism of $C^*(H, \sigma)$. Let $s$ be a positive symmetric bilinear form on $H$ such that for all $f, g \in H$:

$$\tfrac{1}{4}|\sigma(f, g)|^2 \leq s(f, f)\, s(g, g) \qquad [7]$$

and let $\omega_{s,\xi}$ be the linear functional on $C^*(H,\sigma)$ given by

$$\omega_{s,\xi}(W(h)) = \xi(h)\mathrm{e}^{-(1/2)s(h,h)} \qquad [8]$$

then it is straightforward (Brattelli and Robinson 1979, 2002) to check that $\omega_{s,\xi}$ is a state on $C^*(H,\sigma)$. All states of the type [8] are called quasifree states on the CCR algebra $C^*(H,\sigma)$.

A state $\omega$ of $C^*(H,\sigma)$ is called a regular state if, for all $f,g \in H$, the map $\lambda \in \mathbb{R} \to \omega(W(\lambda f + g))$ is continuous. The regularity property of a state yields the existence of a Bose field as follows. Let $(\mathcal{H},\pi,\Omega)$ be the GNS representation (Brattelli and Robinson 1979, 2002) of the state $w$, then the regularity of $w$ implies that there exists a real linear map $b: H \to \mathcal{L}(\mathcal{H})$ (linear operators on $\mathcal{H}$) such that $\forall f \in H$: $b(f)^* = b(f)$ and

$$\pi(W(f)) = \exp(\mathrm{i}b(x))$$

The map $b$ is called the Bose field satisfying the Bose field commutation relations:

$$[b(f), b(g)] = \mathrm{i}\sigma(f,g) \qquad [9]$$

Note that the Bose fields are state dependent. Note also already that if $\xi$ is a continuous character of $H$, then any quasifree state [8] is a regular state guaranteeing the existence of a Bose field.

## Normal Fluctuations

In this section we develop the theory of normal fluctuations for $\nu$-dimensional quantum lattice systems with a quasilocal structure (see the section "Quantum lattice systems") and for technical simplicity we assume that the local $C^*$-algebra $\mathcal{A}_x, x \in \mathbb{Z}^\nu$, are copies of the matrix algebra $M_n(\mathbb{C})$ of $n \times n$ complex matrices. Most of the results stated can be extended to the case where $\mathcal{A}_x$ is a general $C^*$-algebra (Goderis *et al.* 1989, 1990, Goderis and Vets 1989).

We consider a physical system $(\mathcal{B},\omega)$ where $\omega$ is a translation-invariant state of $\mathcal{B}$, that is, $\omega \circ \tau_x = \omega$ for all $x \in \mathbb{Z}^\nu$. Later on we extend the situation to a $C^*$-dynamical system $(\mathcal{B},\omega,\alpha_t)$ and analyze the properties of the dynamics $\alpha_t$ under the central limit.

For any local $A$ we introduced its local fluctuation in the state $\omega$ of the system:

$$F_\Lambda(A) = \frac{1}{|\Lambda|^{1/2}} \sum_{x\in\Lambda} (\tau_x A - \omega(A)) \qquad [10]$$

The main problem is to give a rigorous mathematical meaning to the limits

$$\lim_{\Lambda\to\infty} F_\Lambda(A) \equiv F(A)$$

where the limit is taken for any increasing $\mathbb{Z}^\nu$-absorbing sequence $\{\Lambda\}_\Lambda$ of finite volumes of $\mathbb{Z}^\nu$. The limits $F(A)$ are called the macroscopic fluctuation operators of the system $(\mathcal{B},\omega)$.

Already earlier work (Cushen and Hudson 1971, Sewell 1986) suggested that the fluctuations behave like bosons. We complete this idea by proving that one gets a well-defined representation of a CCR $C^*$-algebra of fluctuations uniquely defined by the original system $(\mathcal{B},\omega)$.

Denote by $\mathcal{A}_{\mathrm{L,sa}}$ and $\mathcal{B}_{\mathrm{sa}}$ the real vector space of the self-adjoint elements of $\mathcal{A}_{\mathrm{L}}$, respectively, $\mathcal{B}$.

**Definition 1** An observable $A \in \mathcal{B}_{\mathrm{sa}}$ satisfies the central-limit theorem if

(i) $\lim_\Lambda \omega(F_\Lambda(A)^2) \equiv s_\omega(A,A)$ exists and is finite, and
(ii) $\lim_\Lambda \omega(\mathrm{e}^{\mathrm{i}tF_\Lambda(A)}) = \mathrm{e}^{(-t/2)^2 s_\omega(A,A)}$ for all $t \in \mathbb{R}$.

Clearly, our definition coincides with the notion in terms of characteristic functions, for classical systems ($\mathcal{A}$ abelian) equivalent with the notion of convergence in distribution. For quantum systems, there does not exist a standard notion of "convergence in distribution." Only the concept of expectations is relevant. This does not exclude the notion of central-limit theorem in terms of the moments, which is the analog of the moment problem (Giri and von Waldenfels 1978).

**Definition 2** The system $(\mathcal{B},\omega)$ is said to have normal fluctuations if $\omega$ is translation invariant and if

(i) $\forall A,B \in \mathcal{A}_{\mathrm{L}}$

$$\sum_{x\in\mathbb{Z}^\nu} |\omega(A\tau_x B) - \omega(A)\omega(B)| < \infty$$

(ii) the central-limit theorem holds for all $A \in \mathcal{A}_{\mathrm{L,sa}}$.

Note that (i) implies that the state $\omega$ is mixing for space translations. Also by (i), one can define a sesquilinear form on $\mathcal{A}_{\mathrm{L}}$:

$$\begin{aligned}\langle A,B\rangle_\omega &= \lim_\Lambda \omega(F_\Lambda(A^*)F_\Lambda(B)) \\ &= \sum (\omega(A^*\tau_x B) - \omega(A^*)\omega(B))\end{aligned}$$

and denote

$$\begin{aligned}s_\omega(A,B) &= \mathrm{Re}\langle A,B\rangle_\omega \\ \sigma_\omega(A,B) &= 2\,\mathrm{Im}\langle A,B\rangle_\omega\end{aligned}$$

For $A,B \in \mathcal{A}_{\mathrm{L,sa}}$ one has

$$\sigma_\omega(A,B) = -\mathrm{i}\sum_{x\in\mathbb{Z}^\nu} \omega([A,\tau_x B]) \qquad [11]$$

$$s_\omega(A,A) = \langle A,A\rangle_\omega \qquad [12]$$

Clearly, $(\mathcal{A}_{\mathrm{L,sa}},\sigma_\omega)$ is a symplectic space and $s_\omega$ a non-negative symmetric bilinear form on $\mathcal{A}_{\mathrm{L,sa}}$.

Following the discussion in the section "CCR representations" we get a natural CCR $C^*$-algebra $C^*(\mathcal{A}_{L,sa}, \sigma_\omega)$ defined on this symplectic space. The following theorem is an essential step in the construction of a macroscopic physical system of fluctuations of the microsystem $(\mathcal{B}, \omega)$.

**Theorem 1** *If the system* $(\mathcal{B}, \omega)$ *has normal fluctuations, then the limits* $\{\lim_\Lambda \omega(e^{iF_\Lambda(A)}) = \exp((-1/2)s_\omega(A,A)), A \in \mathcal{A}_L\}$ *define a quasifree state* $\tilde{\omega}$ *on the CCR* $C^*$*-algebra* $C^*(\mathcal{A}_{L,sa}, \sigma_\omega)$ *by*

$$\tilde{\omega}(W(A)) = \exp\left(-\tfrac{1}{2}s_\omega(A,A)\right)$$

**Proof** The proof is clear from the definition [8] if one can prove that the positivity condition [7] holds. But the latter follows readily from

$$\begin{aligned}\tfrac{1}{4}|\sigma_\omega(A,B)|^2 &= \lim_\Lambda |\mathrm{Im}\,\omega(F_\Lambda(A)F_\Lambda(B))|^2 \\ &\leq \lim_\Lambda \omega(F_\Lambda(A)^2)\omega(F_\Lambda(B)^2) \\ &= s_\omega(A,A)s_\omega(B,B)\end{aligned}$$

by Schwarz inequality. □

This theorem indicates that the quantum-mechanical alternative for (classical) Gaussian measures are quasifree states on CCR algebras. However, the following basic question arises: is it possible to take the limits of products of the form

$$\lim_\Lambda \omega\left(e^{iF_\Lambda(A)}e^{iF_\Lambda(B)}\cdots\right)$$

and, if they exist, do they preserve the CCR structure? Clearly, this is a typical noncommutative problem.

Using the following general bounds: for $C^* = C$ and $D^* = D$ norm-bounded operators one has

$$\begin{aligned}&\left\|e^{i(C+D)} - e^{iC}\right\| \leq \|D\| \\ &\left\|[e^{iC}, e^{iD}]\right\| \leq \|[C,D]\| \\ &\left\|e^{i(C+D)} - e^{iC}e^{iD}\right\| \leq \tfrac{1}{2}\|[C,D]\|\end{aligned}$$

and by the expansion of the exponential function one proves easily that

$$\begin{aligned}\lim_\Lambda &\left\|e^{iF_\Lambda(A)}e^{iF_\Lambda(B)} - e^{i(F_\Lambda(A)+F_\Lambda(B))}\right. \\ &\left.\times\, e^{-(1/2)[F_\Lambda(A),F_\Lambda(B)]}\right\| = 0\end{aligned} \qquad [13]$$

if $A$ and $B$ are one-point observables, that is, if $A, B \in \mathcal{A}_{\{0\}}$. For general local elements the proof is somewhat more technical and can be based on a Bernstein-like argument (for details see Goderis and Vets (1989)). The property [13] can be seen as a Baker–Campbell–Hausdorff formula for fluctuations.

From [13], the mean ergodic theorem, and Theorem 1 we get:

**Theorem 2** *If the system* $(\mathcal{B}, \omega)$ *has normal fluctuations then for* $A, B \in \mathcal{A}_{L,sa}$:

$$\begin{aligned}\lim_\Lambda &\,\omega\left(e^{iF_\Lambda(A)}e^{iF_\Lambda(B)}\right) \\ &= \exp\left\{-\frac{1}{2}s_\omega(A+B, A+B) - \frac{i}{2}\sigma_\omega(A,B)\right\} \\ &= \tilde{\omega}(W(A)W(B))\end{aligned}$$

*with* $\tilde{\omega}$ *a quasifree state on the CCR algebra* $C^*(\mathcal{A}_{L,sa}^{\sigma_\omega})$.

Theorems 1 and 2 describe completely the topological and analytical aspects of the quantum central-limit theorem under the condition of normal fluctuations (Definition 2). In fact, the quantum central limit yields, for every microphysical system $(\mathcal{B}, \omega)$, a macrophysical system $(C^*(\mathcal{A}_{L,sa}, \sigma_\omega), \tilde{\omega})$ defined by the CCR $C^*$-algebra of fluctuation observables $C^*(\mathcal{A}_{L,sa}, \sigma_\omega)$ in the representation defined by the quasifree state $\tilde{\omega}$. As the state $\tilde{\omega}$ is a quasifree state, it is a regular state, that is, the map $\lambda \in \mathbb{R} \to \tilde{\omega}(W(\lambda A + B))$ is continuous. From in section "CCR representations" we know that this regularity property yields the existence of a Bose field, that is, there exists a real linear map

$$F: A \in \mathcal{A}_{L,sa} \to F(A)$$

where $F(A)$ is a self-adjoint operator on the GNS representation space $\tilde{\mathcal{H}}$ of $\tilde{\omega}$, such that for all $A, B \in \mathcal{A}_{L,sa}$:

$$[F(A), F(B)] = i\sigma_\omega(A,B)$$

Moreover, if one has a complex structure J on $(\mathcal{A}_{L,sa}, \sigma_\omega)$ such that $J^2 = -\mathbb{1}$ and for all $A, B \in \mathcal{A}_{L,sa}$:

$$\begin{aligned}&\sigma_\omega(JA, B) = -\sigma_\omega(A, JB) \\ &\sigma_\omega(A, JB) > 0\end{aligned}$$

then one defines the boson creation and annihilation operators

$$F^\pm(A) = \frac{1}{\sqrt{2}}(F(A) \mp iF(JA))$$

satisfying the usual boson commutation relations

$$[F^-(A), F^+(B)] = \sigma_\omega(A, JB) + i\sigma_\omega(A,B)$$

Finally, it is straightforward, nevertheless important, to remark that Theorems 1 and 2 hold true if the linear space of local observables $\mathcal{A}_{L,sa}$ is replaced by any of its subspaces. Some of them can have greater physical importance than others. This means that the quantum central-limit theorems can realize several macrophysical systems of fluctuations. But all of them are Bose field systems.

It is also important to remark that these results end up in giving a probabilistic canonical basis of the canonical commutation relations.

Now we analyze the notion of coarse graining due to the quantum central limit. Consider on $\mathcal{A}_L$ the sesquilinear form (see [11], [12]) again

$$\langle A, B\rangle_\omega = \sum_{x\in\mathbb{Z}^\nu} (\omega(A^*\tau_x B) - \omega(A)\omega(B)) = s_\omega(A,B) + \mathrm{i}\sigma_\omega(A,B) \qquad [14]$$

This form defines a topology on $\mathcal{A}_L$ which is not comparable with the operator topologies induced by $\omega$. In fact, this form is not closable in the weak, strong, ultraweak, or ultrastrong operator topologies.

We call $A$ and $B$ in $\mathcal{A}_L$ equivalent, denoted by $A \sim B$ if $\langle A-B, A-B\rangle_\omega = 0$. Clearly, this defines an equivalence relation on $\mathcal{A}_L$. The property of coarse graining is mathematically characterized by the following: for all $A, B \in \mathcal{A}_{L,sa}$ the relation $A \sim B$ is equivalent with $F(A) = F(B)$. Suppose first that $F(A) = F(B)$, then

$$[W(A), W(B)] = 0$$

hence $\sigma_\omega(A,B) = 0$. Therefore, from Theorem 1:

$$1 = \tilde{\omega}(W(A)W(B)^*) = \tilde{\omega}(W(A)W(-B)) = \tilde{\omega}(W(A-B)) = \exp\left(-\tfrac{1}{2}s_\omega(A-B, A-B)\right)$$

and from [12] and [14]: $\langle A-B, A-B\rangle_\omega = 0$. The converse is equally straightforward.

From this property, it follows immediately that, for example, the action of the translation group is trivial or that $F(\tau_x A) = F(A)$ for all $x \in \mathbb{Z}^\nu$. Therefore, the map $F: \mathcal{A}_{L,sa} \to C^*(\mathcal{A}_{L,sa}, \sigma_\omega)$ is not injective. This expresses the physical phenomenon of coarse graining and gives a mathematical signification of the fluctuations being macroscopic observables.

In the above, we have constructed the new macroscopic physical system of quantum fluctuations for any microsystem with the property of normal fluctuations (see Definition 2). The main problem remains: when the microsystem does have normal fluctuations. We end this section with the formulation of a general sufficient clustering condition for the microstate $\omega$ in order that the microsystem $(\mathcal{B}, \omega)$ has normal fluctuations.

Let $\Lambda, \Lambda' \in \mathcal{D}(\mathbb{Z}^\nu)$ and $\omega$ a translation invariant state, denote

$$\alpha^\omega(\Lambda, \Lambda') = \sup_{\substack{A\in\mathcal{A}_\Lambda:\|A\|=1\\ B\in\mathcal{A}_{\Lambda'}:\|B\|=1}} |\omega(AB) - \omega(A)\omega(B)|$$

The cluster function $\alpha_N^\omega(d)$ is defined by

$$\alpha_N^\omega(d) = \sup\{\alpha^\omega(\Lambda,\Lambda') : d(\Lambda,\Lambda') \geq d \text{ and } \max(|\Lambda|, |\Lambda'|) \leq N\}$$

where $N, d \in \mathbb{R}^+$ and $d(\Lambda, \Lambda')$ is the Euclidean distance between $\Lambda$ and $\Lambda'$. It is obvious that

$$\alpha_N^\omega(d) \leq \alpha_N^\omega(d') \quad \text{if } d \geq d'$$
$$\alpha_N^\omega(d) \leq \alpha_{N'}^\omega(d) \quad \text{if } N \leq N'$$

The clustering condition is expressed by the following scaling law:

$$\exists\delta > 0: \quad \lim_{N\to\infty} N^{1/2}\alpha_N^\omega\left(N^{1/2\nu-\delta}\right) = 0 \qquad [15]$$

or, equivalently,

$$\exists\delta > 0: \quad \lim_{N\to\infty} N^{\nu+\delta}\alpha^\omega_{N^{2(\nu+\delta)}}(N) = 0 \qquad [16]$$

Note that this condition implies that

$$\sum_{x\in\mathbb{Z}^\nu} \alpha_N^\omega(|x|) < \infty$$

that is, that the function $\alpha_N^\omega(\cdot)$ is an $L^1(\mathbb{Z}^\nu)$-function for all $N$. In fact, this condition corresponds to the uniform mixing condition in the commutative (classical) central-limit theorem (see, e.g., Ibragimov and Linnick (1971)). This condition can also be called the modulus of decoupling. Product states, for example, equilibrium states of mean-field systems are uniformly clustering with $\alpha^\omega(d) = 0$ for $d > 0$.

The normality of the fluctuations of the microsystem $(\mathcal{B}, \omega)$ for product states is proved and extensively studied in Goderis *et al.* (1989), and for states satisfying the condition [15] or [16] in Goderis and Vets (1989). In the latter case, the proofs are very technical and based on a generalization of the well-known Bernstein argument (Ibragimov and Linnick 1971) of the classical central-limit theorem to the noncommutative situation. A refinement of these arguments can be found in Goderis *et al.* (1990). For the sake of formal self-consistency we formulate the theorem:

**Theorem 3** (Central-limit theorem) *Take the microsystem $(\mathcal{B}, \omega)$ such that $\omega$ is lattice translation invariant and satisfies the clustering condition [15]; then the system has normal fluctuations for all elements of the vector space of local observables $\mathcal{A}_{L,sa}$.* □

In Goldshtein (1982) a noncommutative central-limit theorem is derived using similar techniques. The main difference, however, is its strictly local character, namely for one local operator separately. The conditions depend on the spectral properties of the operator. It excludes a global approach resulting in a CCR algebra structure.

Even for quantum lattice systems, it is not straightforward to check whether a state satisfies

the degree of mixing as expressed in conditions [15]–[16]. Clearly, one expects the condition to hold for equilibrium states at high enough temperatures. For quantum spin chains, a theorem analogous with Theorem 3 under weaker conditions than [15] is proved for example, in Matsui (2003).

So far we have reviewed the quantum central-limit theorem for physical $C^*$-spin systems $(\mathcal{B}, \omega)$ with normal fluctuations.

Now we extend the physical system to a $C^*$-dynamical system $(\mathcal{B}, \omega, \alpha_t)$ (Brattelli and Robinson 1979, 2002) and we investigate the properties of the dynamics $\alpha_t$ under the central limit. As usual, the dynamics is supposed to be of the short-range type in order to guarantee the norm limit:

$$\alpha_t(\cdot) = n - \lim_{\Lambda} \mathrm{e}^{\mathrm{i}tH_\Lambda} \cdot \mathrm{e}^{-\mathrm{i}tH_\Lambda}$$

and space homogeneous $\alpha_t \cdot \tau_x = \tau_x \cdot \alpha_t, \forall t \in \mathbb{R}, \forall x \in \mathbb{Z}^\nu$. We suppose that the state $\omega$ is both space as time translation invariant. Moreover, we assume that the state $\omega$ satisfies the mixing condition [15] for normal fluctuations.

In [10] we defined, for every local $A \in \mathcal{A}_{\mathrm{L,sa}}$, the local fluctuation $F_\Lambda(A)$ and obtained a clear meaning of $F(A) = \lim_\Lambda F_\Lambda(A)$ from the central-limit theorem. Now we are interested in the dynamics of the fluctuations $F(A)$. Clearly, for all $A \in \mathcal{A}_{\mathrm{L,sa}}$ and all finite $\Lambda$:

$$\alpha_t F_\Lambda(A) = F_\Lambda(\alpha_t A) \qquad [17]$$

and one is tempted to define the dynamics $\tilde{\alpha}_t$ of the fluctuations in the $\Lambda$-limit by the formula

$$\tilde{\alpha}_t F(A) = F(\alpha_t A) \qquad [18]$$

Note, however, that in general $\alpha_t A$ is not a local element of $\mathcal{A}_{\mathrm{L,sa}}$. It is unclear whether the central limit of elements of the type $\alpha_t A$, with $A \in \mathcal{A}_{\mathrm{L,sa}}$ exists or not and hence whether one can give a meaning to $F(\alpha_t A)$. Moreover, if $F(\alpha_t A)$ exists, it remains to prove that $(\tilde{\alpha}_t)_t$ defines a weakly continuous group of $*$-automorphisms on the fluctuation CCR algebra $\tilde{\mathcal{M}} = C^*(\mathcal{A}_{\mathrm{L,sa}}, \sigma_\omega)''$ (the von Neumann algebra generated by the $\tilde{\omega}$-representation of $C^*(\mathcal{A}_{\mathrm{L,sa}}, \sigma_\omega)$). All this needs a proof. In Goderis *et al.* (1990), one finds the proof of the following basic theorem about the dynamics.

**Theorem 4** *Under the conditions on the dynamics* $\alpha_t$ *and on the state* $\omega$ *expressed above, the limit* $F(\alpha_t A) = \lim_\Lambda F_\Lambda(\alpha_t A)$ *exists as a central limit as in Theorem 2, and the maps* $\tilde{\alpha}_t$ *defined by* [18] *extend to a weakly continuous one-parameter group of* $*$*-automorphisms of the von Neumann algebra* $\tilde{\mathcal{M}}$. *The quasifree state* $\tilde{\omega}$ *is* $\tilde{\alpha}_t$*-invariant (time invariant).*

This theorem yields the existence of a dynamics $\tilde{\alpha}_t$ on the fluctuations algebra and shows that it is of the quasifree type

$$\tilde{\alpha}_t F(A) = F(\alpha_t A)$$

where $F(A)$ is a representation of a Bose field in a quasifree state $\tilde{\omega}$, the noncommutative version of a Gaussian distribution. In physical terms, it also means that any microdynamics $\alpha_t$ induces a linear process on the level of its fluctuations.

We can conclude that on the basis of the Theorems 3 and 4 the quantum central-limit theorem realized a map from the microdynamical system $(\mathcal{B}, \omega, \alpha_t)$ to a macrodynamical system $(C^*(\mathcal{A}_{\mathrm{L,sa}}, \sigma_\omega), \tilde{\omega}, \tilde{\alpha}_t)$ of the quantum fluctuations. The latter system is a quasifree Boson system.

Note that, contrary to the central-limit theorem, the law of large numbers [4] maps local observables to their averages forming a trivial commutative algebra of macro-observables. The macrodynamics is mapped to a trivial dynamics as well. Therefore, the consideration of law of large numbers does not allow one to observe genuine quantum phenomena. On the other hand, on the level of the fluctuations, macroscopic quantum phenomena are observable.

## Abnormal Fluctuations

The results about normal fluctuations in the last section contain two essential elements. On the one hand, the central limit has to exist. The condition in order that this occurs is the validity of the cluster condition ([15] or [16]) guaranteeing the normality of the fluctuations. On the other hand, there is the reconstruction theorem, identifying the CCR algebra representation of the fluctuation observables or operators in the quasifree state, which is denoted by $\tilde{\omega}$.

The cluster condition is in general not satisfied for systems with long-range correlations, for example, for equilibrium states at low temperatures with phase transitions. It is a challenging question to also study in this case the existence of fluctuations operators and, if they exist, to study their mathematical structure. Here we detect structures other than the CCR structure, other states or distributions different from quasifree states, etc.

Progress in the elucidation of all these questions started with a detailed study of abnormal fluctuations in the harmonic and anharmonic crystal models (Verbeure and Zagrebnov 1992, Momont *et al.* 1997). More general Lie algebras are obtained than the Heisenberg Lie algebra of the CCR algebra, and more general states $\tilde{\omega}$ or quantum distributions

are computed beyond quasifree states, which is the case for normal fluctuations.

Abnormal fluctuations turn up, if one has an ergodic state $\omega$ with long-range correlations. We have in mind continuous (second-order) phase transitions, then typically, for example, the heat capacity or some more general susceptibilities diverge at critical points or lines. This means that normally scaled (with the factor $|\Lambda|^{-1/2}$) fluctuations of some observables diverge. This is equivalent with the divergence of sums of the type

$$\sum_{x\in\mathbb{Z}^\nu}(\omega(A\tau_x A)-\omega(A)^2)$$

for some local observable $A$.

In order to deal with these situations, we rescale the local fluctuations. One determines a scaling index $\delta_A \in (-1/2, 1/2)$, depending on the observable $A$, such that the abnormally scaled local fluctuations

$$F_\Lambda^{\delta_A} = |\Lambda|^{-\delta_A} F_\Lambda(A)$$

with $F_\Lambda(A)$ as in [10], yield a nontrivial characteristic function: $\forall t \in \mathbb{R}$,

$$\lim_\Lambda \omega_\Lambda(\mathrm{e}^{\mathrm{i}tF_\Lambda^{\delta_A}(A)}) \equiv \phi_A(t) \qquad [19]$$

where we limit our discussion to states $\omega_\Lambda$ local Gibbs states. The index $\delta_A$ is a measure for the abnormality of the fluctuation of $A$. Note that $\delta_A = -1/2$ yields a triviality and that $\delta_A = 1/2$ would lead to a law of large numbers (theory of averages). Observe also that in general the characteristic function $\phi_A$ or the corresponding state $\tilde{\omega}$ need not be Gaussian or quasifree.

In the physics literature, one describes the long-range order by means of the asymptotic form of the connected two-point function in terms of the critical exponent $\eta$

$$\omega_\Lambda(a\tau_x A) - \omega_\Lambda(A)^2 \simeq 0\left(\frac{1}{|x|^{\nu-2+\eta}}\right); \quad |x| \to \infty \qquad [20]$$

Our scaling index $\delta_A$ is related to the critical exponent $\eta$ by the straightforward relation

$$\eta = 2 - 2\nu\delta_A$$

As stated above, the index $\delta_A$ is determined by the existence of the central limit and explicitly computed in several model calculations, for example, Verbeure and Zagrebnov (1992), and for equilibrium states. Apart from the strong model dependence, the indices also depend strongly on the chosen boundary conditions. This fact draws a new light on the universality of the critical exponents.

Suppose now that the indices $\delta_A$ are determined by the existence of the central limit [19]. The next problem is to find out whether also in these cases a reconstruction theorem, comparable to, for example, Theorem 2, can be proved giving again a mathematical meaning to the limits

$$\lim_\Lambda F_\Lambda^{\delta_A}(A) \equiv F^{\delta_A}(A) \qquad [21]$$

as operators, in general unbounded, on a Hilbert space.

Here we develop a proof of the Lie algebra character of the abnormal fluctuations under the conditions: (1) the $\delta$-indices are determined by the existence of the variances (second moments), and (2) the existence of the third moments (for more details see, e.g., Momont *et al.* (1997)).

Consider a local algebra, namely an $n$-dimensional vector space $\mathcal{G}$ with basis $\{v_i\}_{i=1,\ldots,n}$ and product

$$v_j \cdot v_k \equiv [v_j, v_k] = \sum_{\ell=1}^{n} c_{jk}^\ell v_\ell \qquad [22]$$

with structure constants $c_{jk}^\ell$ satisfying

$$c_{jk}^\ell + c_{kj}^\ell = 0$$
$$\sum_r (c_{ij}^r c_{rk}^s + c_{jk}^r c_{ri}^s + c_{ki}^r c_{rj}^s) = 0$$

Consider the concrete Lie algebra basis of operators in $\mathcal{A}_{\{0\}}$

$$\{L_0 = i\mathbb{1}, L_1, \ldots, L_m\}, \quad m < \infty$$

such that $L_j^* = -L_j$, $j = 0, 1, \ldots, m$ and $\omega(L_j) = \lim_\Lambda \omega_\Lambda(L_j) = 0$ for $j > 0$. Clearly, $\omega_\Lambda(L_0) = i$ for all $\Lambda$, and the $\{L_i\}$ satisfy eqn [22]. Because of the special choices of $L_0$ one has $c_{ok}^\ell = c_{ko}^\ell = 0$ and $c_{jk}^o = -\mathrm{i}\lim_\Lambda \omega_\Lambda([L_j, L_k])$. We consider now the fluctuations of these generators and we are looking for a characterization of the Lie algebra of the fluctuations if any.

For a translation-invariant local state $\omega_\Lambda$, $\Lambda \subseteq \mathbb{Z}^\nu$, such that $\omega = \lim_\Lambda \omega_\Lambda$ is mixing, define the local fluctuations, for $j = 1, \ldots, m$,

$$F_j^{\delta_j}, \Lambda = \frac{1}{|\Lambda|^{1/2+\delta_j}} \sum_{x\in\Lambda} \left(\tau_x L_j - \omega_\Lambda(L_j)\right) \qquad [23]$$

and for notational convenience, take

$$F_{0,\Lambda} = \mathrm{i}\mathbb{1}$$

Now we formulate the conditions for our purposes.

**Condition A** We assume that the parameters $\delta_j$ are determined by the existence of the finite and nontrivial variances: for all $j = 1, \ldots, m$,

$$0 < \lim_\Lambda \omega_\Lambda\left((F_{j,\Lambda}^{\delta_j})^2\right) < \infty \qquad [24]$$

After reordering, take $1/2 > \delta_1 \geq \delta_2 \geq \cdots \geq \delta_m > -1/2$.

**Condition B** Assume that all third moments are finite, that is,

$$\lim_{\Lambda} \left| \omega_\Lambda \left( F^{\delta_j}_{j,\Lambda} F^{\delta_k}_{k,\Lambda} F^{\delta_\ell}_{\ell,\Lambda} \right) \right| < \infty$$

We have in mind, that the $\omega_\Lambda$'s are Gibbs states for some local Hamiltonians with some specific boundary conditions. The limit $\Lambda \to \mathbb{Z}^\nu$ may depend very strongly on these boundary conditions, in the sense that they are visible in the values of the indices $\delta_j$ (see, e.g., Verbeure and Zagrebnov (1992)). If for some $j \geq 1$, the corresponding $\delta_j = 0$ then the operator $L_j$ has a normal fluctuation operator

$$F^{\delta_j}_j = \lim_{\Lambda} F^{\delta_j}_{j,\Lambda} \qquad [25]$$

where the limit is understood in the sense of Condition A, namely a finite nontrivial variance. If, for some $j \geq 1$, the corresponding $\delta_j \neq 0$, then the fluctuation [25] is called an abnormal fluctuation operator. In order to satisfy Condition A, it happens sometimes that $\delta_j$ has to be chosen negative (see, e.g., Verbeure and Zagrebnov (1992)). In this case, it is reasonable to limit our discussion to the situation that all $\delta_j > -1/2$.

On the basis of Condition A, the limit set $\{F^{\delta_j}_j\}_{j=0,\ldots,m}$ of fluctuation operators generates a Hilbert space $\mathcal{H}$ with scalar product

$$\left( F^{\delta_j}_j, F^{\delta_k}_k \right) = \lim_{\Lambda} \omega_\Lambda \left( (F^{\delta_j}_{j,\Lambda})^* F^{\delta_k}_{k,\Lambda} \right) \qquad [26]$$

On the basis of Condition B, the fluctuation operators are defined as multiplication operators of the Hilbert space $\mathcal{H}$. Note that the Conditions A and B are not sufficient to obtain a characteristic function. However, they are sufficient to obtain the notion of fluctuation operator. Now we proceed to clarify the Lie algebra character of these fluctuation operators on $\mathcal{H}$.

Consider the Lie product of two local fluctuations for a finite $\Lambda$, one gets

$$\left[ F^{\delta_j}_{j,\Lambda}, F^{\delta_k}_{k,\Lambda} \right] = \sum_{\ell=0}^{m} c^\ell_{jk}(\Lambda) F^{\delta_\ell}_{\ell,\Lambda} \qquad [27]$$

with

$$c^\ell_{jk}(\Lambda) = \frac{c^\ell_{jk}}{|\Lambda|^{1/2+\delta_j+\delta_k-\delta_\ell}}, \quad \ell = 1, \ldots, m$$

$$c^0_{jk}(\Lambda) = |\Lambda|^{-\delta_j-\delta_k} \sum_{\ell=0}^{m} c^\ell_{jk} \omega_\Lambda (F^{\delta_\Lambda}_{\ell,\Lambda})$$

It is an easy exercise to check that the $\{c^\ell_{jk}(\Lambda)\}$ are the structure coefficients of a Lie algebra $\mathcal{G}(\Lambda)$. Hence, by considering local fluctuations, one constructs a map from the Lie algebra $\mathcal{G}$ onto the Lie algebra $\mathcal{G}(\Lambda)$ by a nontrivial change of the structure constants. When the transformed structure constants approach a well-defined limit, a new nonisomorphic Lie algebra might appear. The limit algebra $\mathcal{G}(\mathbb{Z}^\nu)$, called the contracted one of the original one $\mathcal{G}$ is always nonsemisimple. This contraction is a typical Inönü–Wigner contraction (Inönü and Wigner 1953). About the limit algebra $\mathcal{G}(\mathbb{Z}^\nu)$, the following results are obtained (see Momont *et al.* (1997)):

$$\lim_{\Lambda} c^\ell_{jk}(\Lambda) = \begin{cases} 0 & \text{if } \frac{1}{2} + \delta_j + \delta_k - \delta_\ell > 0 \\ c^\ell_{jk} & \text{if } \ldots\ldots\ldots\ldots\ldots = 0 \\ 0 & \text{if } \ldots\ldots\ldots\ldots\ldots < 0 \end{cases} \qquad [28]$$

It is interesting to distinguish a number of special cases:

1. If all fluctuations are normal, one recovers the Heisenberg algebra of the canonical commutation relations with the right symplectic form $\sigma_\omega$.
2. If $1/2 + \delta_j + \delta_k - \delta_\ell > 0$ for all $j, k, \ell$ one obtains an abelian Lie algebra of fluctuations.
3. One gets the richest structure if $1/2 + \delta_j + \delta_k - \delta_\ell = 0$ for all $j, k, \ell$ or for some of them. One notes a phenomenon of scale invariance, the $c^\ell_{jk}(\Lambda)$ are $\Lambda$-independent. Algebras different from the CCR algebra are observed. A particularly interesting case turns up if $\delta_j = -\delta_k \neq 0$, that is, one of the indices is negative, for example, $\delta_j < 0$, the corresponding fluctuation $F^{\delta_j}_j$ shows a property of space squeezing, and then $\delta_k > 0$, the fluctuation $F^{\delta_k}_k$ expresses the property of space dilation. These phenomena are observed and computed in several models (see, e.g., Verbeure and Zagrebnov (1992)). This yields in particular a microscopic explanation of the phenomenon of squeezing (squeezed states and all that) in quantum optics. We refer also to the section "Spontaneous symmetry breaking" for this phenomenon as being the basis of the construction of the Goldstone normal modes of the Goldstone particle appearing in systems showing spontaneous symmetry breakdown.

## Some Applications

The notion of fluctuation operator as presented above, and the mathematical structure of the algebra of fluctuations have been tested in several soluble models. Many applications of this theory of quantum fluctuations can be found in the list of references. Here we are not entering into the details

of any model, but we limit ourselves to mention three applications which are of a general nature and totally model independent.

### Conservation of the KMS Property under the Transition from Micro to Macro

Suppose that we start with a micro-dynamical system $(\mathcal{B}, \omega, \alpha_t)$ with normal fluctuations, that is, we are in the situation as treated in the section "Normal fluctuations." Hence, we know that the quantum central-limit theorem maps the system $(\mathcal{B}, \omega, \alpha_t)$ onto the macrodynamical system $(C^*(\mathcal{A}_{\mathrm{L,sa}}, \sigma_\omega), \tilde{\omega}, \tilde{\alpha}_t)$ of quantum fluctuations.

If the microstate $\omega$ is $\alpha_t$-time invariant ($\omega \cdot \alpha_t = \omega$ for all $t \in \mathbb{R}$), then it also follows readily that the macrostate $\tilde{\omega}$ is $\tilde{\alpha}_t$-time invariant (see Theorem 4, i.e., $\tilde{\omega} \cdot \tilde{\alpha}_t = \tilde{\omega}$ for all $t \in \mathbb{R}$).

A less trivial question to pose is: suppose that the microstate $\omega$ is an equilibrium state for the micro-dynamics $\alpha_t$, is then the macrostate $\tilde{\omega}$ also an equilibrium state for the macrodynamics $\tilde{\alpha}_t$ of the fluctuations? In Goderis *et al.* (1990) this question is answered positively in the following more technical sense: if $\omega$ is an $\alpha_t$-KMS state of $\mathcal{B}$ at inverse temperature $\beta$, then $\tilde{\omega}$ is an $\tilde{\alpha}_t$-KMS state at the same temperature.

This property proves that the notion of equilibrium is preserved under the operation of coarse graining induced by the central-limit theorem. This statement constitutes a proof of one of the basic assumptions of the phenomenological theory of Onsager about small oscillations around equilibrium.

This result also yields a contribution to the discussion whether or not quantum systems should be described at a macroscopic level by classical observables. The result above states that the macroscopic fluctuation observables behave classically if and only if they are time invariant. In other words, it can only be expected *a priori* that conserved quantities behave classically. In principle, other observables follow a quantum dynamics.

### Linear Response Theory

In particular, in the study of equilibrium states (KMS states) a standard procedure is to perturb the system and to study the response of the system as a function of the perturbation. The response elucidates many, if not all, of the properties of the equilibrium state.

Technically, one considers a perturbation of the dynamics by adding a term to the Hamiltonian. One expands the perturbed dynamics in terms of the perturbation and the unperturbed dynamics. It is often argued that when the perturbation is small, one can limit the study of the response to the first-order term in the perturbation in the corresponding Dyson expansion. This is the basis of what is called the "linear response theory of Kubo."

A long-term debate is going on about the validity of the linear response theory. The question is how to understand from a microscopic point of view the validity of the response theory being linear or not. One must realize that the linear response theory actually observed in macroscopic systems seems to have a significant range of validity beyond the criticism being expressed about it.

Here we discuss the main result of the paper (Goderis *et al.* 1991) in which contours are sketched for the exactness of the response being linear.

We assume:

1. that the microdynamics $\alpha_t$ is the norm-limit of the local dynamics $\alpha_t^\Lambda = \mathrm{e}^{\mathrm{i}tH_\Lambda} \cdot \mathrm{e}^{-\mathrm{i}tH_\Lambda}$, where $H_\Lambda$ contains only standard finite-range interactions (as in the section "Normal fluctuations");
2. that the $\omega_\Lambda$ are states such that $\omega = \lim_\Lambda \omega_\Lambda$ is a state which is time and space translation invariant; and
3. that $\omega$ satisfies the cluster condition [15] or [16].

From the time invariance of the state, one has a Hamiltonian GNS representation of the dynamics: $\alpha_t = \mathrm{e}^{\mathrm{i}tH} \cdot \mathrm{e}^{-\mathrm{i}tH}$. On the basis of Theorem 4, one has the dynamics $\tilde{\alpha}_t$ of the fluctuation algebra $C^*(\mathcal{A}_{\mathrm{L,sa}}, \sigma_\omega)$ in the state $\tilde{\omega}$. This GNS representation yields a Hamiltonian representation for $\tilde{\alpha}_t$:

$$\tilde{\alpha}_t = \mathrm{e}^{\mathrm{i}t\tilde{H}} \cdot \mathrm{e}^{-\mathrm{i}t\tilde{H}}$$

Now take any local perturbation $P \in \mathcal{A}_{\mathrm{L,sa}}$ of $\alpha_t$, namely

$$\alpha_{t,\Lambda}^P = \mathrm{e}^{\mathrm{i}t(H + F_\Lambda(P))} \cdot \mathrm{e}^{-\mathrm{i}t(H + F_\Lambda(P))}$$

where $F_\Lambda(P)$ is the local fluctuation of $P$ in $\omega$. Then one proves the following central-limit theorem (Goderis *et al.* 1991): for all $A$ and $B$ in $\mathcal{A}_{\mathrm{L,sa}}$, one has the perturbed dynamics

$$\tilde{\alpha}_t^P = \mathrm{e}^{\mathrm{i}t(\tilde{H} + F(P))} \cdot \mathrm{e}^{-\mathrm{i}t(\tilde{H} + F(P))}$$

of the fluctuation algebra in the sense of [18]:

$$\tilde{\alpha}_t^P F(A) = \lim_\Lambda F(\alpha_{t,\Lambda}^P(A))$$

This proves the existence and the explicit form of the perturbed dynamics lifted to the level of the fluctuations. In particular, one has

$$\lim_\Lambda \omega_\Lambda \left( \alpha_{t,\Lambda}^P (F_\Lambda(A)) \right) = \tilde{\omega}(\tilde{\alpha}_t^P F(A))$$

This is nothing but the existence of the relaxation function of Kubo but lifted to the level of the fluctuations and instead of dealing with strictly local observables here one considers fluctuations.

Assume, furthermore, that the state $\omega$ is an $(\alpha_t, \beta)$-KMS state; then one derives readily Kubo's famous formula of his linear response theory:

$$\frac{\mathrm{d}}{\mathrm{d}t}\tilde{\omega}(\tilde{\alpha}_t^P F(A)) = \mathrm{i}\tilde{\omega}([F(P), \tilde{\alpha}_t F(A)])$$

which shows full linearity in the perturbation observable $P$. Kubo's formula arises as the central limit of the microscopic response to the dynamics perturbed by a fluctuation observable. We remark that if $\omega$ is an equilibrium state, then the right-hand side of the formula above can be expressed in terms of the Duhamel two-point function, which is the common way of doing in linear response theory.

### Spontaneous Symmetry Breaking

SSB is one of the basic phenomena accompanying collective phenomena, such as phase transitions in statistical mechanics, or specific ground states in field theory. SSB goes back to the Goldstone theorem. There are many different situations to consider, for example, in the case of short-range interactions, it is typical that SSB yields a dynamics which remains symmetric, whereas for long-range interactions SSB also breaks the symmetry of the dynamics. However, in all cases the physics literature predicts the appearance of a particular particle, namely the Goldstone boson, to appear as a result of SSB. The theory of fluctuation operators allows the construction of the canonical coordinates of this particle. The most general result can be found in Michoel and Verbeure (2001). We sketch the essentials in two cases, namely for systems of long-range interactions (mean fields) and for systems with short-range interactions.

**Long-range (mean-field) interactions** Here we give explicitly the example of the strong-coupling BCS model in one dimension ($\nu = 1$). The microscopic algebra of observables is $\mathcal{B} = \otimes_i (M_2)_i$, where $M_2$ is the algebra of $2 \times 2$ complex matrices. The local Hamiltonian of the models is given by

$$H_N = \epsilon \sum_{i=-N}^{N} \sigma_i^z - \frac{1}{2N+1} \sum_{i,j=-N}^{N} \sigma_i^+ \sigma_j^-$$
$$0 < \epsilon < \tfrac{1}{2}$$

where $\sigma^z, \sigma^\pm$ are the usual $2 \times 2$ Pauli matrices. In the thermodynamic limit, the KMS equation has the following product state solutions: $\omega_\lambda = \otimes_i \operatorname{tr}\rho_\lambda$, where

$$\rho_\lambda = \frac{\mathrm{e}^{-\beta h_\lambda}}{\operatorname{tr} \mathrm{e}^{-\beta h_\lambda}}, \quad \lambda = \operatorname{tr} \rho_\lambda \sigma^- = \omega_\lambda(\sigma^-)$$
$$h_\lambda = \epsilon\sigma^z - \lambda\sigma^+ - \lambda\sigma^-$$

Note that $\lambda = \operatorname{tr}\rho_\lambda\sigma^-$ is a nonlinear equation for $\lambda$ whose solutions determine the density matrix $\rho_\lambda$. This equation always has the solution $\lambda = 0$, describing the so-called normal phase. For $\beta > \beta_c$, with $th\beta_c\epsilon = 2\epsilon$, one has a solution $\lambda \neq 0$, describing the superconducting phase. Remark that if $\lambda$ is a solution, then also $\lambda e^{i\phi}$ for all $\phi$ is a solution as well. It is clear that $H_N$ is invariant under the continuous gauge transformation automorphism group $\mathcal{G} = \{\gamma_\varphi \mid \varphi \in [0, 2\pi]\}$ of $\mathcal{B}$:

$$\gamma_\varphi(\sigma_i^+) = e^{-i\varphi}\sigma_i^+$$

Hence $\mathcal{G}$ is a symmetry group. On the other hand: $\omega_\lambda(\gamma_\varphi(\sigma_i^+)) = e^{-i\varphi}\omega_\lambda(\sigma_i^+) \neq \omega_\lambda(\sigma_i^+)$. The gauge group $\mathcal{G}$ is spontaneously broken. Remark also that the gauge transformations are implemented locally by the charges

$$Q_N = \sum_{j=-N}^{N} \sigma_i^z, \quad \text{i.e.,} \ \gamma_\varphi(\sigma_i^+) = \mathrm{e}^{-\mathrm{i}\varphi Q_N}\sigma_i^+\mathrm{e}^{\mathrm{i}\varphi Q_N}$$

and $\sigma^z$ is the symmetry generator density. As the states $\omega_\lambda$ are product states, all fluctuations are normal (see the section "Normal fluctuations"). One considers the local operators

$$Q = \frac{|\lambda|^2}{\mu^2}\sigma^z + \frac{\epsilon}{\mu^2}(\lambda\sigma^+ + \bar{\lambda}\sigma^-)$$
$$P = \frac{\mathrm{i}}{\mu}(\lambda\sigma^+ - \bar{\lambda}\sigma^-)$$

where $\mu = (\epsilon^2 + |\lambda|^2)^{1/2}$. Note that $P$ is essentially the order parameter operator, that is, the operator $P$ is breaking the symmetry:

$$\frac{\mathrm{d}}{\mathrm{d}\varphi}\omega_\lambda(\gamma_\varphi(A)) \neq 0, \quad \omega_\lambda(A) = 0$$

On the other hand, $Q$ is essentially the generator of the symmetry $\sigma^z$ normalized to zero, that is, $\omega_\lambda(Q) = 0$.

Michoel and Verbeure (2001) proved in detail that the fluctuations $F(Q)$ and $F(P)$ form a canonical pair

$$[F(Q), F(P)] = \mathrm{i}\frac{4|\lambda|^2}{\mu}$$

and that they behave, under the time evolution, as harmonic oscillator coordinates oscillating with a

frequency equal to $2\mu$. This frequency is called a plasmon frequency. Moreover, the variances are

$$\tilde{\omega}_\lambda(F(Q)^2) = \frac{|\lambda|^2}{\mu^2} = \tilde{\omega}_\lambda(F(P)^2)$$

This means that these coordinates vanish or disappear if $\lambda = 0$. The coordinates $F(Q)$ and $F(P)$ are the canonical coordinates of a particle appearing only if there is spontaneous symmetry breakdown. They are the canonical coordinates of the Goldstone boson, which arise if SSB occurs.

**Short-range interactions** An analogous result, as for long-range interactions, can be derived for systems with short-range interactions. However, in this case we have equilibrium states with poor cluster properties. We are now in the situation as described in the "Abnormal Fluctuations" section. Also in this case we have the phenomenon of SSB, which shows the appearance of a Goldstone particle. Also in this case one is able to construct its canonical coordinates. The details of this construction can be found in Michoel and Verbeure (2001). Here we give a heuristic picture of this construction.

Consider again a microsystem $(\mathcal{B}, \omega, \alpha_t)$ and let $\gamma_s$ be a strongly continuous one-parameter symmetry group of $\alpha_t$ which is locally generated by $Q_\Lambda = \sum_{x \in \Lambda} q_x$. SSB amounts to find an equilibrium (KMS) or ground state $\omega$ which breaks the symmetry, that is, there exists a local observable $A \in \mathcal{A}_{\mathrm{L,sa}}$ such that for $s \neq 0$ holds: $\omega(\gamma_s(A)) \neq \omega(A)$ and $\alpha_t \gamma_s = \gamma_s \alpha_t$. This is equivalent to

$$\left.\frac{\mathrm{d}}{\mathrm{d}s}\omega(\gamma_s(A))\right|_{s=0} = \lim_\Lambda \omega([Q_\Lambda, A]) = c \neq 0$$

with $c$ a constant.

Now we turn this equation into a relation for fluctuations. Using space translation invariance of the state, one gets

$$\lim_\Lambda \frac{1}{|\Lambda|}\omega\left(\left[\sum_{x\in\Lambda}(q_x - \omega(q))\sum_{y\in\Lambda}(\tau_x A - \omega(A))\right]\right) = c$$

We now use another consequence of the Goldstone theorem, namely that SSB implies poor clustering properties for the order parameter $A$, that is, in the line of what is done in the last section, we assume that the lack of clustering is expressed by the existence of a positive index $\delta$ such that

$$\lim_\Lambda \omega\left(\frac{1}{|\Lambda|^{1+2\delta}}\left(\sum_{x\in\Lambda}(\tau_x A - \omega(A))\right)^2\right)$$

is nontrivial and finite. This means that the fluctuation $F^\delta(A)$ exists. Then we get

$$\lim_\Lambda \omega\left(\left[\frac{1}{|\Lambda|^{1/2-\delta}}\sum_{x\in\Lambda}(q_x - \omega(q)), \frac{1}{|\Lambda|^{1/2+\delta}}\sum_{y\in\Lambda}(\tau_x A - \omega(A))\right]\right) = c$$

Hence

$$\tilde{\omega}\big(\big[F^{-\delta}(q), F^\delta(A)\big]\big) = c$$

which for equilibrium states $\omega$, turns into the operator equation for fluctuations

$$[F^{-\delta}(q), F^\delta(A)] = c\mathbb{1}$$

In other words, one obtains a canonical pair $(F^{-\delta}(q), F^\delta(A))$ of normal coordinates of the collective Goldstone mode.

Note that the long-range correlation of the order-parameter operator (positive $\delta$) is exactly compensated by a squeezing, described by the negative index $-\delta$, for the fluctuation operator of the local generator of the broken symmetry. This result can also be expressed as typical for SSB, namely that the symmetry is not completely broken, but only partially. More detailed information about all this is found in Michoel and Verbeure (2001).

# Quantum Channels: Classical Capacity

**A S Holevo**, Steklov Mathematical Institute, Moscow, Russia

## The Definition

A numerical measure of the ability of a classical or quantum information processing system (for definiteness, one speaks of a *communication channel*) to transmit information expressible as a text message (called "classical information" as distinct from quantum information). It is equal to the least upper bound for rates of the asymptotically perfect transmission of classical information through the system, when the transmission time tends to infinity, and arbitrary pre- and post-processing (encoding and decoding) are allowed at the input and the output of the system. Typically, for rates exceeding the capacity, not only the asymptotically perfect transmission is impossible, but the error probability with arbitrary encoding–decoding scheme tends to 1, so that the capacity has a nature of a threshold parameter.

## From Classical to Quantum Information Theory

A central result of the classical information theory is the *Shannon coding theorem*, giving an explicit expression to the capacity in terms of the maximal mutual information between the input and the output of the channel. The issue of the information capacity of quantum communication channels arose soon after the publication of the pioneering papers by Shannon and goes back to the classical works of Gabor, Brillouin, and Gordon, asking for fundamental physical limits on the rate and quality of information transmission. This work laid a physical foundation and raised the question of consistent quantum treatment of the problem. Important steps in this direction were made in the early 1970s when a quantum probabilistic framework for this type of problem was created and the conjectured upper bound for the classical capacity of quantum channel was proved. A long journey to the quantum coding theorem culminated in 1996 with the proof of achievability of the upper bound (the Holevo–Schumacher–Westmoreland theorem; see Holevo (1998) for a detailed historical survey). Moreover, it was realized that quantum channel is characterized by the whole spectrum of capacities depending on the nature of the information resources and the specific protocols used for the transmission. To a great extent, this progress was stimulated by an interplay between the quantum communication theory and quantum information ideas related to more recent development in quantum computing. This new age of quantum information science is characterized by emphasis on the new possibilities (rather than restrictions) opened by the quantum nature of the information processing agent. On the other hand, the question of information capacity is important for the theory of quantum computer, particularly in connection with quantum error-correcting codes, communication and algorithmic complexity, and a number of other important issues.

## The Quantum Coding Theorem

In the simplest and most basic memoryless case, the information processing system is described by the sequence of block channels,

$$\Phi^{\otimes n} = \underbrace{\Phi \otimes \cdots \otimes \Phi}_{n}, \quad n = 1, \ldots$$

of $n$ parallel and independent uses of a channel $\Phi$, $n$ playing the role of transmission time (Holevo 1998). More generally, one can consider memory channels given by open dynamical systems with a kind of ergodic behavior and the limit where the transmission time goes to infinity (Kretschmann and Werner 2005).

Restricting to the memoryless case, encoding is given by a mapping of classical messages $x$ from a given codebook of size $N$ into states (density operators) $\rho_x^{(n)}$ in the input space $\mathcal{H}_1^{\otimes n}$ of the block channel $\Phi^{\otimes n}$, and decoding – by an observable $M^{(n)}$ in the output space $\mathcal{H}_2^{\otimes n}$, that is, a family $\{M_y^{(n)}\}$ of operators constituting a resolution of the identity in $\mathcal{H}_2^{\otimes n}$:

$$M_y^{(n)} \geq 0, \qquad \sum_y M_y^{(n)} = I$$

Here $y$ plays the role of outcomes of the whole decoding procedure involving both the quantum measurement at the output and the possible classical information post-processing. Then the diagram for the classical information transmission is

$$x \to \underbrace{\rho_i^{(n)}}_{\substack{\text{input}\\ \text{state}}} \to \underbrace{\Phi^{\otimes n}[\rho_x^{(n)}]}_{\substack{\text{output}\\ \text{state}}} \stackrel{M^{(n)}}{\to} y$$

The such-described encoding and decoding constitute a quantum block code of length $n$ and size $N$ for the memoryless channel. The conditional probability of obtaining an outcome $y$ provided the message $x$ was sent for a chosen block code is given by the statistical formula

$$p^{(n)}(y|x) = \mathrm{tr}\, \Phi^{\otimes n}[\rho_x^{(n)}] M_y^{(n)}$$

and the error probability for the code is just $\max_x (1 - p^{(n)}(x \mid x))$.

Denoting by $p_e(n, N)$ the infimum of the error probability over all codes of length $n$ and size $N$, the classical capacity $C(\Phi)$ of the memoryless channel is defined as the least upper bound of the rates $R$ for which $\lim_{n\to\infty} p_e(n, 2^{nR}) = 0$.

Let $\Phi$ be a quantum channel from the input to the output quantum systems, assumed to be finite dimensional. The *coding theorem* for the classical capacity says that

$$C(\Phi) = \lim_{n\to\infty} \frac{1}{n} C_\chi(\Phi^{\otimes n}) \qquad [1]$$

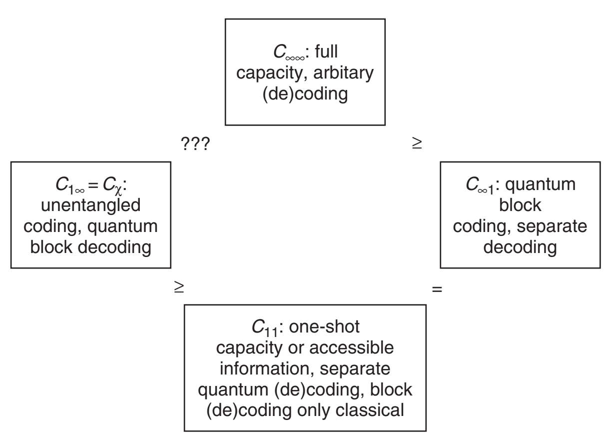
where

$$C_\chi(\Phi) = \max\left\{ H\left(\sum_x p_x \Phi[\rho_x]\right) - \sum_x p_x H(\Phi[\rho_x]) \right\} \qquad [2]$$

$H(\rho) = -\mathrm{tr}\, \rho \log_2 \rho$ is the binary von Neumann entropy, and the maximum is taken over all probability distributions $\{p_x\}$ and collections of density operators $\{\rho_x\}$ in $\mathcal{H}_1$.

## The Variety of Capacities

This basic definition and the formulas [1], [2] generalize the definition of the Shannon capacity and the coding theorem for classical memoryless channels. For quantum channel, there are several different capacities because one may consider sending different kinds (classical or quantum) of information, restrict the admissible coding and decoding operations, and/or allow the use of additional resources, such as shared entanglement, forward or backward communication, leading to really different quantities (Bennett *et al.* 2004). Few of these resources (such as feedback) also exist for classical channels but usually influence the capacity less dramatically (at least for memoryless channels). Restricting to the transmission of classical information with no additional resources, one can distinguish at least four capacities (Bennett and Shor 1998), according to whether, for each block length $n$, one is allowed to use arbitrary entangled quantum operations on the full block of input (resp. output) systems, or if, for each of the parallel channels, one has to use a separate quantum encoding (resp. decoding), and combine these only by classical pre- (resp. post-) processing:



The full capacity $C_{\infty\infty}$ is just the classical capacity $C(\Phi)$ given by [1]. That $C_{1\infty}$ coincides with the

quantity $C_\chi(\Phi)$ given by [2] is the essential content of the HSW theorem, from which [1] is obtained by additional blocking. Since $C_\chi$ is apparently superadditive, $C_\chi(\Phi_1 \otimes \Phi_2) \geq C_\chi(\Phi_1) + C_\chi(\Phi_2)$, one has $C_{\infty\infty} \geq C_\chi$. It is still not known whether the quantity $C_\chi(\Phi)$ is in fact additive for all channels, which would imply the equalities here. Additivity of $C_\chi(\Phi)$ would have the important physical consequence – it would mean that using entangled input states does not increase the classical capacity of quantum channel. While such a result would be very much welcome, giving a single-letter expression for the classical capacity, it would call for a physical explanation of asymmetry between the effects of entanglement in encoding and decoding procedures. Indeed, the inequality in the lower left is known to be strict sometimes (Holevo 1998), which means that entangled decodings *can* increase the classical capacity. There is even an intermediate capacity between $C_{11}$ and $C_{1\infty}$ obtained by restricting the quantum block decodings to adaptive ones (Shor 2002). The additivity of the quantity $C_\chi$ for *all* channels is one of the central open problems in quantum information theory; it was shown to be equivalent to several other important open problems, notably (super)additivity of the entanglement of formation and additivity of the minimal output entropy (Shor 2004).

For infinite-dimensional quantum processing systems, one needs to consider the input constraints such as the power constraint for bosonic Gaussian channels. The definition of the classical capacity and the capacity formula are then modified by introducing the constraint in a way similar to the classical theory (Holevo 1998, Holevo and Werner 2001). Another important extension concerns multiuser quantum information processing systems and their capacity regions (Devetak and Shor 2003).

# Quantum Chromodynamics

**G Sterman**, Stony Brook University, Stony Brook, NY, USA

## Introduction

Quantum chromodynamics, or QCD, as it is normally called in high-energy physics, is the quantum field theory that describes the strong interactions. It is the SU(3) gauge theory of the current standard model for elementary particles and forces, $SU(3) \times SU(2)_L \times U(1)$, which encompasses the strong, electromagnetic, and weak interactions. The symmetry group of QCD, with its eight conserved charges, is referred to as color SU(3). As is characteristic of quantum field theories, each field may be described in terms of quantum waves or particles.

Because it is a gauge field theory, the fields that carry the forces of QCD transform as vectors under the Lorentz group. Corresponding to these vector fields are the particles called "gluons," which carry an intrinsic angular momentum, or spin, of 1 in units of $\hbar$. The strong interactions are understood as the cumulative effects of gluons, interacting among themselves and with the quarks, the spin-1/2 particles of the Dirac quark fields.

There are six quark fields of varying masses in QCD. Of these, three are called "light" quarks, in a sense to be defined below, and three "heavy." The light quarks are the up ($u$), down ($d$), and strange ($s$), while the heavy quarks are the charm ($c$), bottom ($b$),

and top ($t$). Their well-known electric charges are $e_f = 2e/3(u, c, t)$ and $e_f = -e/3(d, s, b)$, with $e$ the positron charge. The gluons interact with each quark field in an identical fashion, and the relatively light masses of three of the quarks provide the theory with a number of approximate global symmetries that profoundly influence the manner in which QCD manifests itself in the standard model.

These quark and gluon fields and their corresponding particles are enumerated with complete confidence by the community of high-energy physicists. Yet, none of these particles has ever been observed in isolation, as one might observe a photon or an electron. Rather, all known strongly interacting particles are colorless; most are "mesons," combinations with the quantum numbers of a quark $q$ and a antiquark $\bar{q}'$, or "baryons" with the quantum numbers of (possibly distinct) combinations of three quarks $qq'q''$. This feature of QCD, that its underlying fields never appear as asymptotic states, is called "confinement." The very existence of confinement required new ways of thinking about field theory, and only with these was the discovery and development of QCD possible.

## The Background of QCD

The strong interactions have been recognized as a separate force of nature since the discovery of the neutron as a constituent of atomic nuclei, along with the proton. Neutrons and protons (collectively, nucleons) possess a force, attractive at intermediate distances and so strong that it overcomes the electric repulsion of the protons, each with charge $e$. A sense of the relative strengths of the electromagnetic and strong interactions may be inferred from the typical distance between mutually repulsive electrons in an atom, $\sim 10^{-8}$ cm, and the typical distance between protons in a nucleus, of order $10^{-13}$ cm.

The history that led up to the discovery of QCD is a fascinating one, beginning with Yukawa's 1935 theory of pion exchange as the source of the forces that bind nuclei, still a useful tool for low-energy scattering. Other turning points include the creation of nonabelian gauge theories by Yang and Mills in 1954, the discovery of the quantum number known as strangeness, the consequent development of the quark model, and then the proposal of color as a global symmetry. The role of pointlike constituents in hadrons was foreshadowed by the identification of electromagnetic and weak currents and the analysis of their quantum-mechanical algebras. Finally, the observation of "scaling" in deep-inelastic scattering, which we will describe below, made QCD, with color as a local symmetry, the unique explanation of the strong interactions, through its property of asymptotic freedom.

## The Lagrangian and Its Symmetries

The QCD Lagrangian may be written as

$$\mathcal{L} = \sum_{f=1}^{n_f} \bar{q}_f \left( \mathrm{i}\, \not{D}[A] - m_f \right) q_f - \frac{1}{2} \operatorname{tr}\left[ F_{\mu\nu}^2(A) \right] - \frac{\lambda}{2} (B_a(A))^2 + \bar{c}_b \left[ \frac{\delta B_b(A)}{\delta \alpha_a} \right] c_a \qquad [1]$$

with $\not{D}[A] = \gamma \cdot \partial + \mathrm{i} g_s \gamma \cdot A$ the covariant derivative in QCD. The $\gamma^\mu$ are the Dirac matrices, satisfying the anticommutation relations, $[\gamma^\mu, \gamma^\nu]_+ = 2g^{\mu\nu}$. The SU(3) gluon fields are $A^\mu = \sum_{a=1}^{8} A_a^\mu T_a$, where $T_a$ are the generators of SU(3) in the fundamental representation. The field strengths $F_{\mu\nu}[A] = \partial_\mu A_\nu - \partial_\nu A_\mu + \mathrm{i} g_s [A_\mu, A_\nu]$ specify the three- and four-point gluon couplings of nonabelian gauge theory. In QCD, there are $n_f = 6$ flavors of quark fields, $q_f$, with conjugate $\bar{q}_f = q_f^\dagger \gamma^0$.

The first two terms in the expression [1] make up the classical Lagrangian, followed by the gauge-fixing term, specified by a (usually, but not necessarily linear) function $B_a(A)$, and the ghost Lagrangian. The ghost (anti-ghost) fields $c_a(\bar{c}_a)$ carry the same adjoint index as the gauge fields.

The classical QCD Lagrangian before gauge fixing is invariant under the local gauge transformations

$$\begin{aligned} A'_\mu(x) &= \frac{\mathrm{i}}{g_s} \partial_\mu \Omega(x) \Omega^{-1}(x) + \Omega(x) A'_\mu(x) \Omega^{-1}(x) \\ &= A_\mu(x) - \partial_\mu \delta\alpha(x) \\ &\quad + \mathrm{i} g_s \left[ \delta\alpha(x), A_\mu(x) \right] + \cdots \\ \psi'_i(x) &= \Omega(x)_{ij} \psi_j(x) = \psi_i(x) \\ &\quad + \mathrm{i} g_s \delta\alpha(x)_{ij} \psi_j(x) + \cdots \\ \delta\alpha(x) &= \sum_{a=1}^{8} \delta\alpha_a(x) T_a \end{aligned} \qquad [2]$$

The full QCD action including gauge-fixing and ghost terms is also invariant under the Bechi, Rouet, Stora, Tyutin (BRST) transformations with $\delta\xi$ an anticommuting variable.

$$\begin{aligned} \delta A_{\mu,a} &= \left( \delta_{ab} \partial_\mu + g A_{\mu c} f_{abc} \right) c_b \delta\xi \\ \delta c_a &= -\tfrac{1}{2} g C_{abc}\, c_b\, c_c \delta\xi, \quad \delta\bar{c} = \lambda B_a \delta\xi \\ \delta\psi_i &= \mathrm{i} g [T_b]_{ij}\, c_b \psi_j \end{aligned} \qquad [3]$$

with $f_{abc}$ the SU(3) structure constants. The Jacobian of these transformations is unity.

In addition, neglecting masses of the light quarks, $u$, $d$, and $s$, the QCD Lagranian has a class of global flavor and chiral symmetries, the latter connecting left- and right-handed components of the quark fields, $\psi_{\mathrm{L,R}} \equiv (1/2)(1 \mp \gamma_5)\psi$,

$$\psi'(x) = \mathrm{e}^{\mathrm{i}\alpha\gamma_5^P}\, \psi(x), \quad P = 0, 1 \qquad [4]$$

Here, power $P = 0$ describes phase, and $P = 1$ chiral, transformations. Both transformations can be extended to transformations among the light flavors, by letting $\psi$ become a vector, and $\alpha$ an element in the Lie algebra of SU($M$), with $M = 2$ if we take only the $u$ and $d$ quarks, and $M = 3$ if we include the somewhat heavier strange quark. These symmetries, not to be confused with the local symmetries of the standard model, are strong isospin and its extension to the "eightfold way," which evolved into the (3-)quark model of Gell–Mann and Zweig. The many successes of these formalisms are automatically incorporated into QCD.

## Green Functions, Phases, and Gauge Invariance

In large part, the business of quantum field theory is to calculate Green functions,

$$G_n(x_1 \dots x_n) = \langle 0|T(\Phi_1(x_1) \dots \Phi_i(x_i) \dots \Phi_n(x_n))|0\rangle \qquad [5]$$

where $T$ denotes time ordering. The $\Phi_i(x)$ are elementary fields, such as $A$ or $q_f$, or composite fields, such as currents like $J^\mu = \bar{q}_f \gamma^\mu q_f$. Such a Green function generates amplitudes for the scattering of particles of definite momenta and spin, when in the limit of large times the $x_i$-dependence of the Green function is that of a plane wave. For example, we may have in the limit $x_i^0 \rightarrow \infty$,

$$G_n(x_1 \dots x_n) \rightarrow \phi_i(p, \lambda)\, \mathrm{e}^{\mathrm{i}p \cdot x_i} \langle (p, \lambda)|T(\Phi_1(x_1) \dots \Phi_{i-1}(x_{i-1})\Phi_{i+1}(x_{i+1}) \dots \Phi_n(x_n))|0\rangle \qquad [6]$$

where $\phi_i(p, \lambda)$ is a solution to the free-field equation for field $\Phi_i$, characterized by momentum $p$ and spin $\lambda$. (An inegral over possible momenta $p$ is understood.) When this happens for field $i$, the vacuum state is replaced by $|(p, \lambda)\rangle$, a particle state with precisely this momentum and spin; when it occurs for all fields, we derive a scattering ($S$)-matrix amplitude. In essence, the statement of confinement is that Green functions with fields $q_f(x)$ never behave as plane waves at large times in the past or future. Only Green functions of color singlet composite fields, invariant under gauge transformations, are associated with plane wave behavior at large times.

Green functions remain invariant under the BRST transformations [3], and this invariance implies a set of Ward identities

$$\frac{\delta}{\delta\xi(z)} \sum_{i=1}^{n} \langle 0|T(\Phi_1(x_1) \dots \delta_{\mathrm{BRS}}\Phi_i(x_i) \dots \Phi_n(x_n))|0\rangle = 0 \qquad [7]$$

The variation of the anti-ghost as in [3] is equivalent to an infinitesimal change in the gauge-fixing term; variations in the remaining fields all cancel single-particle plane wave behavior in the corresponding Green functions. These identities then ensure the gauge invariance of the perturbative $S$-matrix, a result that turns out to be useful despite confinement.

To go beyond a purely perturbative description of QCD, it is useful to introduce a set of nonlocal operators that are variously called nonabelian phases, ordered exponentials, and Wilson lines,

$$U_C(z, y) = P \exp\left[-\mathrm{i}g_\mathrm{s} \int_y^z \mathrm{d}x^\mu A_\mu(x)\right] \qquad [8]$$

where $C$ is some self-avoiding curve between $y$ and $z$. The $U$'s transform at each end linearly in nonabelian gauge transformations $\Omega(x)$ at that point,

$$U'_C(z, y) = \Omega(z) U_C(z, y) \Omega^{-1}(y) \qquad [9]$$

Especially interesting are closed curves $C$, for which $z = y$. The phases about such closed loops are, like their abelian counterparts, sensitive to the magnetic flux that they enclose, even when the field strengths vanish on the curve.

## QCD at the Shortest and Longest Distances

Much of the fascination of QCD is its extraordinary variation of behavior at differing distance scales. Its discovery is linked to asymptotic freedom, which characterizes the theory at the shortest scales. Asymptotic freedom also suggests (and in part provides) a bridge to longer distances.

Most analyses in QCD begin with a path-integral formulation in terms of the elementary fields $\Phi_a = q_f \dots$,

$$G_n(x_i, (z_j, y_j)) = \int \left[\prod_{a=q,\bar{q},G,c,\bar{c}} \mathcal{D}\Phi_a\right] \prod_i \Phi_i(x_i) \times \prod_j U_{C_j}(z_j, y_j)\, \mathrm{e}^{\mathrm{i}S_{\mathrm{QCD}}} \qquad [10]$$

with $S_{\mathrm{QCD}}$ the action. Perturbation theory keeps only the kinetic Lagrangian, quadratic in fields, in the exponent, and expands the potential terms in the coupling. This procedure produces Feynman diagrams, with vertices corresponding to the cubic and quartic terms in the QCD Lagrangian [1].

Most nonperturbative analyses of QCD require studying the theory on a Euclean, rather than Minkowski space, related by an analytic continuation in the times $x^0, y^0, z^0$ in $G_n$ from real to imaginary values. In Euclidean space, we find, for example,

classical solutions to the equations of motion, known as instantons, that provide nonperturbative contributions to the path integral. Perhaps the most flexible nonperturbative approach approximates the action and the measure at a lattice of points in four-dimensional space. For this purpose, integrals over the gauge fields are replaced by averages over "gauge links," of the form of eqn [8] between neighboring points.

Perturbation theory is most useful for processes that occur over short timescales and at high relative energies. Lattice QCD, on the other hand, can simulate processes that take much longer times, but is less useful when large momentum transfers are involved. The gap between the two methods remains quite wide, but between the two they have covered enormous ground, enough to more than confirm QCD as the theory of strong interactions.

### Asymptotic Freedom

QCD is a renormalizable field theory, which implies that the coupling constant $g$ must be defined by its value at a "renormalization scale," and is denoted $g(\mu)$. Usually, the magnitude of $\alpha_s(\mu) \equiv g^2/4\pi$, is quoted at $\mu = m_Z$, where it is $\sim 0.12$. In effect, $g(\mu)$ controls the amplitude that connects any state to another state with one more or one fewer gluon, including quantum corrections that occur over timescales from zero up to $\hbar/\mu$ (if we measure $\mu$ in units of energy). The QCD Ward identities mentioned above ensure that the coupling is the same for both quarks and gluons, and indeed remains the same in all terms in the Lagrangian, ensuring that the symmetries of QCD are not destroyed by renormalization.

Quantum corrections to gluon emission are not generally computable directly in renormalizable theories, but their dependence on $\mu$ is computable, and is a power series in $\alpha_s(\mu)$ itself,

$$\mu^2 \frac{d\alpha_s(\mu)}{d\mu^2} = -b_0 \frac{\alpha_s^2(\mu)}{4\pi} - b_1 \frac{\alpha_s^3(\mu)}{(4\pi)^2} + \cdots \equiv \beta(\alpha_s) \quad [11]$$

where $b_0 = 11 - 2n_f/3$ and $b_1 = 2(31 - 19n_f/3)$. The celebrated minus signs on the right-hand side are associated with both the spin and self-interactions of the gluons.

The solution to this equation provides an expression for $\alpha_s$ at any scale $\mu_1$ in terms of its value at any other scale $\mu_0$. Keeping only the lowest-order, $b_0$, term, we have

$$\alpha_s(\mu_1) = \frac{\alpha_s(\mu_0)}{1 + (b_0/4\pi)\ln\left(\mu_1^2/\mu_0^2\right)} = \frac{4\pi}{b_0 \ln\left(\mu_1^2/\Lambda_{QCD}^2\right)} \quad [12]$$

where in the second form, we have introduced $\Lambda_{QCD}$, the scale parameter of the theory, which embodies the condition that we get the same coupling at scale $\mu_1$ no matter which scale $\mu_0$ we start from. Asymptotic freedom consists of the observation that at larger renormalization masses $\mu$, or correspondingly shorter timescales, the coupling weakens, and indeed vanishes in the limit $\mu \to \infty$. The other side of the coin is that over longer times or lower momenta, the coupling grows. Eventually, near the pole at $\mu_1 = \Lambda_{QCD}$, the lowest-order approximation to the running fails, and the theory becomes essentially nonperturbative. Thus, the discovery of asymptotic freedom suggested, although it certainly does not prove, that QCD is capable of producing very strong forces, and confinement at long distances. Current estimates of $\Lambda_{QCD}$ are $\sim 200$ MeV.

### Spontaneous Breaking of Chiral Symmetry

The number of quarks and their masses is an external input to QCD. In the standard model masses are provided by the Higgs mechanism, but in QCD they are simply parameters. Because the standard model has chosen several of the quarks to be especially light, QCD incorporates the chiral symmetries implied by eqn [4] (with $P = 1$). In the limit of zero quark masses, these symmetries becomes exact, respected to all orders of perturbation theory, that is, for any finite number of gluons emitted or absorbed.

At distances on the order to $1/\Lambda_{QCD}$, however, QCD cannot respect chiral symmetry, which would require each state to have a degenerate partner with the opposite parity, something not seen in nature. Rather, QCD produces, nonperturbatively, nonzero values for matrix elements that mix right- and left-handed fields, such as $\langle 0|\bar{u}_L u_R|0\rangle$, with $u$ the up-quark field. Pions are the Goldstone bosons of this symmetry, and may be thought of as ripples in the chiral condensate, rotating it locally as they pass along. The observation that these Goldstone bosons are not exactly massless is due to the "current" masses of the quarks, their values in $\mathcal{L}_{QCD}$. The (chiral perturbation theory) expansion in these light-quark masses also enables us to estimate them quantitatively: $1.5 \leq m_u \leq 4$ MeV, $4 \leq m_d \leq 8$ MeV, and $80 \leq m_s \leq 155$ MeV. These are the light quarks, with masses smaller than $\Lambda_{QCD}$. (Like $\alpha_s$, the masses are renormalized; these are quoted from Eidelman (2004) with $\mu = 2$ GeV.) For comparison, the heavy quarks have masses $m_c \sim 1$–$1.5$ GeV, $m_b \sim 4$–$4.5$ GeV, and $m_t \sim 180$ GeV (the giant among the known elementary particles).

Although the mechanism of the chiral condensate (and in general other nonperturbative aspects of

QCD) has not yet been demonstrated from first principles, a very satisfactory description of the origin of the condensate, and indeed of much hadronic structure, has been given in terms of the attractive forces between quarks provided by instantons. The actions of instanton solutions provide a dependence $\exp[-8\pi^2/g_s^2]$ in Euclidean path integrals, and so are characteristically nonperturbative.

### Mechanisms of Confinement

As described above, confinement is the absence of asymptotic states that transform nontrivially under color transformations. The full spectrum of QCD, however, is a complex thing to study, and so the problem has been approached somewhat indirectly. A difficulty is the same light-quark masses associated with approximate chiral symmetry. Because the masses of the light quarks are far below the scale $\Lambda_{QCD}$ at which the perturbative coupling blows up, light quarks are created freely from the vacuum and the process of "hadronization," by which quarks and gluons form mesons and baryons, is both nonperturbative and relativistic. It is therefore difficult to approach in both perturbation theory and lattice simulations.

Tests and studies of confinement are thus normally formulated in truncations of QCD, typically with no light quarks. The question is then reformulated in a way that is somewhat more tractable, without relativistic light quarks popping in and out of the vacuum all the time. In the limit that its mass becomes infinite compared to the natural scale of fluctuations in the QCD vacuum, the propagator of a quark becomes identical to a phase operator, [8], with a path $C$ corresponding to a constant velocity. This observation suggests a number of tests for confinement that can be implemented in the lattice theory. The most intuitive is the vacuum expectation value of a "Wilson loop," consisting of a rectangular path, with sides along the time direction, corresponding to a heavy quark and antiquark at rest a distance $R$ apart, and closed at some starting and ending times with straight lines. The vacuum expectation value of the loop then turns out to be the exponential of the potential energy between the quark pair, multiplied by the elapsed time,

$$\left\langle 0 \middle| P \exp\left[-\mathrm{i}g_s \oint_C A_\mu(x)\,\mathrm{d}x^\mu\right] \middle| 0 \right\rangle = \exp(-V(R)T/\hbar) \qquad [13]$$

When $V(R) \propto R$ ("area law" behavior), there is a linearly rising, confining potential. This behavior, not yet proven analytically yet well confirmed on the lattice, has an appealing interpretation as the energy of a "string," connecting the quark and antiquark, whose energy is proportional to its length.

Motivation for such a string picture was also found from the hadron spectrum itself, before any of the heavy quarks were known, and even before the discovery of QCD, from the observation that many mesonic ($\bar{q}q'$) states lie along "Regge trajectories," which consist of sets of states of spin $J$ and mass $m_J^2$ that obey a relation

$$J = \alpha' m_J^2 \qquad [14]$$

for some constant $\alpha'$. Such a relation can be modeled by two light particles ("quarks") revolving around each other at some constant (for simplicity, fixed nonrelativistic) velocity $v_0$ and distance $2R$, connected by a "string" whose energy per unit length is a constant $\rho$.

Suppose the center of the string is stationary, so the overall system is at rest. Then neglecting the masses, the total energy of the system is $M = 2R\rho$. Meanwhile, the momentum density per unit length at distance $r$ from the center is $v(r) = (r/R)v_0$, and the total angular momentum of the system is

$$J = 2\rho v_0 \int_0^R \mathrm{d}r\, r^2 = \frac{2\rho v_0}{3} R^2 = \frac{v_0}{6\rho} M^2 \qquad [15]$$

and for such a system, [14] is indeed satisfied. Quantized values of angular momentum $J$ give quantized masses $m_J$, and we might take this as a sort of "Bohr model" for a meson. Indeed, string theory has its origin in related consideration in the strong interactions.

Lattice data are unequivocal on the linearly rising potential, but it requires further analysis to take a lattice result and determine what field configurations, stringlike or not, gave that result. Probably the most widely accepted explanation is in terms of an analogy to the Meissner effect in superconductivity, in which type II superconductors isolate magnetic flux in quantized tubes, the result of the formation of a condensate of Cooper pairs of electrons. If the strings of QCD are to be made of the gauge field, they must be electric ($F^{\mu 0}$) in nature to couple to quarks, so the analogy postulates a "dual" Meissner effect, in which electric flux is isolated as the result of a condensate of objects with magnetic charge (producing nonzero $F^{ij}$). Although no proof of this mechanism has been provided yet, the role of magnetic fluctuations in confinement has been widely investigated in lattice simulations, with encouraging results. Of special interest are magnetic field configurations, monopoles or vortices, in the $Z_3$ center of SU(3), $\exp[\mathrm{i}\pi k/3]I_{3\times 3}$, $k = 0, 1, 2$. Such configurations, even when localized, influence closed gauge loops [13] through the nonabelian Aharonov–Bohm effect. Eventually, of course, the role of light quarks must be crucial for any complete

description of confinement in the real world, as emphasized by Gribov.

Another related choice of closed loop is the "Polyakov loop," implemented at finite temperature, for which the path integral is taken over periodic field configurations with period $1/T$, where $T$ is the temperature. In this case, the curve $C$ extends from times $t=0$ to $t=1/T$ at a fixed point in space. In this formulation it is possible to observe a phase transition from a confined phase, where the expectation is zero, to a deconfined phase, where it is nonzero. This phase transition is currently under intense experimental study in nuclear collisions.

## Using Asymptotic Freedom: Perturbative QCD

It is not entirely obvious how to use asymptotic freedom in a theory that should (must) have confinement. Such applications of asymptotic freedom go by the term perturbative QCD, which has many applications, not the least as a window to extensions of the standard model.

### Lepton Annihilation and Infrared Safety

The electromagnetic current, $J_\mu = \sum_f e_f \bar{q}_f \gamma_\mu q_f$, is a gauge-invariant operator, and its correlation functions are not limited by confinement. Perhaps, the simplest application of asymptotic freedom, yet of great physical relevance, is the scalar two-point function,

$$\pi(Q) = \frac{-\mathrm{i}}{3} \int \mathrm{d}^4 x\, \mathrm{e}^{-\mathrm{i}Q\cdot x} \langle 0 | \mathrm{T}(J^\mu(0) J_\mu(x)) | 0 \rangle \qquad [16]$$

The imaginary part of this function is related to the total cross section for the annihilation process $\mathrm{e}^+\mathrm{e}^- \to$ hadrons in the approximation that only one photon takes part in the reaction. The specific relation is $\sigma_{\mathrm{QCD}} = (e^4/Q^2)\, \mathrm{Im}\, \pi(Q^2)$, which follows from the optical theorem, illustrated in Figure 1. The perturbative expansion of the function $\pi(Q)$ depends, in general, on the mass scales $Q$ and the quark masses $m_f$ as well as on the strong coupling $\alpha_s(\mu)$ and on the renormalization scale $\mu$. We may also worry about the influence of other, truly nonperturbative scales, proportional to powers of $\Lambda_{\mathrm{QCD}}$. At large values of $Q^2$, however, the situation simplifies greatly, and dependence on all scales below $Q$ is suppressed by powers of $Q$. This may be expressed in terms of the operator product expansion,

$$\begin{aligned} &\langle 0 | T(J^\mu(0) J_\mu(x)) | 0 \rangle \\ &\quad = \sum_{O_I} (x^2)^{-3+d_I/2} C_I(x^2\mu^2, \alpha_s(\mu)) \\ &\quad \times \langle 0 | O_I(0) | 0 \rangle \end{aligned} \qquad [17]$$

where $d_I$ is the mass dimension of operator $O_I$, and where the dimensionless coefficient functions $C_I$ incorporate quantum corrections. The sum over operators begins with the identity ($d_I = 0$), whose coefficient function is identified with the sum of quantum corrections in the approximation of zero masses. The sum continues with quark mass corrections, which are suppressed by powers of at least $m_f^2/Q^2$, for those flavors with masses below $Q$. Any QCD quantity that has this property, remaining finite in perturbation theory when all particle masses are set to zero, is said to be "infrared safe."

The effects of quarks whose masses are above $Q$ are included indirectly, through the couplings and masses observed at the lower scales. In summary, the leading power behavior of $\pi(Q)$, and hence of the cross section, is a function of $Q$, $\mu$, and $\alpha_s(\mu)$ only. Higher-order operators whose vacuum matrix elements receive nonperturbative corrections include the "gluon condensate," identified as the product $\alpha_s(\mu) G_{\alpha\beta} G^{\alpha\beta} \propto \Lambda_{\mathrm{QCD}}^4$.

Once we have concluded that $Q$ is the only physical scale in $\pi$, we may expect that the right choice of the renormalization scale is $\mu = Q$. Any observable quantity is independent of the choice of renormalization scale, $\mu$, and neglecting quark masses, the chain rule gives

$$\mu \frac{\mathrm{d}\sigma(Q/\mu, \alpha_s(\mu))}{\mathrm{d}\mu} = \mu \frac{\partial \sigma}{\partial \mu} + 2\beta(\alpha_s) \frac{\partial \sigma}{\partial \alpha_s} = 0 \qquad [18]$$

which shows that we can determine the beta function directly from the perturbative expansion of the cross section. Defining $a \equiv \alpha_s(\mu)/\pi$, such a perturbative calculation gives

$$\begin{aligned} \mathrm{Im}\pi(Q^2) = \frac{3}{4\pi} \sum_f e_f^2 \Bigg(1 + a + a^2 \Bigg(1.986 \\ - 0.115 n_f - (b_0/4\pi) \ln \frac{Q^2}{\mu^2}\Bigg)\Bigg) \end{aligned} \qquad [19]$$

with $b_0$ as above. Now, choosing $\mu = Q$, we see that asymptotic freedom implies that when $Q$ is large, the total cross section is given by the lowest order,

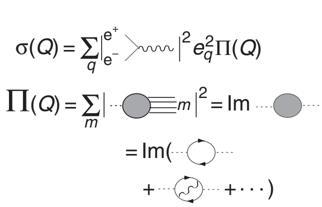

**Figure 1** First line: schematic relation of lowest order $\mathrm{e}^+\mathrm{e}^-$ annihilation to sum over quarks $q$, each with electric charge $e_q$. Second line: perturbative unitarity for the current correlation function $\pi(Q)$.

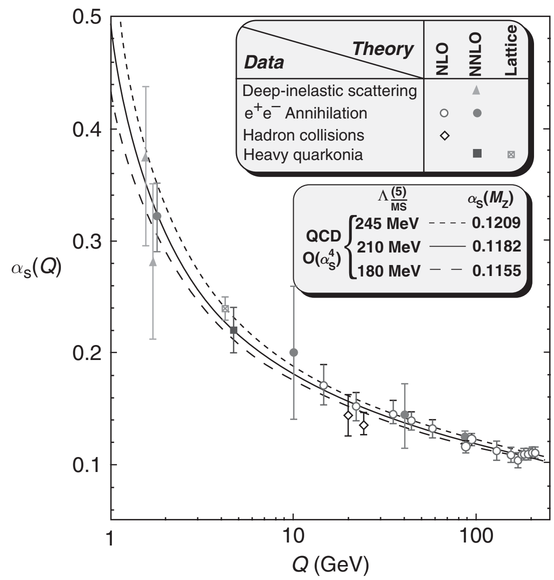

**Figure 2** Experimental variation of the strong coupling with scales. Reproduced from Bethke S (2004) Alpha(s) at Zinnowitz. *Nuclear Physics Proceedings Supplements* 135: 345–352, with permission from Elsevier.

plus small and calculable QCD corrections, a result that is borne out in experiment. Comparing experiment to an expression like [19], one can measure the value of $\alpha_s(Q)$, and hence, with eqn [12], $\alpha_s(\mu)$ for any $\mu \gg \Lambda_{\mathrm{QCD}}$. Figure 2 shows a recent compilation of values of $\alpha_s$ from this kind of analysis in different experiments at different scales, clearly demonstrating asymptotic freedom.

## Factorization, Scaling, and Parton distributions

One step beyond vacuum matrix elements of currents are their expectation values in single-particle states, and here we make contact with the discovery of QCD, through scaling. Such expectations are relevant to the class of experiments known as deep-inelastic scattering, in which a high-energy electron exchanges a photon with a nucleon target. All QCD information is contained in the tensor matrix element

$$W_N^{\mu\nu}(p,q) \equiv \frac{1}{8\pi}\sum_\sigma \int d^4x\, e^{-iq\cdot x}\langle p,\sigma|J^\mu(0)J^\nu(x)|p,\sigma\rangle \quad [20]$$

with $q$ the momentum transfer carried by the photon, and $p,\sigma$ the momentum and spin of the target nucleon, $N$. This matrix element is not infrared safe, since it depends in principle on the entire history of the nucleon state. Thus, it is not accessible to direct perturbative calculation.

Nevertheless, when the scattering involves a large momentum transfer compared to $\Lambda_{\mathrm{QCD}}$, we may expect a quantum-mechanical incoherence between the scattering reaction, which occurs (by the uncertainty principle) at short distances, and the forces that stabilize the nucleon. After all, we have seen that the latter, strong forces, should be associated with long distances. Such a separation of dynamics, called factorization, can be implemented in perturbation theory, and is assumed to be a property of full QCD. Factorization is illustrated schematically in Figure 3. Of course, short and long distances are relative concepts, and the separation requires the introduction of a so-called factorization scale, $\mu_F$, not dissimilar to the renormalization scale described above. For many purposes, it is convenient to choose the two equal, although this is not required.

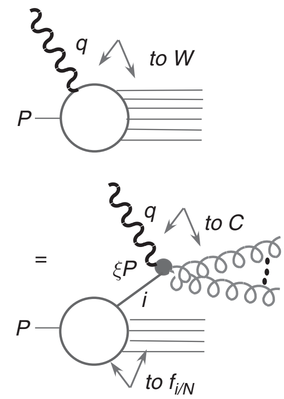

**Figure 3** Schematic depiction of factorization in deep-inelastic scattering.

The expression of factorization for deep-inelastic scattering is

$$W_N^{\mu\nu}(p,q) = \sum_{i=q_f,\bar{q}_f,G}\int_x^1 d\xi\, C_i^{\mu\nu}(\xi p, q, \mu_F, \alpha_s(\mu_F)) \times f_{i/N}(\xi,\mu_F) \quad [21]$$

where the functions $C_i^{\mu\nu}$ (the coefficient functions) can be computed as an expansion in $\alpha_s(\mu_F)$, and describe the scattering of the "partons," quarks, and gluons, of which the target is made. The variable $\xi$ ranges from unity down to $x \equiv -q^2/2p\cdot q > 0$, and has the interpretation of the fractional momentum of the proton carried by parton $i$. (Here $-q^2 = Q^2$ is positive.) The parton distributions $f_{i/N}$ can be defined in terms of matrix elements in the nucleon, in which the currents are replaced by quark (or antiquark or gluon) fields, as

$$f_{q/N}(x,\mu) = \frac{1}{4\pi}\int_{-\infty}^{\infty} d\lambda\, e^{-i\lambda x p^+} \times \langle p,\sigma|\bar{q}(\lambda n)U_n(n\lambda,0)n\cdot\gamma q(0)|p,\sigma\rangle \quad [22]$$

$n^{\mu}$ is a light-like vector, and $U_n$ a phase operator whose path $C$ is in the $n$-direction. The dependence of the parton distribution on the factorization scale is through the renormalization of the composite operator consisting of the quark fields, separated along the light cone, and the nonabelian phase operator $U_n(n\lambda, 0)$, which renders the matrix element gauge invariant by eqn [9]. By combining the calculations of the $C$'s and data for $W_N^{\mu\nu}$, we can infer the parton distributions, $f_{i/N}$. Important factorizations of a similar sort also apply to some exclusive processes, including amplitudes for elastic pion or nucelon scattering at large momentum transfer.

Equation [21] has a number of extraordinary consequences. First, because the coefficient function is an expansion in $\alpha_s$, it is natural to choose $\mu_F^2 \sim Q^2 \sim p \cdot q$ (when $x$ is of order unity). When $Q$ is large, we may approximate $C_i^{\mu\nu}$ by its lowest order, which is first order in the electromagnetic coupling of quarks to photons, and zeroth order in $\alpha_s$. In this approximation, dependence on $Q$ is entirely in the parton distributions. But such dependence is of necessity weak (again for $x$ not so small as to produce another scale), because the $\mu_F$ dependence of $f_{i/N}(\xi, \mu_F)$ must be compensated by the $\mu_F$ dependence of $C_i^{\mu\nu}$, which is order $\alpha_s$. This means that the overall $Q$ dependence of the tensor $W_N^{\mu\nu}$ is weak for $Q$ large when $x$ is moderate. This is the scaling phenomenon that played such an important role in the discovery of QCD.

### Evolution: Beyond Scaling

Another consequence of the factorization [21], or equivalently of the operator definition [22], is that the $\mu_F$-dependence of the coefficient functions and the parton distributions are linked. As in the lepton annihilation cross section, this may be thought of as due to the independence of the physically observable tensor $W_N^{\mu\nu}$ from the choice of factorization and renormalization scales. This implies that the $\mu_F$-dependence of $f_{i/N}$ may be calculated perturbatively since it must cancel the corresponding dependence in $C_i$. The resulting relation is coventionally expressed in terms of the "evolution equations,"

$$\mu \frac{\mathrm{d}f_{a/N}(x,\mu)}{\mathrm{d}\mu} = \sum_c \int_x^1 \mathrm{d}\xi \; P_{ac}(x/\xi, \alpha_s(\mu)) f_{c/N}(\xi, \mu) \qquad [23]$$

where $P_{ac}(\xi)$ are calculable as power series, now known up to $\alpha_s^3$. This relation expands the applicability of QCD from scales where parton distributions can be inferred directly from experiment, to arbitrarily high scales, reachable in accelerators under construction or in the imagination, or even on the cosmic level.

At very high energy, however, the effective values of the variable $x$ can become very small and introduce new scales, so that eventually the evolution of eqn [23] fails. The study of nuclear collisions may provide a new high-density regime for QCD, which blurs the distinction between perturbative and nonperturbative dynamics.

### Inclusive Production

Once we have evolution at our disposal, we can take yet another step, and replace electroweak currents with any operator from any extension of QCD, in the standard model or beyond, that couples quarks and gluons to the particles of as-yet unseen fields. Factorization can be extended to these situations as well, providing predictions for the production of new particles, $F$ of mass $M$, in the form of factorized inclusive cross sections,

$$\begin{aligned} &\sigma_{AB\to F(M)}(M, p_A, p_B) \\ &\quad = \sum_{i,j=q_f\bar{q}_f,G} \int \mathrm{d}\xi_a \, \mathrm{d}\xi_b f_{i/A}(\xi_a,\mu) f_{j/B}(\xi_b,\mu) \\ &\quad\quad \times H_{ij\to F(M)}(x_a p_A, x_b p_B, M, \mu, \alpha_s(\mu)) \end{aligned} \qquad [24]$$

where the functions $H_{ij\to F}$ may be calculated perturbatively, while the $f_{i/A}$ and $f_{j/B}$ parton distributions are known from a combination of lower-energy observation and evolution. In this context, they are said to be "universal," in that they are the same functions in hadron–hadron collisions as in the electron–hadron collisions of deep-inelastic scattering. In general, the calculation of hard-scattering functions $H_{ij}$ is quite nontrivial beyond lowest order in $\alpha_s$. The exploration of methods to compute higher orders, currently as far as $\alpha_s^2$, has required extraordinary insight into the properties of multidimensional integrals.

The factorization method helped predict the observation of the $W$ and $Z$ bosons of electroweak theory, and the discovery of the top quark. The extension of factorization from deep-inelastic scattering to hadron production is nontrivial; indeed, it only holds in the limit that the velocities, $\beta_i$, of the colliding particles approach the speed of light in the center-of-momentum frame of the produced particle. Corrections to the relation [24] are then at the level of powers of $\beta_i - 1$, which translates into inverse powers of the invariant mass(es) of the produced particle(s) $M$. Factorizations of this sort do not apply to low-velocity collisions. Arguments for this

result rely on relativistic causality and the uncertainty principle. The creation of the new state happens over timescales of order $1/M$. Before that well-defined event, the colliding particles are approaching at nearly the speed of light, and hence cannot affect the distributions of each others' partons. After the new particle is created, the fragments of the hadrons recede from each other, and the subsequent time development, when summed over all possible final states that include the heavy particle, is finite in perturbation theory as a direct result of the unitarity of QCD.

### Structure of Hadronic Final States

A wide range of semi-inclusive cross sections are defined by measuring properties of final states that depend only on the flow of energy, and which bring QCD perturbation theory to the threshold of nonperturbative dynamics. Schematically, for a state $N = |k_1 \dots k_N\rangle$, we define $\mathcal{S}(N) = \sum_i s(\Omega_i) k_i^0$, where $s(\Omega)$ is some smooth function of directions. We generalize the $e^+e^-$ annihilation case above, and define a cross section in terms of a related, but highly nonlocal, matrix element,

$$\frac{\mathrm{d}\sigma(Q)}{\mathrm{d}\mathcal{S}} \equiv \sigma_0 \int \mathrm{d}^4 x\, \mathrm{e}^{-\mathrm{i}Q\cdot x} \left\langle 0 \middle| J^\mu(0) \times \delta\left( \int \mathrm{d}^2\Omega s(\Omega)\mathcal{E}(\Omega) - \mathcal{S} \right) J_\mu(x) \middle| 0 \right\rangle \qquad [25]$$

where $\sigma_0$ is a zeroth-order cross section, and where $\mathcal{E}$ is an operator at spatial infinity, which measures the energy flow of any state in direction $\Omega$: $\mathcal{E}(\Omega) |k_1 \dots k_N\rangle = (1/Q) \sum_i k_i^0 \delta^2(\Omega - \Omega_i)$. This may seem a little complicated, but like the total annihilation cross section, the only dimensional scale on which it depends is $Q$. The operator $\mathcal{E}$ can be defined in a gauge-invariant manner, through the energy–momentum tensor for example, and has a meaning independent of partonic final states. At the same time, this sort of cross section may be implemented easily in perturbation theory, and like the total annihilation cross section, it is infrared safe. To see why, notice that when a massless ($k^2 = 0$) particle decays into two particles of momenta $xk$ and $(1-x)k$ ($0 \le x \le 1$), the quantity $\mathcal{S}$ is unchanged, since the sum of the new energies is the same as the old. This makes the observable $\mathcal{S}(N)$ insensitive to processes at low momentum transfer.

For the case of leptonic annihilation, the lowest-order perturbative contribution to energy flow requires no powers of $\alpha_s$, and consists of an oppositely moving quark and antiquark pair. Any measure of energy flow that includes these configurations will dominate over correlations that require $\alpha_s$ corrections. As a result, QCD predicts that in most leptonic annihilation events, energy will flow in two back-to-back collimated sets of particles, known as "jets." In this way, quarks and gluons are observed clearly, albeit indirectly.

With varying choices of $\mathcal{S}$, many properties of jets, such as their distributions in invariant mass, and the probabilities and angular distributions of multijet events, and even the energy dependence of their particle multiplicities, can be computed in QCD. This is in part because hadronization is dominated by the production of light quarks, whose production from the vacuum requires very little momentum transfer. Paradoxically, the very lightness of quarks is a boon to the use of perturbative methods. All these considerations can be extended to hadronic scattering, and jet and other semi-inclusive properties of final states also computed and compared to experiment.

## Conclusions

QCD is an extremely broad field, and this article has hardly scratched the surface. The relation of QCD-like theories to supersymmetric and string theories, and implications of the latter for confinement and the computation of higher-order perturbative amplitudes, have been some of the most exciting developments of recent years. As another example, we note that the reduction of the heavy-quark propagator to a nonabelian phase, noted in our discussion of confinement, is related to additional symmetries of heavy quarks in QCD, with many consequences for the analysis of their bound states. Of the bibliography given below, one may mention the four volumes of Shifman (2001, 2002), which communicate in one place a sense of the sweep of work in QCD.

Our confidence in QCD as the correct description of the strong interactions is based on a wide variety of experimental and observational results. At each stage in the discovery, confirmation, and exploration of QCD, the mathematical analysis of relativistic quantum field theory entered new territory. As is the case for gravity or electromagnetism, this period of exploration is far from complete, and perhaps never will be.

## Introduction

Classical gravity, through its attractive nature, leads to a high curvature in important situations. In particular, this is realized in the very early universe where in the backward evolution energy densities are growing until the theory breaks down. Mathematically, this point appears as a singularity where curvature and physical quantities diverge and the evolution breaks down. It is not possible to set up an initial-value formulation at this place in order to determine the further evolution.

In such a regime, quantum effects are expected to play an important role and to modify the classical behavior such as the attractive nature of gravity or the underlying spacetime structure. Any candidate for quantum gravity thus allows us to reanalyze the singularity problem in a new light which implies the tests of the characteristic properties of the respective candidate. Moreover, close to the classical singularity, in the very early universe, quantum modifications will give rise to new equations of motion which turn into Einstein's equations only on larger scales. The analysis of these equations of motion leads to new classes of early universe phenomenology.

The application of quantum theory to cosmology presents a unique problem with not only mathematical but also many conceptual and philosophical ramifications. Since by definition there is only one universe which contains everything accessible, there is no place for an outside observer separate from the quantum system. This eliminates the most straightforward interpretations of quantum mechanics and requires more elaborate, and sometimes also more realistic, constructions such as decoherence. From the mathematical point of view, this situation is often expected to be mirrored by a new type of theory which does not allow one to choose initial or boundary conditions separately from the dynamical laws. Initial or boundary conditions, after all, are meant to specify the physical system prepared for observations which is impossible in cosmology. Since we observe only one universe, the expectation goes, our theories should finally present us with only

one, unique solution without any freedom for further conditions. This solution then contains all the information about observations as well as observers. Mathematically, this is an extremely complicated problem which has received only scant attention. Equations of motion for quantum cosmology are usually of the type of partial differential or difference equations such that new ingredients from quantum gravity are needed to restrict the large freedom of solutions.

## Minisuperspace approximation

In most investigations, the problem of applying full quantum gravity to cosmology is simplified by a symmetry reduction to homogeneous or isotropic geometries. Originally, the reduction was performed at the classical level, leaving in the isotropic case only one gravitational degree of freedom given by the scale factor $a$. Together with homogeneous matter fields, such as a scalar $\phi$, there are then only finitely many degrees of freedom which one can quantize using quantum mechanics. The classical Friedmann equation for the evolution of the scale factor, depending on the spatial curvature $k = 0$ or $\pm 1$, is then quantized to the Wheeler–DeWitt equation, commonly written as

$$\left(\frac{1}{9}\ell_{\mathrm{P}}^{4} a^{-x}\frac{\partial}{\partial a}a^{x}\frac{\partial}{\partial a} - ka^{2}\right)\psi(a,\phi) = -\frac{8\pi G}{3}a\hat{H}_{\mathrm{matter}}(a)\psi(a,\phi) \qquad [1]$$

for the wave function $\psi(a,\phi)$. The matter Hamiltonian $\hat{H}_{\mathrm{matter}}(a)$, such as

$$\hat{H}_{\mathrm{matter}}(a) = -\frac{1}{2}\hbar^{2}a^{-3}\frac{\partial^{2}}{\partial\phi^{2}} + a^{3}V(\phi) \qquad [2]$$

is left unspecified here, and $x$ parametrizes factor ordering ambiguities (but not completely). The Planck length $\ell_{\mathrm{P}} = \sqrt{8\pi G\hbar}$ is defined in terms of the gravitational constant $G$ and the Planck constant $\hbar$.

The central conceptual issue then is the generality of effects seen in such a symmetric model and its relation to the full theory of quantum gravity. This is completely open in the Wheeler–DeWitt form since the full theory itself is not even known. On the other hand, such relations are necessary to value any potential physical statement about the origin and early history of the universe. In this context, symmetric situations thus present models, and the degree to which they approximate full quantum gravity remains mostly unknown. There are examples, for instance, of isotropic models in anisotropic but still homogeneous models, where a minisuperspace quantization does not agree at all with the information obtained from the less symmetric model. However, often those effects already have a classical analog such as instability of the more symmetric solutions. A wider investigation of the reliability of models and when correction terms from ignored degrees of freedom have to be included has not been done yet.

With candidates for quantum gravity being available, the current situation has changed to some degree. It is then not only possible to reduce classically and then simply use quantum mechanics, but also perform at least some of the reduction steps at the quantum level. The relation to models is then much clearer, and consistency conditions which arise in the full theory can be made certain to be observed. Moreover, relations between models and the full theory can be studied to elucidate the degree of approximation. Even though new techniques are now available, a detailed investigation of the degree of approximation given by a minisuperspace model has not been completed due to its complexity.

This program has mostly been developed in the context of loop quantum gravity, where the specialization to homogeneous models is known as loop quantum cosmology. More specifically, symmetries can be introduced at the level of states and basic operators, where symmetric states of a model are distributions in the full theory, and basic operators are obtained by the dual action on those distributions. In such a way, the basic representation of models is not assumed but derived from the full theory where it is subject to much stronger consistency conditions. This has implications even in homogeneous models with finitely many degrees of freedom, despite the fact that quantum mechanics is usually based on a unique representation if the Weyl operators $e^{isq}$ and $e^{itp}$ for the variables $q$ and $p$ are represented weakly continuously in the real parameters $s$ and $t$.

The continuity condition, however, is not necessary in general, and so inequivalent representations are possible. In quantum cosmology this is indeed realized, where the Wheeler–DeWitt representation assumes that the conjugate to the scale factor, corresponding to extrinsic curvature of an isotropic slice, is represented through a continuous Weyl operator, while the representation derived for loop quantum cosmology shows that the resulting operator is not weakly continuous. Furthermore, the scale factor has a continuous spectrum in the Wheeler–DeWitt representation but a discrete spectrum in the loop representation. Thus, the underlying geometry

of space is very different, and also evolution takes a new form, now given by a difference equation of the type

$$\begin{aligned}&(V_{\mu+5}-V_{\mu+3})\mathrm{e}^{\mathrm{i}k}\psi_{\mu+4}(\phi)\\&\quad-(2+k^2)(V_{\mu+1}-V_{\mu-1})\psi_{\mu}(\phi)\\&\quad+(V_{\mu-3}-V_{\mu-5})\mathrm{e}^{-\mathrm{i}k}\psi_{\mu-4}(\phi)\\&\quad=-\tfrac{4}{3}\pi G\ell_{\mathrm{P}}^{2}\hat{H}_{\mathrm{matter}}(\mu)\psi_{\mu}(\phi)\end{aligned}\qquad[3]$$

in terms of volume eigenvalues $V_\mu=(\ell_{\mathrm{P}}^2|\mu|/6)^{3/2}$. For large $\mu$ and smooth wave functions, one can see that the difference equation reduces to the Wheeler–DeWitt equation with $|\mu|\propto a^2$ to leading order in derivatives of $\psi$. At small $\mu$, close to the classical singularity, however, both equations have very different properties and lead to different conclusions. Moreover, the prominent role of difference equations leads to new mathematical problems.

This difference equation is not simply obtained through a discretization of [1], but derived from a constraint operator constructed with methods from full loop quantum gravity. It is, thus, to be regarded as more fundamental, with [1] emerging in a continuum limit. The structure of [3] depends on the properties of the full theory such that its qualitative analysis allows conclusions for full quantum gravity.

## Applications

Traditionally, quantum cosmology has focused on three main conceptual issues:

- the fate of classical singularities,
- initial conditions and the "prediction" of inflation (or other early universe scenarios), and
- arrow of time and the emergence of a classical world.

The first issue consists of several subproblems since there are different aspects to a classical singularity. Often, curvature or energy densities diverge and one can expect quantum gravity to provide a natural cutoff. More importantly, however, the classical evolution breaks down at a singularity, and quantum gravity, if it is to cure the singularity problem, has to provide a well-defined evolution which does not stop. Initial conditions are often seen in relation to the singularity problem since early attempts tried to replace the singularity by choosing appropriate conditions for the wave function at $a=0$. Different proposals then lead to different solutions for the wave function, whose dependence on the scalar $\phi$ can be used to determine its probability distribution such as that for an inflaton. Since initial conditions often provide special properties early on, the combination of evolution and initial conditions has been used to find a possible origin of an arrow of time.

### Singularities

While classical gravity is based on spacetime geometry and thus metric tensors, this structure is viewed as emergent only at large scales in canonical quantum gravity. A gravitational system, such as a whole universe, is instead described by a wave function which, at best, yields expectation values for a metric. The singularity problem thus takes a different form since it is not metrics which need to be continued as solutions to Einstein's field equations but the wave function describing the quantum system. In the strong curvature regime around a classical singularity, one does not expect classical geometry to be applicable, such that classical singularities may just be a reflection of the breakdown of this picture, rather than a breakdown of physical evolution. Nevertheless, the basic feature of a singularity as presenting a boundary to the evolution of a system equally applies to the quantum equations. One can thus analyze this issue, using new properties provided by the quantum evolution.

The singularity issue is not resolved in the Wheeler–DeWitt formulation since energy densities, with $a$ being a multiplication operator, diverge and the evolution does not continue anywhere beyond the classical singularity at $a=0$. In some cases one can formally extend the evolution to negative $a$, but this possibility is not generic and leaves open what negative $a$ means geometrically. This is different in the loop quantization: here, the theory is based on triad rather than metric variables. There is thus a new sign factor corresponding to spatial orientation, which implies the possibility of negative $\mu$ in the difference equation. The equation is then defined on the full real line with the classical singularity $\mu=0$ in the interior. Outside $\mu=0$, we have positive volume at both sides, and opposite orientations. Using the difference equation, one can then see that the evolution does not break down at $\mu=0$, showing that the quantum evolution is singularity free.

For the example [3] shown here, one can follow the evolution, for instance, backward in internal time $\mu$, starting from initial values for $\psi$ at large positive $\mu$. By successively solving for $\psi_{\mu-4}$, the wave function at lower $\mu$ is determined. This goes on in this manner only until the coefficient $V_{\mu-3}-V_{\mu-5}$ of $\psi_{\mu-4}$ vanishes, which is the case if and only if $\mu=4$.

The value $\psi_0$ of the wave function exactly at the classical singularity is thus not determined by initial data, but one can easily see that it completely drops out of the evolution. In fact, the wave function at all negative $\mu$ is uniquely determined by initial values at positive $\mu$. Equation [3] corresponds to one particular ordering, which in the Wheeler–DeWitt case is usually parametrized by the parameter $x$ (although the particular ordering obtained from the continuum limit of [3] is not contained in the special family [1]). Other nonsingular orderings exist, such as that after symmetrizing the constraint operator, in which case the coefficients never become 0.

In more complicated systems, this behavior is highly nontrivial but still known to be realized in a similar manner. It is not automatic that the internal time evolution does not continue since even in isotropic models one can easily write difference equations for which the evolution breaks down. That the most natural orderings imply nonsingular evolution can be taken as a support of the general framework of loop quantum gravity. It should also be noted that the mechanism described here, providing essentially a new region beyond a classical singularity, presents one mechanism for quantum gravity to remove classical singularities, and so far the only known one. Nevertheless, there is no claim that the ingredients have to be realized in any nonsingular scenario in the same manner. Different scenarios can be imagined, depending on how quantum evolution is understood and what the interpretation of nonsingular behavior is. It is also not claimed that the new region is semiclassical in any sense when one looks at it at large volume. If the initial values for the wave function describe a semiclassical wave packet, its evolution beyond the classical singularity can be deformed and develop many peaks. What this means for the re-emergence of a semiclassical spacetime has to be investigated in particular models, and also in the context of decoherence.

## Initial Conditions

Traditional initial conditions in quantum cosmology have been introduced by physical intuition. The main mathematical problem, once such a condition is specified in sufficient detail, then is to study well-posedness, for instance, for the Wheeler–DeWitt equation. Even formulating initial conditions generally, and not just for isotropic models, is complicated, and systematic investigations of the well-posedness have rarely been undertaken. An exception is the historically first such condition, due to DeWitt, that the wave function vanishes at parts of minisuperspace, such as $a=0$ in the isotropic case, corresponding to classical singularities. This condition, unfortunately, can easily be seen to be ill posed in anisotropic models where in general the only solution vanishes identically. In other models, $\lim_{a\to 0}\psi(a)$ does not even exist. Similar problems of the generality of conditions arise in other scenarios. Most well known are the no-boundary and tunneling proposal where initial conditions are still imposed at $a=0$, but with a nonvanishing wave function there.

This issue is quite different for difference equations since at first the setup is less restrictive: there are no continuity or differentiability conditions for a solution. Moreover, oscillations that become arbitrarily rapid, which can be responsible for the nonexistence of $\lim_{a\to 0}\psi(a)$, cannot be supported on a discrete lattice. It can then easily happen that a difference equation is well posed, while its continuum limit with an analogous initial condition is ill posed. One example are the dynamical initial conditions of loop quantum cosmology which arise from the dynamical law in the following way: the coefficients in [3] are not always nonzero but vanish if and only if they are multiplied with the value of the wave function at the classical singularity $\mu=0$. This value thus decouples and plays no role in the evolution. The instance of the difference equation that would determine $\psi_0$, for example, the equation for $\mu=4$ in the backward evolution, instead implies a condition on the previous two values, $\psi_4$ and $\psi_8$, in the example. Since they have already been determined in previous iteration steps, this translates to a linear condition on the initial values chosen. We thus have one example where indeed initial conditions and the evolution follow from only one dynamical law, which also extends to anisotropic models. Without further conditions, the initial-value problem is always well posed, but may not be complete, in the sense that it results in a unique solution up to norm. Most of the solutions, however, will be rapidly oscillating. In order to guarantee the existence of a continuum approximation, one has to add a condition that these oscillations are suppressed in large volume regimes. Such a condition can be very restrictive, such that the issue of well-posedness appears in a new guise: nonzero solutions do exist, but in some cases all of them may be too strongly oscillating.

In simple cases, one can use generating function techniques advantageously to study oscillating solutions, at least if oscillations are of alternating nature between two subsequent levels of the difference equation. The idea is that a generating function $G(x)=\sum_n \psi_n x^n$ has a stronger pole at $x=-1$ if $\psi_n$

is alternating compared to a solution of constant sign. Choosing initial conditions which reduce the pole order thus implies solutions with suppressed oscillations. As an example, we can look at the difference equation

$$\psi_{n+1} + \frac{2}{n}\psi_n - \psi_{n-1} = 0 \qquad [4]$$

whose generating function is

$$G(x) = \frac{\psi_1 x + \psi_0(1 + 2x(1 - \log(1 - x)))}{(1 + x)^2} \qquad [5]$$

The pole at $x = -1$ is removed for initial values $\psi_1 = \psi_0(2\log 2 - 1)$ which corresponds to nonoscillating solutions. In this way, analytical expressions can be used instead of numerical attempts which would be sensitive to rounding errors. Similarly, the issue of finding bounded solutions can be studied by continued fraction methods. This illustrates how an underlying discrete structure leads to new questions and the application of new techniques compared to the analysis of partial differential equations which appear more commonly.

## More General Models

Most of the time, homogeneous models have been studied in quantum cosmology since even formulating the Wheeler–DeWitt equation in inhomogeneous cases, the so-called midisuperspace models, is complicated. Of particular interest among homogeneous models is the Bianchi IX model since it has a complicated classical dynamics of chaotic behavior. Moreover, through the Belinskii–Khalatnikov–Lifschitz (BKL) picture, the Bianchi IX mixmaster behavior is expected to play an important role even for general inhomogeneous singularities. The classical chaos then indicates a very complicated approach to classical singularities, with structure on arbitrarily small scales.

On the other hand, the classical chaos relies on a curvature potential with infinitely high walls, which can be mapped to a chaotic billiard motion. The walls arise from the classical divergence of curvature, and so quantum effects have been expected to change the picture, and shown to do so in several cases.

Inhomogeneous models (e.g., the polarized Gowdy models) have mostly been studied in cases where one can reformulate the problem as that of a massless free scalar on flat Minkowski space. The scalar can then be quantized with familiar techniques in a Fock space representation, and is related to metric components of the original model in rather complicated ways. Quantization can thus be performed, but transforming back to the metric at the operator level and drawing conclusions is quite involved. The main issue of interest in the recent literature has been the investigation of field theory aspects of quantum gravity in a tractable model. In particular, it turns out that self-adjoint Hamiltonians, and thus unitary evolution, do not exist in general.

Loop quantizations of inhomogeneous models are available even in cases where a reformulation such as a field theory on flat space does not exist, or is not being made use of to avoid special gauges. This is quite valuable in order to see if specific features exploited in reformulations lead to artifacts in the results. So far, the dynamics has not been investigated in detail, even though conclusions for the singularity issue can already be drawn.

From a physical perspective, it is most important to introduce inhomogeneities at a perturbative level in order to study implications for cosmological structure formation. On a homogeneous background, one can perform a mode decomposition of metric and matter fields and quantize the homogeneous modes as well as amplitudes of higher modes. Alternatively, one can first quantize the inhomogeneous system and then introduce the mode decomposition at the quantum level. This gives rise to a system of infinitely many coupled equations of infinitely many variables, which needs to be truncated, for example, for numerical investigations. At this level, one can then study the question to which degree a given minisuperspace model presents a good approximation to the full theory, and where additional correction terms should be introduced. It also allows one to develop concrete models of decoherence, which requires a “bath” of many weakly interacting degrees of freedom usually thought of as being provided by inhomogeneities in cosmology, and an understanding of the semiclassical limit.

## Interpretations

Due to the complexity of full gravity, investigations without symmetry assumptions or perturbative approximations usually focus on conceptual issues. As already discussed, cosmology presents a unique situation for physics since there cannot be any outside observer. While this fact has already implications on the interpretation of observations at the classical level, its full force is noticed only in quantum cosmology. Since some traditional interpretations of quantum mechanics require the role of

observers outside the quantum system, they do not apply to quantum cosmology.

Sometimes, alternative interpretations such as Bohm theory or many-world scenarios are championed in this situation, but more conventional relational pictures are most widely adopted. In such an interpretation, the wave function yields relational probabilities between degrees of freedom rather than absolute probabilities for measurements done by an outside observer. This has been used, for instance, to determine the probability of the right initial conditions for inflation, but it is marred by unresolved interpretational issues and still disputed. These problems can be avoided by using effective equations, in analogy to an effective action, which modify classical equations on small scales. Since the new equations are still of classical type, that is, differential equations in coordinate time, no interpretational issues arise at least if one stays in semiclassical regimes. In this manner, new inflationary scenarios motivated from quantum cosmology have been developed.

In general, a relational interpretation, though preferable conceptually, leads to technical complications since the situation is much more involved and evolution is not easy to disentangle. In cosmology, one often tries to single out one degree of freedom as internal time with respect to which evolution of other degrees of freedom is measured. In homogeneous models, one can simply take the volume as internal time, such as $a$ or $\mu$ earlier, but in full no candidate is known. Even in homogeneous models, the volume is not suitable as internal time to describe a possible recollapse. One can use extrinsic curvature around such a point, but then one has to understand what changing the internal time in quantum cosmology implies, that is, whether evolution pictures obtained in different internal time formulations are equivalent to each other.

There are thus many open issues at different levels, which, strictly speaking, do not apply only to quantum cosmology but to all of physics. After all, every physical system is part of the universe, and thus a potential ingredient of quantum cosmology. Obviously, physics works well in most situations without taking into account its being part of one universe. Similarly, much can be learned about a quantum universe if only some degrees of freedom of gravity are considered as in mini- or midisuperspace models. In addition, complicated interpretational issues, as important as they are for a deep understanding of quantum physics, do not prevent the development of physical applications in quantum cosmology, just as they did not do so in the early stages of quantum mechanics.

# Quantum Dynamical Semigroups

**R Alicki**, University of Gdańsk, Gdańsk, Poland

## Introduction

With a given quantum system we associate a Hilbert space $\mathcal{H}$ such that pure states of the system are represented by normalized vectors $\psi$ in $\mathcal{H}$ or equivalently by one-dimensional projections $|\psi\rangle\langle\psi|$, whereas mixed states are given by density matrices $\rho = \sum_j p_j |\psi_j\rangle\langle\psi_j|, p_j > 0, \sum_j p_j = 1$, that is, positive trace-1 operators and observables are identified with self-adjoint operators $A$ acting on $\mathcal{H}$. The mean value of an observable $A$ at a state $\rho$ is given by the following expression:

$$< A >_\rho = \mathrm{tr}(\rho A) \qquad [1]$$

The time evolution of the isolated system is determined by the self-adjoint operator $H$ (Hamiltonian) corresponding to the energy of the system. The infinitesimal change of state of the isolated system can be written as

$$\begin{aligned} \psi(t+dt) &= \psi(t) - \mathrm{i}H\mathrm{d}t\psi(t), \quad \text{or} \\ \rho(t+\mathrm{d}t) &= \rho(t) - \mathrm{i}\mathrm{d}t[H,\rho] \end{aligned} \qquad [2]$$

what leads to a reversible purity preserving unitary dynamics $\psi(t) = \mathrm{e}^{-\mathrm{i}tH}\psi, \rho(t) = \mathrm{e}^{-\mathrm{i}tH}\rho\mathrm{e}^{\mathrm{i}tH}$. We use the notation $[A,B] \equiv AB - BA, \{A,B\} = AB + BA$ and put $\hbar \equiv 1$. An interaction with environment leads to irreversible changes of the density matrix transforming, in general, pure states into mixed ones. Such a process can be modeled phenomenologically by a transition map $V : \mathcal{H} \mapsto \mathcal{H}$ leading to

$$\rho(t+\mathrm{d}t) = \rho(t) + \mathrm{d}tV\rho V^* - \mathrm{d}t\frac{1}{2}\{V^*V,\rho\} \qquad [3]$$

Combining Hamiltonian dynamics with several irreversible processes governed by a family of transition operators $\{V_j\}$ we obtain the following formal evolution equation in the Schrödinger picture (quantum Markovian master equation)

$$\begin{aligned} \frac{\mathrm{d}}{\mathrm{d}t}\rho(t) &= \mathcal{L}\rho(t) \\ &= -\mathrm{i}[H,\rho(t)] + \frac{1}{2}\sum_{j\in I}\left([V_j,\rho(t)V_j^*] + [V_j\rho(t),V_j^*]\right) \\ &= D\rho(t) + \rho(t)D^* + \Phi\rho(t) \end{aligned} \qquad [4]$$

with the initial condition $\rho(0) = \rho$. Here $D = -\mathrm{i}H - (1/2)\sum_j V_j^* V_j$, $\Phi\rho = \sum_{j\in I} V_j\rho V_j^*$, and $I$ is a certain countable set of indices. Assume for the moment that the Hilbert space $\mathcal{H} = \mathbb{C}^n$. Then the eqn [4] is always meaningful and its solution is given in terms of the exponential $\rho(t) = \Lambda(t)\rho \equiv \mathrm{e}^{t\mathcal{L}}\rho$. The linear map $\Phi$ is a general completely positive map on matrices, which preserves the positivity of $\rho$ and $\Phi \otimes \mathbb{I}_d$ preserves positivity of $nd \times nd$ matrices for arbitrary $d = 1,2,3,\ldots$ A useful Dyson-type expansion

$$\begin{aligned} \mathrm{e}^{t\mathcal{L}}\rho = \mathcal{W}(t)\rho + \sum_{k=1}^{\infty}\int_0^t dt_k \int_0^{t_k} dt_{k-1}\cdots \\ \times \int_0^{t_2} dt_1 \mathcal{W}(t-t_k)\Phi\mathcal{W}(t_k - t_{k-1}) \\ \times \Phi\cdots\Phi\mathcal{W}(t_1)\rho \end{aligned} \qquad [5]$$

with $\mathcal{W}(t)\rho \equiv W(t)\rho W(t)^*, W(t) = \mathrm{e}^{tD}$ shows that $\Lambda(t)$ is also completely positive. It is often convenient to describe quantum evolution in terms of observables (Heisenberg picture)

$$\begin{aligned} < A >_{\rho(t)} &= \mathrm{tr}\left((\mathrm{e}^{t\mathcal{L}}\rho)A\right) \\ &= \mathrm{tr}\left(\rho\,\mathrm{e}^{t\mathcal{L}^*}A\right) = < A(t) >_\rho \end{aligned} \qquad [6]$$

$$\begin{aligned} \frac{\mathrm{d}}{\mathrm{d}t}A(t) &= \mathcal{L}^*A(t) \\ &= \mathrm{i}[H,A(t)] + \frac{1}{2}\sum_{j\in I}\left(V_j^*[A(t),V_j] + [V_j^*,A(t)]V_j\right) \\ &= D^*\rho(t) + \rho(t)D + \Phi^*\rho(t) \end{aligned} \qquad [7]$$

with the initial condition $A(0) = A$, completely positive $\Phi^*A = \sum_{j\in I} V_j^* A V_j$ and the corresponding Dyson expansion.

The solutions of eqns [4] and [7] are given in terms of dynamical semigroups. Their general mathematical properties and particular examples will be reviewed in this article. Various methods of derivation of master equations for open quantum systems from the underlying Hamiltonian dynamics of composed systems will also be presented.

## Semigroups and Their Generators

For standard quantum-mechanical models it is convenient to define quantum dynamical semigroup in the Schrödinger picture as a one-parameter family $\{\Lambda(t); t \geq 0\}$ of linear and bounded maps acting on the Banach space of trace-class operators $\mathcal{T}(\mathcal{H})$ equipped with the norm $\|\sigma\|_1 = \mathrm{tr}(\sigma\sigma^*)^{1/2}$ and satisfying the following conditions:

1. *Composition (semigroup) law*

$$\Lambda(t)\Lambda(s) = \Lambda(t+s), \quad \text{for all } t,s \geq 0 \qquad [8]$$

2. *Complete positivity*

$$\Lambda(t) \otimes \mathbb{I}_d \text{ is positive on } \mathcal{T}(\mathcal{H} \otimes \mathbb{C}^d) \text{ for all } d = 1, 2, 3, \ldots \text{ and } t \geq 0 \quad [9]$$

3. *Conservativity* (*trace preservation*)

$$\mathrm{tr}(\Lambda(t)\rho) = \mathrm{tr}(\rho), \quad \text{for all } \rho \in \mathcal{T}(\mathcal{H}) \quad [10]$$

4. *Continuity* (*in a weak sense*)

$$\lim_{t \to 0} \mathrm{tr}(A\Lambda(t)\rho) = \mathrm{tr}(A\rho) \text{ for all } \rho \in \mathcal{T}(\mathcal{H}),\ A \in \mathcal{B}(\mathcal{H}) \quad [11]$$

From a general theory of one-parameter semigroups on Banach spaces it follows that under the conditions (1)–(4) $\Lambda(t)$ is a one-parameter strongly continuous semigroup of contractions on $\mathcal{T}(\mathcal{H})$ uniquely characterized by a generally unbounded but densely defined semigroup generator $\mathcal{L}$ with the domain $\mathrm{dom}(\mathcal{L}) \subset \mathcal{T}(\mathcal{H})$ such that for any $\rho \in \mathrm{dom}(\mathcal{L})$

$$\frac{\mathrm{d}}{\mathrm{d}t}\rho(t) = \mathcal{L}\rho(t), \quad \rho(t) = \Lambda(t)\rho \quad [12]$$

One can show that for $\lambda > 0$ the resolvent $R(\lambda) = (\lambda\mathbb{I} - \mathcal{L})^{-1}$ can be extended to a bounded operator satisfying $\|R(\lambda)\| \leq \lambda^{-1}$ and, therefore, the following formula makes sense:

$$\lim_{n \to \infty} \left(\mathbb{I} - \frac{t}{n}\mathcal{L}\right)^{-n} \rho = \Lambda(t)\rho, \quad \text{for all } \rho \in \mathcal{T}(\mathcal{H}) \quad [13]$$

Under the additional assumption that the generator $\mathcal{L}$ is bounded (and hence everywhere defined) Gorini, *et al.* (1976) and Lindblad (1976) proved that eqns [4] and [7] with bounded $H, V_j$ and $\sum_j V_j V_j^*$ provide the most general form of $\mathcal{L}$. The choice of $H$ and $V_j$ is not unique and the sum over $j$ can be replaced by an integral. In the case of $n$-dimensional Hilbert space we can always choose the form of eqn [4] with at most $n^2 - 1$ $V_j$'s. Sometimes the structure [4] is hidden as for the following useful example of the relaxation process to a fixed density matrix $\rho_0$ with the rate $\mu > 0$:

$$\frac{\mathrm{d}}{\mathrm{d}t}\rho(t) = \mu(\rho_0 - \rho(t)) \quad [14]$$

The general structure of an unbounded $\mathcal{L}$ is not known. However, the formal expressions [4] and [7] with possibly unbounded $D$ and $V_j$ are meaningful under the following conditions:

- the operator $D$ generates a strongly continuous contracting semigroup $\{\mathrm{e}^{tD}; t \geq 0\}$ on $\mathcal{H}$;
- $\mathrm{dom}(V_j) \supseteq \mathrm{dom}(D)$, for all $j$;
- $\langle\phi, D\psi\rangle + \langle D\phi, \psi\rangle + \sum_j \langle V_j\phi, V_j\psi\rangle = 0$, for all $\phi, \psi \in \mathrm{dom}(D)$.

We can solve eqn [4] in terms of a minimal solution. Defining by $Z$ the generator of the contracting semigroup $\rho \mapsto \mathrm{e}^{tD}\rho\mathrm{e}^{tD^*}$ and denoting by $J$ the completely positive (unbounded) map $\rho \mapsto \sum_{j \in I} V_j \rho V_j^*$, one can show that for any $\lambda > 0$, $J(\lambda\mathbb{I} - Z)^{-1}$ possesses a unique bounded completely positive extension denoted by $A_\lambda$ with $\|A_\lambda\| \leq 1$. Hence, for any $0 \leq r < 1$ there exists a strongly continuous, completely positive and contracting semigroup $\Lambda^{(r)}(t)$ with the resolvent explicitly given by

$$R^{(r)}(\lambda) = (\lambda\mathbb{I} - Z)^{-1} \sum_{k=0}^{\infty} r^k A_\lambda^k \quad [15]$$

As $\|R^{(r)}(\lambda)\| \leq 1$ the limit $\lim_{r \to 1} R^{(r)}(\lambda) = R(\lambda)$, where $R(\lambda)$ is the resolvent of the semigroup $\Lambda(t)$ satisfying (1), (2), and (4) and called the minimal solution of the eqn [4]. The minimal solution need not be a unique solution or conservative (generally $\mathrm{tr}\,\rho(t) \leq \mathrm{tr}\,\rho(0)$ and for any other solution $\rho'(t) \geq \rho(t)$). There exist useful sufficient conditions for conservativity, an example of a sufficient and necessary condition is the following: $A_\lambda^n \to 0$ strongly as $n \to \infty$ for all $\lambda > 0$ (Chebotarev and Fagnola 1988).

### Examples

**Bloch equation** The simplest two-level system can be described in terms of spin operators $S_k = (1/2)\sigma_k, k = 1, 2, 3$, where $\sigma_k$ are Pauli matrices. The most general master equation of the form [4] can be written as (Alicki and Fannes 2001, Ingarden *et al.* 1997)

$$\frac{\mathrm{d}\rho}{\mathrm{d}t} = -\mathrm{i}\sum_{k=1}^{3} h_k[S_k, \rho] + \frac{1}{2}\sum_{k,l=1}^{3} a_{kl}\{[S_k\rho, S_l] + [S_k, \rho S_l]\} \quad [16]$$

where $h_k \in \mathbb{R}$ and $[a_{kl}]$ is a $3 \times 3$ complex, positively defined matrix. Introducing the magnetization vector $M_k(t) = \mathrm{tr}(\rho(t)S_k)$, we obtain the following Bloch equation used in the magnetic resonance theory:

$$\frac{\mathrm{d}}{\mathrm{d}t}\boldsymbol{M}(t) = \boldsymbol{h} \times (\boldsymbol{M}(t) - \boldsymbol{M}_0) - \mathbb{F}(\boldsymbol{M}(t) - \boldsymbol{M}_0) \quad [17]$$

where the tensor $\mathbb{F}$ (real, symmetric, and positive $3 \times 3$ matrix) and the vector $\boldsymbol{M}_0$ are functions of $[a_{kl}]$. In particular, complete positivity implies the following inequalities for the inverse relaxation times $\gamma_1, \gamma_2, \gamma_3$ (eigenvalues of $\mathbb{F}$):

$$\gamma_k \geq 0, \quad \gamma_1 + \gamma_2 \geq \gamma_3, \quad \gamma_3 + \gamma_1 \geq \gamma_2, \quad \gamma_2 + \gamma_3 \geq \gamma_1 \quad [18]$$

**Damped and pumped harmonic oscillator** The quantum master equation for a linearly damped and pumped harmonic oscillator with frequency $\omega$ and the damping (pumping) coefficient $\gamma_{\downarrow}(\gamma_{\uparrow})$ has form

$$\frac{d\rho}{dt} = -i\omega[a^*a,\rho] + \frac{\gamma_{\downarrow}}{2}([a\rho,a^*]+[a,\rho a^*]) + \frac{\gamma_{\uparrow}}{2}([a^*\rho,a]+[a^*,\rho a]) \quad [19]$$

where $a^*, a$ are creation and annihilation operators satisfying $[a,a^*]=1$. Taking diagonal elements $p_n = <n,\rho n>$ in the "particle number" basis $a^*a|n>=n|n>$, $n=0,1,2,\ldots$, which evolve independently of the off-diagonal elements, one obtains the birth and death process,

$$\frac{dp_n}{dt} = \gamma_{\downarrow}(n+1)p_{n+1} + \gamma_{\uparrow}np_{n-1} - \big(\gamma_{\downarrow}n + \gamma_{\uparrow}(n+1)\big)p_n \quad [20]$$

It is convenient to use the Heisenberg picture and find an explicit solution in terms of Weyl unitary operators $W(z) = \exp[(i/\sqrt{2})(za+\bar{z}a^*)]$,

$$\Lambda^*(t)W(z) = \exp\left\{-\frac{|z|^2}{4}\frac{\gamma_{\downarrow}}{\gamma_{\downarrow}-\gamma_{\uparrow}}\left(1-e^{-(\gamma_{\downarrow}-\gamma_{\uparrow})t}\right)\right\}W(z(t)) \quad [21]$$

where $z(t)=\exp\{-(i\omega+\frac{1}{2}(\gamma_{\downarrow}-\gamma_{\uparrow}))t\}, t\geq 0$. For $\gamma_{\downarrow}>\gamma_{\uparrow}$ the solution of eqn [19] always tends to the stationary Gibbs state

$$\rho_{\beta} = Z^{-1}e^{-\beta\omega a^*a}, \qquad Z = \mathrm{tr}e^{-\beta\omega a^*a}$$
$$\beta = \frac{1}{\omega}\ln(\gamma_{\downarrow}/\gamma_{\uparrow}) \quad [22]$$

**Quasifree semigroups** The previous example is the simplest instance of the dynamical semigroups for noninteracting bosons and fermions which are completely determined on the single-particle level. Such systems are defined by a single-particle Hilbert space $\mathcal{H}_1$ and a linear map $\mathcal{H}_1 \ni \phi \mapsto a^*(\phi)$ into creation operators satisfying canonical commutation or anticommutation relations (CCRs or CARs, respectively) for bosons and fermions, respectively

$$[a(\psi),a^*(\phi)]_{\pm} = <\psi,\phi>$$
$$[A,B]_{\pm} \equiv AB - (\pm 1)BA \quad [23]$$

In all expressions containing $(\pm)$, sign $(+)$ refers to bosons and $(-)$ to fermions.

Consider a nonhomogeneous evolution equation on the trace-class operators $\sigma \in \mathcal{T}(\mathcal{H}_1)$:

$$\frac{d\sigma}{dt} = -i[H_1,\sigma] - \frac{1}{2}\{(\Gamma_{\downarrow}-(\pm)\Gamma_{\uparrow}),\sigma\} + \Gamma_{\uparrow} \quad [24]$$

with a single-particle Hamiltonian $H_1$ and a damping (pumping) positive operator $\Gamma_{\downarrow}(\Gamma_{\uparrow}) \geq 0$. The operators $H_1, \Gamma_{\downarrow}$, and $\Gamma_{\uparrow}$ need not be bounded provided $-iH_1 - (1/2)\{(\Gamma_{\downarrow} - (\pm)\Gamma_{\uparrow})$ generates a (contracting in the fermionic case) semigroup $\{T(t); t\geq 0\}$ on $\mathcal{H}_1$ and the formal solution of eqn [24]

$$\sigma(t) = T(t)\sigma(0)T^*(t) + Q(t)$$
$$\text{where } Q(t) = \int_0^t T(s)\Gamma_{\uparrow}T^*(s)ds \quad [25]$$

is meaningful. We can now define the quasifree dynamical semigroup for the many-particle system described by the Fock space $\mathcal{F}_{\pm}(\mathcal{H}_1)$ (Alicki and Lendi 1987, Alicki and Fannes 2001). The simplest definition involves Heisenberg evolution of the ordered monomials in $a^*(\psi_j)$ and $a(\phi_j)$:

$$\Lambda^*(t)a^*(\psi_1)\cdots a^*(\psi_m)a(\phi_1)\cdots a(\phi_n) = \sum_P \epsilon^{\pm}\mathrm{Det}_{\pm}\big[<\psi_{j_k},Q(t)\phi_{i_l}>\big]_{k,l=1,2,\ldots,r} \times a^*(T^*(t)\psi_{\alpha_1})\cdots a^*(T^*(t)\psi_{\alpha_{m-r}}) \times a\big(T^*(t)\phi_{\beta_1}\big)\cdots a\big(T^*(t)\phi_{\beta_{n-r}}\big) \quad [26]$$

The sum is taken over all partitions $\{(j_1,\ldots,j_r)(\alpha_1,\ldots,\alpha_{m-r})\}, \{(i_1,\ldots,i_r)(\beta_1,\ldots,\beta_{n-r}\}$ such that $j_1<j_2<\cdots<j_r$, $\alpha_1<\alpha_2,\cdots<\cdots<\alpha_{m-r}$, $i_1<i_2<\cdots<r_r$, $\beta_1<\beta_2\cdots<\alpha_{n-r}$; $\epsilon^+\equiv 1$, $\epsilon^-$ is a product of signatures of the permutations $\{1,2,\ldots,m\}\mapsto\{j_1,\ldots,j_r,\alpha_1,\ldots,\alpha_{m-r}\}, \{1,2,\ldots,n\}\mapsto\{i_1,\ldots,i_r,\beta_1,\ldots,\beta_{n-r}\}$; a permanent $\mathrm{Det}_+$ is taken for bosons, a determinant $\mathrm{Det}_-$ for fermions.

Introducing an orthonormal basis $\{e_k\}$ in $\mathcal{H}_1$ and using the notation $a^*(e_k)\equiv a_k^*$, we can write a formal master equation for density matrices on the Fock space corresponding to eqn [26]:

$$\frac{d\rho}{dt} = -i[H_F,\rho] + \frac{1}{2}\sum_{k,l}\Big(\Gamma_{\downarrow}^{kl}\big([a_k\rho,a_l^*] + [a_k,\rho a_l^*]\big) + \Gamma_{\uparrow}^{kl}\big([a_k^*\rho,a_l]+[a_k^*,\rho a_l]\big)\Big) \quad [27]$$

Again, formally,

$$H_F = \sum_{k,l} <e_k,H_1e_l>a_k^*a_l$$
$$\Gamma_{\downarrow}^{kl} = <e_k,\Gamma_{\downarrow}e_l>, \qquad \Gamma_{\uparrow}^{kl} = <e_k,\Gamma_{\uparrow}e_l> \quad [28]$$

Often the formulas [27], [28] are not well-defined, but replacing the (infinite) matrices by (distribution-valued) integral kernels, sums by integrals, and $a_k^*, a_l$ by quantum fields, we can obtain meaningful objects.

Quasifree dynamical semigroups find applications in the theory of unstable particles, quantum linear

optics, solid-state physics, quantum information theory, etc. (Alicki and Lendi 1987, Sewell 2002).

## Ergodic Properties

Dynamical semigroups which possess stationary states satisfying $\mathcal{L}\rho_0 = 0$ are of particular interest, for example, in the description of relaxation processes toward equilibrium states (Frigerio 1977, Spohn 1980, Alicki and Lendi 1987). The dynamical semigroup $\{\Lambda(t)\}$ with a stationary state $\rho_0$ is called ergodic if

$$\lim_{t\to\infty} \Lambda(t)\rho = \rho_0, \quad \text{for any initial } \rho \qquad [29]$$

For the case of finite-dimensional $\mathcal{H}$ at least one stationary state always exists. If, moreover, it is strictly positive, $\rho_0 > 0$, then we have the following sufficient condition of ergodicity:

$$\{V_j; j\in I\}' \equiv \{A; A\in\mathcal{B}(\mathcal{H}), [A, V_j] = 0, j\in I\} = \mathbb{C}\mathbf{1} \qquad [30]$$

Open systems interacting with heat baths at the temperature $T$ are described by the semigroups with generators [4] of the special form

$$\frac{\mathrm{d}}{\mathrm{d}t}\rho(t) = -\mathrm{i}[H,\rho(t)] + \frac{1}{2}\sum_{\omega_j\geq 0}\Big\{\Big([V_j,\rho(t)V_j^*] + [V_j\rho(t), V_j^*]\Big) + \mathrm{e}^{-\beta\omega_j}\Big([V_j^*,\rho(t)V_j] + [V_j^*\rho(t), V_j]\Big)\Big\} \qquad [31]$$

where

$$\beta = \frac{1}{k_{\mathrm{B}}T}, \qquad [H, V_j] = -\omega_j V_j \qquad [32]$$

The Gibbs state $\rho_\beta = Z^{-1}\,\mathrm{e}^{-\beta H}$ is a stationary state for eqn [31] and the condition $\{V_j, V_j^*; j\in I\}' = \mathbb{C}\mathbf{1}$ implies ergodicity (return to equilibrium). Moreover, the matrix elements of $\rho$ diagonal in $H$-eigenbasis transform independently of the off-diagonal ones and satisfy the Pauli master equation

$$\frac{\mathrm{d}p_k}{\mathrm{d}t} = \sum_l (a_{kl}p_l - a_{lk}p_k) \qquad [33]$$

with the detailed balance condition $a_{kl}\,\mathrm{e}^{-\beta E_l} = a_{lk}\,\mathrm{e}^{-\beta E_k}$, where $E_k$ are eigenvalues of $H$.

Define the new Hilbert space $\mathcal{L}^2(\mathcal{H},\rho_\beta)$ as a completion of $\mathcal{B}(\mathcal{H})$ with respect to the scalar product $(A,B)_{\rho_\beta} \equiv \mathrm{tr}(\rho_\beta A^* B)$. The semigroup's generators in the Heisenberg picture corresponding to eqn [31] are normal operators in $\mathcal{L}^2(\mathcal{H},\rho_\beta)$ with the Hamiltonian part $\mathrm{i}[H,\cdot\,]$ being the anti-Hermitian one (automatically for bounded $\mathcal{L}^*$, and for unbounded one under technical conditions concerning domains). This allows spectral decomposition of $\mathcal{L}^*$ and a proper definition of damping rates for the obtained eigenvectors. The normality condition is one of the possible definitions of quantum detailed balance. The other, based on the time-reversal operation, often coincides with the previous one for important examples.

Interesting examples of nonergodic dynamical semigroups are given for open systems consisting of $N$ identical particles with Hamiltonians $H^{(N)}$ and operators $V_j^{(N)}$ invariant with respect to particles permutations. Then the commutant $\{H^{(N)}, V_j^{(N)}, j\in I\}'$ contains an abelian algebra generated by projections on irreducible tensors corresponding to Young tables.

## From Hamiltonian Dynamics to Semigroups

One of the main tasks in the quantum theory of open systems is to derive master equations [4] from the model of a "small" open system $S$ interacting with a "large" reservoir $R$ at a certain reference state $\omega_R$ (Davies 1976, Spohn 1980, Alicki and Lendi 1987, Breurer and Petruccione 2002, Garbaczewski and Olkiewicz 2002). Starting with the total Hamiltonian $H_\lambda = H_S\otimes\mathbf{1}_R + \mathbf{1}_S\otimes H_R + \lambda\sum_\alpha S_\alpha\otimes R_\alpha$, where $S_\alpha = S_\alpha^*, R_\alpha = R_\alpha^*, \mathrm{tr}(\omega_R R_\alpha) = 0$, and $\lambda$ is a coupling constant, we define the reduced dynamics of $S$ by

$$\rho(t) = \Lambda^{(\lambda)}(t)\rho = \mathrm{tr}_R\big(U_\lambda(t)\rho\otimes\omega_R U_\lambda^*(t)\big) \qquad [34]$$

with $U_\lambda(t) = \exp(-\mathrm{i}tH_\lambda)$. Here $\mathrm{tr}_R$ denotes a partial trace over $R$ defined in terms of an arbitrary basis $\{e_k\}$ of $R$ by the formula $<\phi,(\mathrm{tr}_R A)\phi> = \sum_k <\phi\otimes e_k, A\phi\otimes e_k>$. Generally, $\Lambda^{(\lambda)}(t+s)\neq\Lambda^{(\lambda)}(t)\Lambda^{(\lambda)}(s)$, but dynamical semigroups can provide good approximations in important cases.

### Weak-Coupling Limit

Under the conditions of sufficiently fast decay of multitime correlation functions constructed from the observables $R_\alpha$ at the state $\omega_R$, one can prove that for small coupling constant $\lambda$ the exact dynamical map $\Lambda^{(\lambda)}(t)$ can be approximated by the dynamical semigroup corresponding to the following master equation:

$$\frac{\mathrm{d}}{\mathrm{d}t}\rho(t) = -\mathrm{i}[H,\rho(t)] + \frac{\lambda^2}{2}\sum_{\alpha\beta}\sum_{\omega\in Sp} C_{\alpha\beta}(\omega) \times\Big([V_\omega^\alpha,\rho(t)V_\omega^{\beta*}] + [V_\omega^\alpha\rho(t), V_\omega^{\beta*}]\Big) \qquad [35]$$

where $H = H_S + \lambda^2 \sum_{\alpha\beta} \sum_{\omega\in Sp} K_{\alpha\beta}(\omega) V_\omega^{\alpha*} V_\omega^\beta$ is a renormalized Hamiltonian, $\sum_{\omega\in Sp}$ denotes the sum over eigenfrequencies of $-[H,\cdot]$, $e^{itH} S_\alpha e^{-itH} = \sum_{\omega\in Sp} V_\omega^\alpha e^{-i\omega t}$ and

$$\int_0^\infty e^{i\omega t}\mathrm{tr}\big(\omega_R e^{itH_R} R_\alpha e^{-itH_R} R_\beta\big)dt = \tfrac{1}{2} C_{\alpha\beta}(\omega) + iK_{\alpha\beta}(\omega) \quad [36]$$

The rigorous derivation involves van Hove or weak coupling limit, $\lambda \to 0$, with $\tau = \lambda^2 t$ kept fixed.

It follows from the Bochner theorem that the matrix $[C_{\alpha\beta}(\omega)]$ is positively defined and therefore by its diagonalization we can convert eqn [35] into the standard form [4]. If the reservoir's state $\omega_R$ is an equilibrium state (Kubo–Martin–Schwinger state) then $C_{\alpha\beta}(-\omega) = e^{-\omega/k_B T}\ C_{\beta\alpha}(\omega)$ and therefore eqn [35] can be written in a form [31]. Moreover, transition probabilities $a_{kl}$ from eqn [33] coincide with those obtained using the "Fermi golden rule."

### Low-Density Limit

If the reservoir can be modeled by a gas of noninteracting particles (bosons or fermions) at low density $\nu$, we can derive the following master equation which approximates an exact dynamics [34] in the low-density limit ($\nu \to 0$, with $\tau = \nu t$ kept fixed)

$$\frac{d}{dt}\rho(t) = -i[H,\rho(t)] + \nu\pi \sum_{\omega\in S} \int_{\mathbb{R}^6} d^3\boldsymbol{p}\, d^3\boldsymbol{p}' G(\boldsymbol{p}) \times \delta\big(E_{p'} - E_p + \omega\big)\big([T_\omega(\boldsymbol{p},\boldsymbol{p}'),\rho(t)T_\omega(\boldsymbol{p},\boldsymbol{p}')^*] + [T_\omega(\boldsymbol{p},\boldsymbol{p}')\rho(t), T_\omega(\boldsymbol{p},\boldsymbol{p}')^*]\big) \quad [37]$$

Here $H$ is a renormalized Hamiltonian of the system S, $e^{itH} T e^{-itH} = \sum_{\omega\in S} T_\omega e^{-i\omega t}$, $T$ is a $T$-matrix describing the scattering process involving $S$ and a single particle, $T = V\Omega_+$, where $V$ is a particle-system potential and $\Omega_+$ is a Møller operator. $T_\omega(\boldsymbol{p},\boldsymbol{p}')$ denotes the integral kernel corresponding to $T_\omega$ expressed in terms of momenta of the bath particle, $E_p$ the kinetic energy of a particle, and $G(\boldsymbol{p})$ its probability distribution in the momentum space. If $G(\boldsymbol{p}) \sim \exp(-E_p/k_B T)$ and microreversibility conditions, $E_p = E_{-p}$ and $T_\omega(-\boldsymbol{p},-\boldsymbol{p}') = T_\omega(\boldsymbol{p}',\boldsymbol{p})$, hold, then eqn [37] satisfies the quantum detailed-balance condition with the stationary Gibbs state $\rho_\beta$, $\beta = 1/k_B T$.

## Entropy and Purity

The relative entropy $S(\rho\,|\,\sigma) = \mathrm{tr}(\rho\ln\rho - \rho\ln\sigma)$ is monotone with respect to any trace-preserving completely positive map $\Lambda$, that is, $S(\Lambda\rho|\Lambda\sigma) \le S(\rho|\sigma)$. Hence, for the quantum dynamical semigroup $\Lambda(t)$ with the stationary state $\rho_0$ we obtain the following relation for the von Neumann entropy $S(\rho) = -\mathrm{tr}(\rho\ln\rho)$:

$$\frac{d}{dt}S(\rho(t)) = -\frac{d}{dt}S(\rho(t)|\rho_0) - \frac{d}{dt}\mathrm{tr}(\rho(t)\ln\rho_0) \quad [38]$$

where $-(d/dt)S(\rho(t)\,|\,\rho_0) \ge 0$ is an entropy production and the second term describes entropy exchange with environment (Spohn 1980, Alicki and Lendi 1987).

Bistochastic dynamical semigroups preserve the maximally mixed state, that is, $\mathcal{L}(\mathbf{1}) = 0$. For them, the von Neumann entropy does not decrease and the purity $\mathrm{tr}\,\rho^2$ never increases (Streater 1995). Two important classes of master equations, used to describe decoherence, yield bistochastic dynamical semigroups:

$$\frac{d}{dt}\rho(t) = -i[H,\rho(t)] - \sum_j [A_j,[A_j,\rho(t)]],\ \ A_j = A_j^* \quad [39]$$

$$\frac{d}{dt}\rho(t) = -i[H,\rho(t)] + \int_M \mu(d\alpha)(U(\alpha)\rho(t)U^*(\alpha) - \rho(t)) \quad [40]$$

where $U(\alpha)$ are unitary and $\mu(\cdot)$ is a (positive) measure on $M$.

## Itô–Schrödinger Equations

Up to technical problems in the case of unbounded operators, the master equation [4] is completely equivalent to the following stochastic differential equation (in Itô form):

$$d\psi(t) = -iH\psi(t)\,dt - \frac{1}{2}\sum_{j\in I} V_j^* V_j \psi(t)\,dt - i\sum_{j\in I} V_j\psi(t)dX_j(t) \quad [41]$$

where $X_j(t)$ are arbitrary statistically independent stochastic processes with independent increments (continuous or jump processes) such that the expectation $E(dX_j(t)\,dX_k(t)) = \delta_{jk}\,dt$. Equation [41] should be understood as an integral equation involving stochastic Itô integrals with respect to $\{X_j(t)\}$ computed according to the Itô rule: $dX_j(t)\,dX_k(t) = \delta_{jk}\,dt$. Taking the average $\rho(t) = E(|\psi(t)><\psi(t)|)$ one can show, using the Itô rule, that $\rho(t)$ satisfies eqn [4]. For numerical

applications, it is convenient to use the nonlinear version of eqn [41] for the normalized stochastic vector $\phi(t) = \psi(t)/\|\psi(t)\|$, which can be easily derived from eqn [41] (Breurer and Petruccione 2002).

Introducing quantum noises, for example, quantum Brownian motions defined in terms of bosonic or fermionic fields and satisfying suitable quantum Itô rules one can develop the theory of noncommutative stochastic differential equations (NSDE) (Hudson and Parthasarathy 1984). Both, eqn [41] and NSDE, provide examples of unitary dilations – (physically singular) mathematical constructions of the environment $R$ and the $R$–$S$ coupling which exactly reproduce dynamical semigroups as reduced dynamics [34].

## Algebraic Formalism

In order to describe open systems in thermodynamical limit (e.g., infinite spin systems) or systems in the quantum field theory one needs the formalism based on $C^*$ or von Neumann algebras. In the $C^*$-algebraic language, by dynamical semigroup (in the Heisenberg picture) we mean a family $\{T(t); t \geq 0\}$ of linear maps on the unital $C^*$-algebra $\mathcal{A}$ satisfying the following conditions: (1) complete positivity, (2) $T(t)T(s) = T(t+s)$, (3) weak (or strong) continuity, and (4) $T(t)\mathbf{1} = \mathbf{1}$. Assuming the existence of a faithful stationary state $\omega = \omega \circ T(t)$ on $\mathcal{A}$, one can use a Gelfand–Naimark–Segal (GNS) representation $\pi_\omega(\mathcal{A})$ of $\mathcal{A}$ in terms of bounded operators on the suitable Hilbert space $\mathcal{H}_\omega$ with the cyclic and separating vector $\Omega$ satisfying $\omega(A) = <\Omega, \pi_\omega(A)\Omega>$ for all $A \in \mathcal{A}$. Then the dynamical semigroup can be defined on the von Neumann algebra $\mathcal{M}$ (obtained by a weak closure of $\pi_\omega(\mathcal{A})$) as $\hat{T}(t)\pi_\omega(A) \equiv \pi_\omega(T(t)A)$. The Kadison inequality valid even for 2-positive bounded maps $\Lambda$ on $\mathcal{A}$

$$\Lambda(AA^*) \geq \Lambda(A)\Lambda(\mathbf{1})\Lambda(A^*) \qquad [42]$$

implies that $\omega([T(t)A]^* T(t)A) \leq \omega(A^*A)$, which allows one to extend the dynamical semigroup to the contracting semigroup $\tilde{T}(t)[\pi_\omega(A)\Omega] \equiv [\pi_\omega(T(t)A)]\Omega$ on the GNS Hilbert space $\mathcal{H}_\omega$. Typically, one tries to define the semigroup in terms of the proper limiting procedures $T(t) = \lim_{n\to\infty} T_n(t)$, where $T_n(t)$ is well defined on $\mathcal{A}$. However, the limit may not exist as an operator on $\mathcal{A}$ but can be well defined on the von Neumann algebra $\mathcal{M}$. If not, the contracting semigroup on $\mathcal{H}_\omega$ may still be a useful object.

Although there exists a rich ergodic theory of dynamical semigroups for the special types of von Neumann algebras, the most difficult problem of constructing physically relevant semigroups for generic infinite systems remains unsolved (Majewski and Zegarliński 1996, Garbaczewski and Olkiewicz 2002).

## Nonlinear Dynamical Semigroups

The reduced description of many-body classical or quantum systems in terms of single-particle states (probability distributions, wave functions, or density matrices) leads to nonlinear dynamics (e.g., Boltzmann, Vlasov, Hartree, or Hartree–Fock equations) (Spohn 1980, Garbaczewski and Olkiewicz 2002). A large class of nonlinear evolution equations for single-particle density matrices $\rho$ can be written as Alicki and Lendi (1987)

$$\frac{\mathrm{d}\rho}{\mathrm{d}t} = \mathcal{L}[\rho]\rho \qquad [43]$$

where $\sigma \mapsto \mathcal{L}[\sigma]$ is a map from density matrices to semigroup generators of the type [4]. Under certain technical conditions the solution of eqn [43] exists and defines a nonlinear dynamical semigroup – a family $\{\Gamma(t); t \geq 0\}$ of maps on the set of density matrices satisfying the composition law $\Gamma(t+s) = \Gamma(t)\Gamma(s)$.

A simple example is provided by an open $N$-particle system with the total Hamiltonian invariant with respect to particle permutations. The Markovian approximation combined with the mean-field method leads to a nonlinear dynamical semigroup which preserves purity and for initial pure states is governed by the nonlinear Schrödinger equation with the following structure:

$$\begin{aligned}\frac{\mathrm{d}\psi}{\mathrm{d}t} &= -\mathrm{i}(h + NU(\psi))\psi \\ &\quad + \frac{N}{2}\sum_j \Big( <\psi, V_j^*\psi> V_j\psi \\ &\quad - <\psi, V_j\psi> V_j^*\psi \Big)\end{aligned} \qquad [44]$$

Here $h$ is a single-particle Hamiltonian, $U(\psi)$ a Hartree potential, and $V_j$ are single-particle operators describing collective dissipation.

# Quantum Dynamics in Loop Quantum Gravity

**H Sahlmann**, Universiteit Utrecht, Utrecht, The Netherlands

## Introduction

In general relativity, the metric is a dynamic entity, there is no preferred notion of time, and the theory is invariant under diffeomorphisms. Therefore, one expects the concept of dynamics to be very different from that in mechanical or special relativistic systems. Indeed, in a canonical formulation, the diffeomorphism symmetry manifests itself through the appearance of constraints (*see* Constrained Systems). In particular, in the absence of boundaries, the Hamiltonian turns out to be a linear combination of them. Thus, the dynamics is completely encoded in the constraints.

To quantize such a system following Dirac, one has to define operators corresponding to the constraints on an auxiliary Hilbert space. Solutions to the quantum dynamics are then vectors that are annihilated by all the constraint operators. Technical complications can arise, and the solutions might not lie in the auxiliary Hilbert space but in an appropriately chosen dual.

Physical observables on the other hand are associated with operators on the auxiliary space that commute with the constraints or, equivalently, operators that act within the space of solutions.

Since the solutions of the quantum dynamics will not depend on any sort of time parameter in an explicit way, they cannot be readily interpreted as a (quantum) spacetime history. The conceptual questions related to this are known as the "problem of time" in quantum gravity.

We should mention that there is a proposal – consistent discretizations – that allows us to eliminate constraints, at the expense of a discretization of the classical theory and dynamical specification of Lagrange multipliers. Application of this technique to gravity is currently under study.

Loop quantum gravity (LQG) (*see* Loop Quantum Gravity) is based on the choice of a canonical pair $(A_a, E^b)$ of an SU(2) connection and an su(2)-valued vector density. The constraints come in three classes:

$$G_i[A,E](x) = 0, \qquad V_a[A,E](x) = 0, \qquad C[A,E](x) = 0$$

the Gauss, vector, and scalar constraints, respectively.

Before giving some detail about the quantization of the constraints and their solutions, we should mention that there exists an analogous classical formulation in terms of complex (self-dual) variables. The quantization in that formulation faces serious technical obstacles, but in the case of positive cosmological constant an elegant formal solution to all the constraints – the Kodama state – is known. It is related to the Chern–Simons action on the spatial slice.

As said before, strictly speaking, implementing the dynamics comprises quantizing and satisfying all the constraints. Here we will however focus on $C$ since it is the most challenging, and most closely related to standard dynamics in that it generates changes under timelike deformations of the Cauchy surface $\Sigma$ on which the canonical formulation is based.

The quantum solutions of the other constraints, linear combinations of $s$-knots, lie in a Hilbert space $\mathcal{K}_{\text{diff}}$ which is part of the dual of the kinematical Hilbert space $\mathcal{K}$ of the theory. For details on these solutions as well as some basic definitions that will be used without comment below (*see* Loop Quantum Gravity). Since $s$-knots are labeled, among other things, by a diffeomorphism equivalence class of a graph, relations to knot theory are emerging at this level (*see* Knot Invariants and Quantum Gravity).

It is important to note that $C$ does not Poisson-commute with the diffeomorphism constraints. Therefore, in the quantum theory it does matter in which order the constraints are solved. It turns out that on the quantum solutions to the other constraints, the scalar constraint can be defined by introducing a regulator, and stays well defined even when the regulator is removed. This ultraviolet finiteness on $\mathcal{K}_{\text{diff}}$ can be intuitively understood from the diffeomorphism invariance of its elements: There is no problematic short-distance regime since the states do not contain any scale at all.

In the following we will briefly review the implementation of the scalar constraint in LQG and comment on some ramifications and open questions.

## The Scalar Constraint Operator

In the Lorentzian theory the scalar constraint $C$ is the sum of the scalar constraint $C^{\text{E}}$ of the Euclidean theory:

$$C^{\text{E}} = (\det q)^{-1/2}\,\text{tr}(F_{ab}[E^a, E^b])$$

a second term of a similar form, but with the curvature $F$ of the connection $A$ replaced by the curvature associated to a certain triad $e$, and possibly matter terms. In the following we will just discuss $C^{\text{E}}$, the other terms can be handled in a similar fashion.

There appear to be a number of obstacles to the quantization of $C^{\text{E}}$: for one, the inverse of the determinant would likely be ill defined, as the volume operator – essentially a quantization of $\int(\det q)^{1/2}$ – has a large kernel. In addition, there are no well-defined operators corresponding to $F$ and $E$ evaluated at points. Rather, only holonomies $h_e[A]$ of $A$ along curves $e$ and certain functionals of $E$ are well defined as operators. These issues can however be dealt with in an elegant way as follows.

The first step is to absorb the determinant factor into a Poisson bracket,

$$C^{\text{E}} = \frac{2}{\kappa}\epsilon^{abc}\,\text{tr}(F_{ab}\{A_c, V\})$$

where $V$ is the volume of the spatial slice $\Sigma$. Then one approximates the curvature by (identity minus) the holonomy around a small loop. In the present case one finds that for a small tetrahedron $\Delta$ with base point $v$, one can approximate

$$\begin{aligned} C^{\text{E}}_{\Delta}(N) &:= 2\kappa^{-1}\int_{\Delta} N\,\text{tr}(F\wedge\{A,V\}) \\ &\approx -\frac{2}{3\kappa}N(v)\epsilon^{ijk}\,\text{tr}(h_{\alpha_{ij}}h_{s_k}\{h_{s_k}^{-1}, V\}) \quad [1] \end{aligned}$$

where (see **Figure 1a**)) the $s_i$ are edges of $\Delta$ incident at $v$ and the $\alpha_{ij}$ loops around the faces of $\Delta$ incident at $v$.

This suggests how to define an operator $\widehat{C}^{\text{E}}_{\Gamma}$ that acts on cylindrical functions on a given graph $\Gamma$: one chooses a triangulation adapted to the graph and quantizes the $C^{\text{E}}_{\Delta}(N)$ (where $\Delta$ is a tetrahedron of this triangulation) using the right-hand side of [1] – holonomies are quantized by the holonomy operators of the quantum theory, $V$ by the volume operator $\widehat{V}$, and the Poisson bracket by the corresponding commutator divided by $i\hbar$. To be more precise, the triangulation is chosen such that the $s_k$ in [1] are part of $\Gamma$, and the operators corresponding to the $h_\alpha$ are creating new edges that connect the endpoints of the $s_k$ (see **Figure 1b**).

Still this is not sufficient, since the definition of $\widehat{C}^{\text{E}}_{\Gamma}$ depends quite heavily on the choice of the triangulation, and there is no natural way to choose one. Furthermore, there is no choice that would guarantee

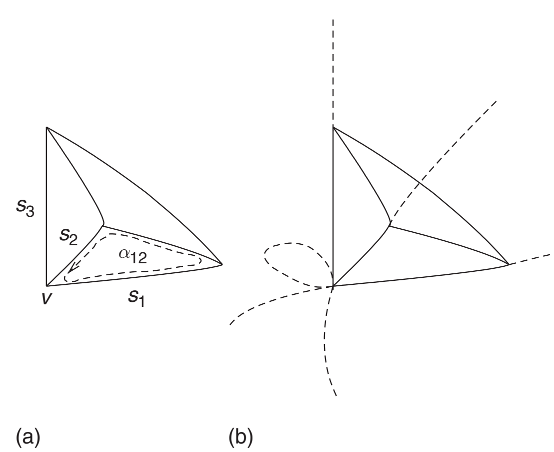

**Figure 1** (a) A tetrahedron $\Delta$ and its labeling of edges and loops. (b) A tetrahedron $\Delta$ adapted to the edges (dashed lines) of a graph $\Gamma$.

that the $\widehat{C}^{E}_{\Gamma}$ for different $\Gamma$ are consistent in the sense that they correspond to the action of the same operator $\widehat{C}^{E}$ on two different cylindrical subspaces. Here, the diffeomorphism invariance of the theory comes to the rescue: a well-defined operator largely free of ambiguities can be obtained by letting the operators above act (by duality) on $\mathcal{K}_{\text{diff}}$ to give elements in $\mathcal{K}^*$. When acting on diffeomorphism-invariant states, the ambiguities in the definition of the triangulations can be eliminated, and the operators $\widehat{C}^{E}_{\Gamma}$ for different $\Gamma$ are consistent and together define an operator $\widehat{C}^{E}(N)$. Roughly speaking, for a diffeomorphism-invariant state, it does not matter anymore where on the graph the endpoints of the $s_k$ lie and how they are connected to form the loops $\alpha$. The final picture looks as follows: for each s-knot $s$, the operator gives a sum of contributions, one for each vertex of $s$, that is, $\widehat{C}^{E}(N)s = \sum_v \widehat{C_v}(N)s$. The terms in this sum are not diffeomorphism invariant. Their evaluation on a spin network $S$ is of the form

$$(\widehat{C_v}s)[S] = \sum_{s'} c(s')N(x(v))s'[S] \qquad [2]$$

where the $s'$ are $s$-knots that differ from $s$ by the addition or deletion of certain edges, and corresponding changes in coloring (by $\pm 1/2$) and intertwiners. As an example, Figure 2 schematically depicts the action on a trivalent vertex. The point $x(v)$ on which $N$ is evaluated in the above formula gets determined as follows: the evaluation $s'[S]$ is zero unless the graph $\Gamma$ on which $S$ is based is an element in the diffeomorphism equivalence class on which $s'$ is based. $x(v)$ is the position of the vertex $v$ in this element of the equivalence class. Because of this $x(v)$, the action of $\widehat{C}^{E}(N)$ is not diffeomorphism invariant.

Similar techniques give a quantization $\widehat{C}$ of the full constraint. The solutions to the constraint can be determined as the vectors $\psi \in \mathcal{K}_{\text{diff}}$ that are annihilated by $\widehat{C}$ in the sense that $(\widehat{C}(N)\psi)[f] = 0$ for all functions $N$ and elements $f$ of $\mathcal{K}$. The solutions are more or less explicitly known; however, the task of interpreting them is a hard one and remains an object of current research.

It should be mentioned that, strictly speaking, one can arrive at several slightly different versions of the

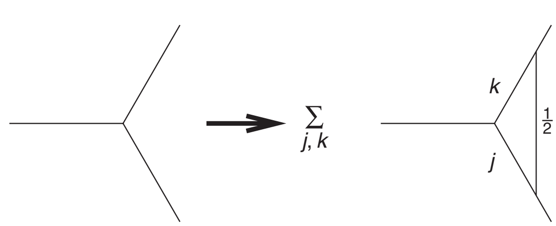

**Figure 2** A schematic rendering of the action of the operator $\widehat{C}_v$ for a trivalent vertex.

constraint operator along the lines sketched above. The quantization ambiguities include changes in the power of the volume operator and the spin quantum number that the constraint creates or annihilates. An interesting check on these quantizations would be to inspect the algebra of constraint operators for anomalies. In the present situation, this can only be carried out to a certain extent, because $\widehat{C}$ is defined on diffeomorphism-invariant states. The Poisson bracket between two scalar constraints is proportional to a diffeomorphism constraint, and indeed it turns out that in the quantum theory the commutator of two scalar constraint operators vanishes for quantizations as described above. In that sense they are ambiguity free; however, this criterion is not strong enough to distinguish between the candidates.

Recently, a slightly different strategy has been proposed, which, if successfully implemented, would eliminate some of the questions regarding the constraint algebra. The idea is to combine the constraints $C(N)$ for different lapse functions $N$ into one master constraint

$$M = \int_{\Sigma} (\det q)^{-1/2} C^2 \, \mathrm{d}^3 x$$

$M$ is manifestly diffeomorphism invariant and could replace all the noncommuting constraints $C(N)$, hence simplifying the constraint algebra considerably.

The interpretation of the solutions of all the constraints hinges on the construction of observables for the theory. This is already a difficult task in the classical theory, and thus even more so after quantization. Though there is no general solution to this problem available, interesting proposals are being studied.

Finally, it should be said that the quantization of the scalar constraint can be used to obtain a picture that resembles more the standard time evolution in quantum field theory. The (formal) power series expansion of the projector

$$P = \prod_{x \in \Sigma} \delta(\widehat{C}(x)) = \int D[N] \exp\left[ \mathrm{i} \int_{\Sigma} N(x)\widehat{C}(x) \right]$$

onto the kernel of $\widehat{C}$ can be described by a spin foam model (*see* Spin Foams).

## Introduction

Quantum electrodynamics (QED) describes the interaction of the electromagnetic field (EMF) with charged particles. Any physical particle interacts, directly or indirectly, with any other particle (including itself); in the case of the electron, however, at low and medium energy (say, up to a few GeV) the interaction with the EMF is by and far the most important, so that QED describes with great precision the dynamics of the electron, and at the same time the electron provides with the most stringent tests of QED currently available.

In the various sections of this article we will discuss, in the following order, the origin of QED, the structure of the radiative corrections, the application of QED to various bound states problems (the hydrogen-like atoms, the muonium, and positronium) and the anomalous magnetic moments of the leptons (the muon and the electron).

## Origin of QED

The origin of QED can ideally be traced back to the very beginning of quantum mechanics, the blackbody formula by M Planck (1900), which was soon understood as pointing to a discretization of the energy and momentum associated to the EMF into quanta of light or photons (Einstein 1905).

The quantization of the EMF was first worked out by P Jordan, within the article (1926) by M Born, W Heisenberg, and P Jordan (usually referred to as the *Dreimännerarbeit*) and then in the paper "The quantum theory of emission and absorption of radiation" by PAM Dirac, commonly considered the beginning of the so-called second quantization formalism.

In the subsequent year (1928) Dirac published the famous equation for the relativistic electron, from which it was immediately deduced, on a firmer basis, that the electron has spin 1/2, that its spin gyromagnetic ratio (the ratio between spin and associated magnetic moment in suitable dimensionless units; see below for more details) is twice the value predicted by classical physics (a result expressed as $g_e = 2$) and that the levels of atomic hydrogen with the same principal quantum number $n$ are not fully degenerate, as in the nonrelativistic limit, but do possess the so-called fine structure splitting. In particular, the energy of the $n = 2$ levels splits into two values, one value for $2P_{3/2}$ states with total angular momentum $J = 3/2$ and another value for the states $2S_{1/2}$ and $2P_{1/2}$, which have $J = 1/2$; note that the $2S_{1/2}$ and $2P_{1/2}$ states are still degenerate.

Very soon it was realized that Dirac's equation also requires that each particle must be accompanied by its antiparticle, with exactly the same mass and opposite charge. The antiparticle of the electron, the positron, was indeed discovered by C Anderson

(1932), establishing Dirac's equation as one of the cornerstones of theoretical physics.

All the ingredients needed for the evaluation of the perturbative corrections to the QED theory (usually called radiative corrections) were already present at that moment, but radiative corrections were not systematically investigated for several years, due perhaps to the length and difficulty of the calculations and the absence of important disagreements between theoretical predictions and experimental results.

The situation changed in 1947, when two experiments were carried out, measuring the energy difference between the $2^2S_{1/2}$ and $2^2P_{1/2}$ levels of the hydrogen atom and the gyromagnetic ratios of the electron.

Lamb and Retherford (1947), by using the "great wartime advances in microwaves techniques," succeeded in establishing that in the hydrogen atom "the $2^2S_{1/2}$ state is higher than the $2^2P_{1/2}$ by about 1000 Mc/sec.," while (as observed above) according to the Dirac theory the two states are expected to have exactly the same energy. Subsequent refinements of the experiment (Triebwasser *et al.* 1953) gave for the difference (now referred to as Lamb shift) the value $1057.77 \pm 0.10$ MHz, with a relative error $1 \times 10^{-4}$.

The authors of the second 1947 experiment (Kusch and Foley 1947) measured the frequencies associated with the Zeeman splitting of two different states of gallium, finding an inconsistency with the theoretical values of the gyromagnetic ratios of the electron. More exactly, write the magnetic moments $\boldsymbol{\mu}_L, \boldsymbol{\mu}_S$ associated to the (dimensionless) orbital and spin angular momenta $\boldsymbol{L}, \boldsymbol{S}$ of the electron as

$$\boldsymbol{\mu}_L = -g_L \frac{e\hbar}{2m_e c}\boldsymbol{L}, \quad \boldsymbol{\mu}_S = -g_S \frac{e\hbar}{2m_e c}\boldsymbol{S} \qquad [1]$$

where $(-e)$ is the charge of the electron $(e > 0)$, $m_e$ its mass, $c$ the speed of light and $g_L, g_S$, respectively, the orbital and spin gyromagnetic ratios; the Dirac theory then predicts $g_L = 1$ and $g_S = 2$, while the results of Kusch and Foley (1947) gave a discrepancy which could be accounted for by taking $g_S = 2.00229 \pm 0.00008$ and $g_L = 1$, or alternatively $g_S = 2$ and $g_L = 0.99886 \pm 0.00004$. In modern notation the first conjecture can be rewritten as

$$g_S = g_e = 2(1 + a_e), \quad a_e = 0.001145 \pm 0.00004 \qquad [2]$$

where $a_e$ is the anomalous magnetic moment (or magnetic anomaly) of the electron.

The need of explaining the two experimental results gave rise to a rapid development of covariant perturbation theory (which replaced the previous noncovariant "old fashioned" perturbation theory) and of the renormalization theory, which liberated the perturbative expansion from the divergences plaguing the older approach, opening the path to the evaluation of radiative corrections and to the great success of precision predictions of QED.

The formalism improved quickly, evolving in the more general quantum field theory (QFT) approach; three of the main contributors were Sin-Itiro Tomonaga, Julian Schwinger, and Richard P Feynman, awarded a few years later (1965) the Nobel price "for their fundamental work in quantum electrodynamics, with deep-ploughing consequences for the physics of elementary particles." QFT was then successfully used for describing the weak interactions in the electroweak model and later on also for the strong interactions theory, dubbed quantum chromodynamics (or QCD, in analogy with the popular QED acronym). For more details and references to original works, the reader is invited to look at any treatise on QED or QFT, such as, for instance, Weinberg (1995).

Initially, the Lamb shift was perhaps more important than the electron magnetic anomaly both for the establishment of renormalization theory and as a test of QED, but in the following years it was supplanted by the latter as a precision test of QED.

In 1947 the "best values" for some fundamental constants were indeed

$$\begin{aligned} c &= (2.99776 \pm 0.00004) \times 10^{10}\,\text{cm s}^{-1} \\ R_\infty &= \frac{m_e c^2 \alpha^2}{2hc} = 109737.303 \pm 0.017\,\text{cm}^{-1} \\ 1/\alpha &= 137.030 \pm 0.016 \end{aligned} \qquad [3]$$

where $R_\infty$ is the Rydberg constant for infinite mass, $h$ the Planck constant, and $\alpha$ the fine structure constant (let us observe here in passing that $R_\infty$ was and is still known much better than the separate values of $m_e, \alpha$, and $h$ entering in its definition); for comparison, the current (2005) values for $c$ and $R_\infty$ are

$$\begin{aligned} c &= 299792458\,\text{m s}^{-1} \\ R_\infty &= 109737.31568525(73)\,\text{cm}^{-1} \end{aligned} \qquad [4]$$

where the value of $c$ is exact (it is in fact the definition of the meter), and the relative error in $R_\infty$ is $6.6 \times 10^{-12}$ (the value of $\alpha$ will be discussed later). The measurement of the Lamb shift, repeated several times, gave results in nice agreement with the original value, and for several years it was providing either a test of QED or a precise value for $\alpha$. But the Lamb shift is the energy difference between the metastable level $2S_{1/2}$ (whose lifetime

is about 1/7 s) and the $2P_{1/2}$ level, which has a lifetime of about 1.596 ns or a natural linewidth of 99.7 MHz. Such a large linewidth poses a strong intrinsic limitation to the precision attainable in the measure of the Lamb shift, which is just ten times larger; as a matter of fact, that precision could never reach the $1 \times 10^{-6}$ relative error level, while in the meantime the relative precision in $a_e$ reached the $10^{-9}$ range, replacing the Lamb shift in the role of the leading quantity in high-precision QED.

## The Structure of Radiative Corrections

For obvious space problems we can only superficially sketch here the lines along which the perturbative expansion of QED leading to the evaluation of radiative corrections can be built, considering for simplicity only the photon and the electron. One can start from a QED Lagrangian, formally similar to the classical Lagrangian, involving the electron field and the vector potentials of the electromagnetic (or photon) field. The theory is a gauge theory (its physical content should not change if a gradient is added to the vector potentials); it is further an abelian gauge theory as the EMF does not interact directly with itself.

The QED Lagrangian is separated into a free part and an interaction part. From the free part, one derives the wave functions of the free-particle states and the corresponding time-evolution operators (free Green's functions or propagators; let us just recall here that to obtain a convenient photon propagator one has to break the gauge invariance by adding to the Lagrangian a suitable gauge-breaking term), while the interaction part of the Lagrangian gives the "interaction vertices" of the theory.

Aim of the theory is to build the Green's function for the various processes in the presence of the interaction; from these Green's functions, one then derives all the physical quantities of interest.

With the free propagators and the interaction vertices, one generates the perturbative expansion of the Green's functions. The result, namely the contributions to the perturbative expansion (or radiative corrections), can be depicted in terms of Feynman graphs: they consist of various particle lines joined in the interaction vertices, with external lines corresponding to the initial and final particles and internal lines corresponding to intermediate or virtual particle states. Each graph stands for an integral on the momenta of all the intermediate states, each vertex implying among other things an interaction constant, which is $(-e)$ in the case of electron QED, and a $\delta$-function imposing the conservation of the momenta at that vertex. For each process, the Feynman graphs are naturally classified by the total number of the interaction vertices they contain. In the simplest graphs for a given process (the so-called tree graphs) the $\delta$-functions at the vertices make the integrations trivial; but when the number of vertices increases, closed loops of virtual particle states appear, whose evaluation quickly becomes extremely demanding. In QED, each loop gives an extra factor $(-e)^2$ with respect to the tree graph; it is customary to express it in terms of $(\alpha/\pi) = (e/2\pi)^2$, so that the resulting power of $(\alpha/\pi)$ corresponds to the number of internal loops. The typical QED prediction for a physical quantity is then expressed as a series of powers of the fine structure constant $\alpha$ (and of its logarithm in bound-state problems). As $\alpha$ is small ($\alpha \simeq 1/137$), and the first coefficients of the expansions are usually of the order of 1, a small number of terms in the expansion is in general sufficient to match the precision of the available experimental data.

But the number of different graphs for a given number of loops grows quickly with the number of the loops; in turn, each graph consists in general of a great number of terms and the loop integrations become prohibitively difficult when the number of loops increases, so that the evaluation of radiative corrections proved to be one of the major computational challenges of theoretical physics. As a matter of fact, it prompted the development of computer programs (Veltman 1999) for processing the huge algebraic expressions usually encountered, and of many sophisticated numerical and analytical techniques for performing the loop integrations.

It should be further mentioned here that Feynman graphs written by naively following the above sketched rules are often mathematically ill-defined, taking the form of nonconvergent integrals on the loop momenta. A regularization procedure is needed to give an unambiguous meaning to all the integrals; currently the most powerful regularization is the continuous dimensional regularization scheme, in which the loop integrations are carried out in $d$ continuous dimensions, with $d$ unspecified; renormalization counter-terms are also evaluated in the same scheme, and the physical quantities are recovered in the $d \to 4$ limit (unrenormalized loop integrals and renormalization counterterms are usually singular as powers of $1/(d-4)$ in the $d \to 4$ limit, but all those divergences cancel out in the physical combinations of interest).

QED describes the main interaction of the charged leptons (e, $\mu$, and $\tau$) which have, however, weak interactions as well. Strictly speaking, pure

QED processes do not exist; it is an essential feature of QFT that any existing particle can contribute to the Feynman graphs for any process, when the approximation is pushed to a sufficiently high degree. In particular the photon, which is the main carrier of the QED interaction, is directly coupled also to the strongly interacting particles (the resulting contributions are referred to as "hadronic vacuum polarization" effects).

The precision tests of QED are then to be necessarily searched for in those phenomena where non-QED contributions are presumably small and which involve quantities already well known independently of QED itself. But such high-precision quantities are not always available, and as QED is known better than the rest of physics, very often it is taken to be correct by assumption, and used as a tool for extracting or measuring some of the non-QED quantities relevant to various physical processes.

In any case, as QED predictions are expressed in terms of the fine structure constant $\alpha$, a determination of $\alpha$ independent of QED is needed; without it, the most precise predictions of QED would simply become measures of $\alpha$ and not tests of the theory.

Finally, it is to be recalled that, ironically, the problem of the convergence of the expansion in powers of $\alpha$ is still open, even if it is commonly accepted that convergence problems will matter only for precisions and corresponding perturbative orders (say at order $1/\alpha \simeq 137$) absolutely out of reach of present experimental and computational possibilities, involving further extremely high energies, where the other fundamental interactions are expected to be as important as QED, so that it would be meaningless to consider only QED.

In the following we will discuss only the QED predictions for bound states and the anomalous magnetic moments of $\mu$ and e.

## The Bound States

A very good review of the current status of the theory of hydrogen-like atoms can be found in Eides *et al.* (2001), to which we refer for more details and citation of the original papers. The starting point for studying the bound-state problem in QED is the scattering amplitude of two charged particles, predicted by perturbative QED (pQED) as a (formal) series expansion in powers of $\alpha$. In the static limit $v \to 0$, where $v$ is the relative velocity of the two particles, some of the pQED terms behave as $\alpha/v$, so that the naive expansion in $\alpha$ becomes meaningless. Fortunately, it is relatively easy to identify the origin of those terms (which are essentially due to the Coulomb interaction between the two charges) and to devise techniques for their resummation. Among them, one can quote the Bethe–Salpeter equation, formally very elegant and complete but difficult to use in practice. A great progress has been achieved by the NRQED (nonrelativistic QED) approach, which is a nonrelativistic theory designed to reproduce the full QED scattering amplitude in the nonrelativistic limit by the *ad hoc* definition, *a posteriori*, of a suitable effective Hamiltonian. The Hamiltonian is then divided into a part containing the Coulomb interaction, which is treated exactly and which gives rise to the bound states, and all the rest, to be treated perturbatively. The power of the NRQED approach was further boosted by the continuous dimensional regularization technique of Feynman graph integrals.

Traditionally, the results are expressed in terms of the energies of the bound states, but as in practice the precise measurements concern the transition frequencies between various levels, it is customary to express any energy contribution to some level, say $\Delta E$, also in terms of the associated frequency $\nu = (\Delta E)/h$, where $h$ is the Planck constant.

### The Hydrogen-Like Atoms

Quite in general, a hydrogen-like atom consists of a single electron bound to a positively charge particle, which is a proton for the hydrogen atom, a deuteron nucleus for deuterium, a Helium nucleus for an $He^+$ ion, a $\mu^+$ meson for muonium, or a positron for positronium. Even if QED alone is not sufficient to treat the dynamical properties of the nuclei, their strong interactions can be described by introducing suitable form factors and a few phenomenological parameters; weak interactions could be treated perturbatively, but are not yet required at the precision levels achieved so far.

The QED results for the hydrogen-like atoms can be expressed in terms of the mass $M$ of the positive particle and of its charge $Ze$ (of course $Z = 1$ for hydrogen). When the electron mass $m_e$ is smaller then $M$ (which is always the case, except the positronium case) one can take as a starting point the QED electron moving in the external field of the positive particle, and treat all the other aspects of the relativistic two-body problem (the so-called recoil effects) perturbatively in $m_e/M$.

Neglecting the spin of the positive particle, the energy levels of the hydrogen-like atom are identified by the usual principal quantum number $n$, the orbital angular momentum $l$ (with the convention of writing $S, P, D, \ldots$ instead of $l = 0$, $l = 1$, $l = 2, \ldots$) and $j$, the total angular momentum including the spin of the electron. It turns out that the bound

levels consist of very many contributions of different kinds; dropping quantum number indices for simplicity, the energy levels can be written as an expression of the form

$$E = -\frac{m_e c^2 (Z\alpha)^2}{2}\left(\frac{m_r}{m_e}\right) \times \left[\frac{1}{n^2} + (Z\alpha)^2 f_4 + (Z\alpha)^4 f_6 + \cdots\right] + \Delta E_{rad} + \Delta E_{rec} + \Delta E_{nucl} + \cdots \qquad [5]$$

Let us observe that it is convenient to write explicitly the $Z$ factors even when $Z = 1$ for a better bookkeeping of the various corrections. As usual, $m_r$ is the reduced mass of the electron, $m_r = m_e M/(m_e + M)$ the mass of the nucleus being $M$; the first term in the square bracket, $1/n^2$, the familiar Balmer term, is by and far the dominant one, giving for the $n = 1$ level in the $Z = 1$ case an energy of about 13.6 eV or a corresponding frequency of $3.3 \times 10^{15}$ Hz. The other terms in the square bracket, $f_4$ and $f_6$, are known coefficients (depending also on the small parameter $m_e/M; f_4$ is essentially the fine structure).

The term $\Delta E_{rad}$, is the bulk of the radiative QED corrections; it can be written as a multiple expansion on $(Z\alpha), \alpha$ and $L = \ln[1/(Z\alpha)^2]$, which turns out to have the following explicit form:

$$\Delta E_{rad} = m_e c^2 (Z\alpha)^4 \frac{1}{n^3}\left\{\left(\frac{\alpha}{\pi}\right)\left[A_{41}L + A_{40} + (Z\alpha)A_{50} + (Z\alpha)^2\left(A_{62}L^2 + A_{61}L + A_{60}\right) + \cdots\right] + \left(\frac{\alpha}{\pi}\right)^2\left[B_{40} + (Z\alpha)B_{50} + (Z\alpha)^2\left(B_{63}L^3 + B_{62}L^2 + B_{61}L + B_{60}\right) + \cdots\right] + \left(\frac{\alpha}{\pi}\right)^3[C_{40} + (Z\alpha)C_{50} + \cdots] + \cdots\right\} \qquad [6]$$

The first index of the coefficients refers to the power of $(Z\alpha)$, the second to the power of $L$; as a rule, there are three powers of $(Z\alpha)$ due to the normalization of the wave function and one power of $(Z\alpha)$ for each interaction with the nucleus (in the leading term of eqn [5] one must subtract two powers of $(Z\alpha)$ due to the long-range nature of the Coulomb interaction), while the terms in $L = \ln[1/(Z\alpha)^2]$ are related to the infrared divergences of the scattering amplitude, with the binding energy acting as infrared cutoff. The $A$-coefficients refers to order $(\alpha/\pi)$ or one-loop virtual correction (we do not distinguish here between one-loop self-mass and vacuum-polarization contribution, as usually done in the literature), the $B$-coefficients to two loops, etc. The coefficients are pure numbers, entirely determined within QED, even if their actual calculation is an extremely demanding task. One of the first results obtained in 1947 was $A_{41} = (4/3)\delta_{l0}$, contributing to the $2S$ but not to the $2P$ states (quite in general, most corrections are much bigger for $l = 0$ states than for higher-angular-momentum states), which is sufficient to give the right order of magnitude of the $(2S_{1/2}–2P_{1/2})$ Lamb shift (about 1000 MHz). The other coefficients are now known, thanks to the strenuous and continued efforts (Eides *et al.* 2001) since then, which is impossible to refer properly here in any detail. The current frontier of the theoretical calculation (around the dots in the previous formula) corresponds to 8–9 total powers of $(\alpha/\pi)$ and $(Z\alpha)$ or some kHz for the $1S$ state.

The next term in eqn [5], $\Delta E_{rec}$ contains contributions of order $m_e c^2 (Z\alpha)^5 (m_e/M)$ or smaller (some care must be done for classifying the contributions of order $m_e/M$, which can be accounted for by proper use of $m_r$ rather than $m_e$ and genuine $m_e/M$ contributions), and are sufficiently known for practical purposes; the same is true for many other contributions discussed in Eides *et al.* (2001) and skipped in eqn [5]. A troublesome contribution comes however from $\Delta E_{nucl}$; at leading order, one has

$$\Delta E_{nucl} = \frac{2(Z\alpha)^4 mc^2}{3n^3}\left(\frac{mcR_p}{\hbar}\right)^2 \delta_{l0}$$

where $R_p$ is the so-called root-mean-square charge radius of the proton, which is not well known experimentally (in the literature, there are indeed two direct measurements, $R_p = 0.805(11)$ fm and $R_p = 0.862(12)$ fm, in poor agreement with each other; a new independent measurement is strongly needed).

**The hyperfine splitting** The effect of the interaction of the electron with the spin of the positive particle introduces the so-called hyperfine splitting of all the levels. The order of magnitude of the hyperfine splitting of the $1S$ state is given by the Fermi energy

$$E_F = \frac{4}{3} m_e c^2 (Z\alpha)^4 g_p \frac{m_e}{m_p}$$

where $g_p \simeq 5.586$ is the $g$-factor of the proton, which gives $\simeq 1.42$ GHz. It was dubbed hyperfine because it is smaller than the fine structure terms by the factor $m_e/m_p$. Many classes of corrections can be worked out, with patterns similar to those of the previous subsection, and also in this case the nuclear contributions (this time mainly due to the theoretically unknown magnetic form factor and the

so-called polarizability of the proton) prevent from obtaining predictions with an error less than 1 kHz (or a relative precision better than $1 \times 10^{-6}$).

**The comparison with the experiments** Experimen- Experimentally, one measures transition frequencies among the various levels. For many years the precision record was given by the hyperfine splitting of the ground states of hydrogen $\nu_{\mathrm{hfs}}(1S)$ was measured long ago (see Hellwig *et al.* (1970) and Essen *et al.* (1971)),

$$\nu_{\mathrm{hfs}}(1S) = 1\,420\,405.751\,766\,7(9)\,\mathrm{kHz} \qquad [7]$$

with a relative error $6 \times 10^{-13}$. The current record in the optical range is the value of the $(1S\text{–}2S)$ hydrogen transition frequency, obtained by means of two-photon Doppler-free spectroscopy Niering *et al.* (2000),

$$\nu(1S\text{–}2S) = 2\,466\,061\,413\,187.103(46)\,\mathrm{kHz} \qquad [8]$$

with a relative precision $1.9 \times 10^{-14}$; other optical transitions, such as $(2S\text{–}8D)$, $(2S\text{–}12D)$ are measured with precision of about $1 \times 10^{-11}$.

The measurement of the Lamb shift was repeated several times, with results in nice agreement with the original value, such as Lundeen and Pipkin (1986), 1057.845(9) MHz. The most precise value, $1057.8514 \pm 0.0019$ MHz was given in Palchikov *et al.* (1985) (the result depends, however, on the theoretical value of the lifetime, and should be changed into $1057.8576 \pm 0.0021$ according to subsequent analysis (see Karshenboim (1996)). The experimental $(2S_{1/2}\text{–}2P_{1/2})$ Lamb shift was also obtained as the difference between the measured fine structure separation $(2P_{3/2}\text{–}2S_{1/2})$ and the theoretical value of the $(2P_{3/2}\text{–}2P_{1/2})$ frequency, and the radiative corrections $\Delta E_{\mathrm{rad}}$ to any level are now referred to as the Lamb shift of that level.

As a somewhat deceiving conclusion, the wonderful experimental results of eqns [7] and [8] cannot be used as a high-precision test of the theory or to obtain precise values of many fundamental constants, as the theoretical calculations depend, unfortunately, on hadronic quantities which are not known accurately. Combining theoretical predictions, the above transitions and Lamb shift data, and the available values of $\alpha$ and $m_e/m_p$, one can indeed obtain a measure of $R_p$ ($R_p = 0.883 \pm 0.014$, according to Melnikov and van Ritbergen (2000)) and the value of $R_\infty$ already quoted above.

### Muonium

The muonium is the bound state of a positive $\mu^+$ meson and an electron. At variance with the proton, the $\mu^+$ lepton has no strong interactions, the $\mu^+e^-$ system can be studied theoretically within pure QED, with the weak interactions giving a known and small perturbation. Further, the ratio of the masses $m_e/m_\mu \simeq 4.8 \times 10^{-3}$ is small, so that the external field approximation holds. However, the $\mu$ is unstable (lifetime $\simeq 2.2\,\mu$s), which makes experiments more difficult to carry out. The best measured quantity is the hyperfine splitting of the 1S ground state (see Liu *et al.* (1999))

$$\nu_{\mathrm{hfs}}(\mu e, 1S) = 4\,463\,302\,765(53)\,\mathrm{Hz}$$

with a relative precision of $12 \times 10^{-9}$. The theoretical treatment is similar to the case of hydrogen, with the important advantage that nuclear interactions are absent and everything can be evaluated within QED, so that the bulk of the contribution is given by a formula with the structure of eqn [6]. But the prediction depends, in any case, on the $m_e/m_\mu$ mass, which is not known with the required precision. Indeed, a recent theoretical calculation (Czarnecki *et al.* 2002) (which includes also a contribution of 0.233(3) kHz from hadronic vacuum polarization) gives 4 463 302 680(510) (30)(220) Hz, where the first (and biggest) error comes from $m_e/m_\mu$, the second from $\alpha$, and the third is the theoretical error (an estimation of higher-order contributions not yet evaluated).

### Positronium

The positronium is the bound state of an electron and a positron. Theoretically, it is an ideal system to study, as it can be described entirely within QED, without any unknown parameter of non-QED origin. As the masses of the two constituents, positron and electron, are strictly equal, the reduced mass of the system is exactly equal to half of the electron mass, $m_r = m_e/2$, and the energy scale of the bound states is half of $R_\infty$.

At variance with the muonium case, the external field approximation is not valid, so that positronium must be treated with the full two-body bound-state machinery of QFT, of which it provides an excellent test (Karshenboim 2004).

Experimentally, radioactive positron sources are available, so that positronium is easier to produce than muonium. It is, however, unstable; states with total spin $S$ equal 0 (also called parapositronium states) annihilate into an even number (mainly two) of gammas, and states with $S = 1$ (orthopositronium) into an odd number (mainly three) of gammas, with short lifetimes (which make precise measurements difficult). Further, as positronium is the lightest

atom, Doppler-broadening effects are very important, reducing the precision of spectroscopical measurements.

**Positronium decay rates** There has been a long-time discrepancy between theory and experiment in decay rate of ground-state orthopositronium, which prompted thorough theoretical investigations looking for errors in the calculations or flaws in the formalism, but it turned out that the flaw was on the experimental side. The current theoretical prediction for the ground state $S=1$ decay is (Adkins *et al.* 2002)

$$\Gamma(1S,\text{ortho}) = \Gamma_0\left\{1 + A\left(\frac{\alpha}{\pi}\right) + \frac{1}{3}\alpha^2\ln\alpha + B\left(\frac{\alpha}{\pi}\right)^2 - \frac{3\alpha^3}{2\pi}\ln^2\alpha + C\frac{\alpha^3}{\pi}\ln\alpha + \cdots\right\} = 7.039979(11)\,\mu\text{s}^{-1}$$

where $\Gamma_0 = 2(\pi^2 - 9)m_e\alpha^6/(9\pi) = 7.2111670(1)$, $A = -10.286606(10), B = 45.06(26), C = -5.517$, in nice agreement with the less precise experimental result of Karshenboim (2004, ref. 38) 7.0404 (10)(8) $\mu\text{s}^{-1}$. As a curiosity, the coefficients $A$, $B$ above are among the greatest coefficients so far appeared in QED radiative corrections.

The agreement between theory and experiment for the ground-state parapositronium decay rate has always been good; the current status of Karshenboim (2004, ref. 41) is 7990.9(1.7) $\mu\text{s}^{-1}$ for the experimental result and of Karshenboim (2004, ref. 43) 7989.64(2) $\mu\text{s}^{-1}$ for the theoretical prediction.

**Positronium levels** The quantum number structure of the levels is similar to muonium, with the important difference, however, that the hyperfine splitting (which in hydrogen or muonium is small because it is proportional to the ratio of the masses of the two components) is in fact of the same order as the fine structure. The theoretical evaluation of the energy levels provides a very stringent check of QED and of the overall treatment of the bound-state problem. Corrections have been evaluated, typically, up to order $mc^2\alpha^7$. The best-known quantities are the ground state (hyper)fine splitting, experimental value (Ritter *et al.* 1984) 203.38910(74) GHz ($3.6\times10^{-6}$ relative error), theoretical (Karshenboim 2004) 203.3917(6), and the 1*S*–2*S* transition for orthopositronium, experiment (Fee *et al.* 1993) 1 233 607 216.4 (3.2) MHz, theory 1 233 607 222.2(6). The general agreement is good; the precisions achieved are, however, not yet sufficient to allow a determination of $R_\infty$ or $\alpha$ competitive with other measurements.

## The Anomalous Magnetic Moments of Leptons

The precision of the measurements requires, for both the $e$ and $\mu$ leptons, to also take into account graphs with contributions from the other leptons as virtual intermediate states and those of hadronic and weak origin. Quite in general, if the mass of the virtual particle, say $m_v$, is smaller than the mass of the external lepton, say $m_l$, one can have an $\ln(m_l/m_v)$ behavior of the contributions; that is the case of the virtual electron contributions to the muon magnetic anomaly $a_\mu$, which can be enhanced by powers of $\ln(m_\mu/m_e)$. In the opposite case, $m_v > m_l$, the contribution has the behavior $(m_l/m_v)^2$; that is the case of the $(m_\mu/m_\tau)^2$ contributions to $a_\mu$ from $\tau$ loops and of the $(m_e/m_\mu)^2$ contributions from $\mu$ loops to th electron magnetic anomaly, $a_e$. As strong and weak interactions are in general associated with heavy-mass particles, they are expected to be more important for $a_\mu$ than $a_e$; further, a given heavy particle contribution to $a_e$ is smaller by a factor $(m_e/m_\mu)^2$ than the corresponding contribution to $a_\mu$.

### The Magnetic Anomaly $a_\mu$ of the $\mu$

The $a_\mu$ has been reviewed in Passera (2005). The present (2005) world average experimental value is

$$a_\mu(\text{exp}) = 116\,592\,080(60)\times10^{-11}$$

with a relative error $0.5\times10^{-6}$.

Theoretically, one can write

$$a_\mu = a_\mu(\text{QED}) + a_\mu(\text{had}) + a_\mu(\text{EW}) \qquad [9]$$

where the three terms stand for the contributions from pure QED, strong interacting hadrons and electroweak interactions. In turn, one can expand $a_\mu(\text{QED})$ in powers of $\alpha$ as

$$a_\mu(\text{QED}) = \sum_l C_l\left(\frac{\alpha}{\pi}\right)^l = \sum_l\left[A_1^{(l)} + A_2^{(l)}\left(\frac{m_\mu}{m_e}\right) + A_2^{(l)}\left(\frac{m_\mu}{m_\tau}\right) + A_3^{(l)}\left(\frac{m_\mu}{m_e},\frac{m_\mu}{m_\tau}\right)\right]\left(\frac{\alpha}{\pi}\right)^l \qquad [10]$$

The coefficients $A_1^{(l)}$ involve only the photon and the external lepton as virtual states, are identically the same as in $a_e$; they are known up to $l=4$ included (but, strictly speaking, the contribution of $A_1^{(4)}$ is smaller than the experimental error of $a_\mu$) and will be discussed later for the electron. The $A_2^{(l)}(m_\mu/m_e)$ are very large, being enhanced by powers of $\ln(m_\mu/m_e)$, and are required and known up to $l=5$; $A_2^{(l)}(m_\mu/m_\tau)$ starts with $A_2^{(2)}(m_\mu/m_\tau)\simeq$

$1/45(m_\mu/m_\tau)^2$, contributing $4.2\times10^{-11}$ to $a_\mu$, so that the $A_2^{(l)}(m_\mu/m_\tau)$ with higher values of $l$ are not needed. $A_3^{(l)}(m_\mu/m_e,\ m_\mu/m_\tau)$, finally, starts from $l=3$, and gives a negligible contribution $0.7\times10^{-11}$. Summing up, one finds $C_1=1/2$, $C_2=0.765\,857\,410(27)$ (the error is from the experimental errors in the lepton masses) $C_3=24.050\,509\,64(43)$, $C_4=131.011(8)$, and $C_5=677(40)$. As already observed, the coefficients are large due to the presence of $\ln(m_\mu/m_e)$ factors. The last term $C_5$ contributes $4.6(0.3)\times10^{-11}$ to $a_\mu$, and the total QED contribution is

$$a_\mu(\text{QED}) = 116\,584\,718.8(0.3)(0.4)\times10^{-11}$$

where the first error is due to the uncertainties in the coefficients $C_2, C_3$, and $C_5$ and the second from the value of $\alpha$ coming from atom interferometry measurements (see below).

The hadronic contributions are of two kinds, those due to vacuum polarization, $a_\mu$(vac.pol), which can be evaluated by sound theoretical methods by using existing experimental data, and those due to light-by-light hadronic scattering, $a_\mu$(lbl), whose evaluation relies on much less firmer grounds and are entirely model-dependent. The value of $a_\mu$(vac.pol) varies slightly among the various authors (see Passera (2005) for reference to original work), let us take as a typical value $a_\mu(\text{vac.pol})=6834(92)\times10^{-11}$ (based on $e^+e^-$ scattering data and including also first-order radiative corrections). The model-dependent value of the light-by-light contribution changed several times in the years (also in sign!) but now there is a general consensus that it should be positive; let us take, somewhat arbitrarily, $a_\mu(\text{lbl})=136(25)\times10^{-11}$, so that the total hadronic contribution becomes

$$a_\mu(\text{had}) = 6970(92)\times10^{-11}$$

The electroweak contribution, finally, is

$$a_\mu(\text{EW}) = 154(2)\times10^{-11}$$

which accounts for a one-loop purely weak contribution and a two-loop electromagnetic and weak contribution, which turns out to be very large ($-42\times10^{-11}$) for the presence of logarithms in the masses (the error is due to the uncertainty in the Higgs boson mass).

Summing up, eqn [9] gives $a_\mu=116\,591\,842(92)\times10^{-11}$, so that

$$a_\mu(\text{exp}) - a_\mu = 138(60)(90)\times10^{-11}$$

The substantial agreement can be considered to be a good overall check of QED and electroweak interactions. But another attitude is often adopted in the scientific community: the validity of QED and electroweak models is taken for granted, and a disagreement, if any, is considered to be an indication of new physics. To obtain significant information in that direction, however, the experimental and the theoretical errors (dominated in turn by the experimental error in $e^+e^-$ scattering data) should be significantly reduced.

### The Magnetic Anomaly $a_e$ of the Electron

Experimentally, one has the 1987 value (Kinoshita 2005, ref. 1).

$$a_e(\text{exp}) = 1\,159\,652\,188.4(4.3)\times10^{-12} \qquad [11]$$

with a relative error $3.7\times10^{-9}$ and the preliminary Harvard (2004) measurement (Kinoshita 2005, ref. 3).

$$a_e(\text{Harvard}) = 1\,159\,652\,180.86(0.57)\times10^{-12} \qquad [12]$$

with $0.5\times10^{-9}$ relative error, that is, an increase in precision by a factor 7.

Theoretically, eqns [9] and [10] apply also to the electron; given the smallness of the electron mass, the relevant terms up to the precision of the experimental data are

$$\begin{aligned} a_e &= A_1^{(1)}\left(\frac{\alpha}{\pi}\right) + A_1^{(2)}\left(\frac{\alpha}{\pi}\right)^2 + A_1^{(3)}\left(\frac{\alpha}{\pi}\right)^3 \\ &\quad + A_1^{(4)}\left(\frac{\alpha}{\pi}\right)^4 + \cdots + A_2^{(2)}\left(\frac{m_e}{m_\mu}\right)\left(\frac{\alpha}{\pi}\right)^2 \\ &\quad + a_e(\text{had}) + a_e(\text{EW}) \end{aligned} \qquad [13]$$

The explicit calculation gives

$$A_1^{(1)} = \frac{1}{2} \quad \text{(Passera 2005, ref. 1)}$$

$$\begin{aligned} A_1^{(2)} &= \frac{197}{144} + \frac{1}{12}\pi^2 - \frac{1}{2}\pi^2\ln 2 + \frac{3}{4}\zeta(3) \\ &= -0.328\,478\,965\,579\ldots \\ &\qquad \text{(Passera 2005, ref. 17)} \end{aligned}$$

$$\begin{aligned} A_1^{(3)} &= \frac{83}{72}\pi^2\zeta(3) - \frac{215}{24}\zeta(5) \\ &\quad + \frac{100}{3}\left[a_4 + \frac{1}{24}\ln^4 2 - \frac{1}{24}\pi^2\ln^2 2\right] \\ &\quad - \frac{239}{2160}\pi^4 + \frac{139}{18}\zeta(3) - \frac{298}{9}\pi^2\ln 2 \\ &\quad + \frac{17101}{810}\pi^2 + \frac{28259}{5184} \\ &= 1.181\,241\,456\ldots \quad \text{(Laporta and Remiddi 1996)} \end{aligned}$$

$$A_1^{(4)} = -1.7283(35) \quad \text{(Kinoshita 2005)}$$

and

$$A_2^{(2)}\left(\frac{m_e}{m_\mu}\right)\left(\frac{\alpha}{\pi}\right)^2 \simeq \frac{1}{45}\left(\frac{m_e}{m_\mu}\right)^2\left(\frac{\alpha}{\pi}\right)^2 \simeq 2.72\times 10^{-12}$$
$$a_e(\text{had}) = 1.67(0.02)\times 10^{-12}$$
$$a_e(\text{EW}) = 0.03\times 10^{-12} \qquad [14]$$

For obtaining a meaningful prediction, one needs now a precise value of $\alpha$. The most precise value available at present is that of Passera (2005, ref. 49)

$$\alpha^{-1}(\text{aif}) = 137.036\,000\,3(10)$$

with relative error $7\times 10^{-9}$, obtained by the atom interferometry method (which is independent of QED, depending only on the kinematics of the Doppler effect). With that value of $\alpha$, the theoretical prediction for $a_e$ becomes

$$a_e = 1\,159\,652\,175.9(8.5)(0.1)10^{-12}$$

where the first error comes from $\alpha$ and the second from $C_4$; conversely, one can use the QED prediction for $a_e$ and $a_e$(Harvard) for obtaining $\alpha$; one obtains in that way

$$\alpha^{-1}(\text{QED}, a_e) = 137.035\,999\,708(12)(67)$$

where the first uncertainty is from $C_4$ and the second from the experiment. We see that theory and experiment are in good agreement.

As a concluding remark, another independent and more precise (or analytic!) evaluation of $C_4$ contribution would be welcome. The five-loop term is not known; but as $(\alpha/\pi)^5 \approx 0.07\times 10^{-12}$, if $C_5$ is, say, not greater than 2, its contribution to $a_e$ becomes equal to the contribution of the error $\Delta C_4$ of $C_4$ and is not yet required to match the current precision of $a_e(\exp)$. The ultimate theoretical limit, the error of the hadronic contribution, $\Delta a_e(\text{had}) = 0.02\times 10^{-12}$, is still smaller, corresponding to a change $\Delta C_4 = 0.0007$ of $C_4$ or $\Delta C_5 = 0.3$ of $C_5$.

# Quantum Entropy

**D Petz**, Budapest University of Technology and Economics, Budapest, Hungary

In the past 50 years, entropy has broken out of thermodynamics and statistical mechanics and invaded communication theory, ergodic theory mathematical statistics, and even the social and life sciences. The favorite subjects of entropy concern macroscopic phenomena, irreversibility, and incomplete knowledge. In the strictly mathematical sense entropy is related to the asymptotics of probabilities or concerns the asymptotic behavior of probabilities.

This review is organized as follows. First the history of entropy is discussed generally and then we concentrate on the von Neumann entropy again somewhat historically following the work of von Neumann. Umegaki's quantum relative entropy is discussed both in case of finite systems and in the setting of $C^*$-algebras. An axiomatization is presented. To show physical applications of the concept of entropy, the statistical thermodynamics is reviewed in the setting of spin chains. The relative entropy shows up in the asymptotic theory of hypothesis testing and data compression.

## General Introduction to Entropy: From Clausius to von Neumann

The word "entropy" was created by Rudolf Clausius and it appeared in his work *Abhandlungen über die mechanische Wärmetheorie* published in 1864. The word has a Greek origin, its first part reminds us of "energy" and the second part is from "tropos," which means "turning point." Clausius' work is the foundation stone of classical thermodynamics. According to Clausius, the change of entropy of a system is obtained by adding the small portions of heat quantity received by the system divided by the absolute temperature during the heat absorption. This definition is satisfactory from a mathematical point of view and gives nothing other than an integral in precise mathematical terms. Clausius postulated that the entropy of a closed system cannot decrease, which is generally referred to as the second law of thermodynamics.

The concept of entropy was really clarified by Ludwig Boltzmann. His scientific program was to deal with the mechanical theory of heat in connection with probabilities. Assume that a macroscopic system consists of a large number of microscopic ones, we simply call them particles. Since we have ideas of quantum mechanics in mind, we assume that each of the particles is in one of the energy levels $E_1 < E_2 < \cdots < E_m$. The number of particles in the level $E_i$ is $N_i$, so $\sum_i N_i = N$ is the total number of particles. A macrostate of our system is given by the occupation numbers $N_1, N_2, \ldots, N_m$. The energy of a macrostate is $E = \sum_i N_i E_i$. A given macrostate can be realized by many configurations of the $N$ particles, each of them at a certain energy level $E_i$. These configurations are called microstates. Many microstates realize the same macrostate. We count the number of ways of arranging $N$ particles in $m$ boxes (i.e., energy levels) such that each box has $N_1, N_2, \ldots, N_m$ particles. There are

$$\binom{N}{N_1, N_2, \ldots, N_m} := \frac{N!}{N_1! N_2! \ldots N_m!} \qquad [1]$$

such ways. This multinomial coefficient is the number of microstates realizing the macrostate $(N_1, N_2, \ldots, N_m)$ and it is proportional to the probability of the macrostate if all configurations are assumed to be equally likely. Boltzmann called [1] the thermodynamical probability of the macrostate, in German "thermodynamische Wahrscheinlichkeit," hence the letter $W$ was used. Of course, Boltzmann argued in the framework of classical mechanics and the discrete values of energy came from an approximation procedure with "energy cells."

If we are interested in the thermodynamic limit $N$ increasing to infinity, we use the relative numbers $p_i := N_i/N$ to label a macrostate and, instead of the total energy $E = \sum_i N_i E_i$, we consider the average energy pro particle $E/N = \sum_i p_i E_i$. To find the most probable macrostate, we wish to maximize [1] under a certain constraint. The Stirling approximation of the factorials gives

$$\frac{1}{N}\log\binom{N}{N_1, N_2, \ldots, N_m} = H(p_1, p_2, \ldots, p_m) + O(N^{-1}\log N) \qquad [2]$$

where

$$H(p_1, p_2, \ldots, p_m) := \sum_i -p_i \log p_i \qquad [3]$$

If $N$ is large then the approximation [2] yields that instead of maximizing the quantity [1] we can maximize [3]. For example, maximizing [3] under the constraint $\sum_i p_i E_i = e$, we get

$$p_i = \frac{e^{-\lambda E_i}}{\sum_j e^{-\lambda E_j}} \qquad [4]$$

where the constant $\lambda$ is the solution of the equation

$$\sum_i E_i \frac{e^{-\lambda E_i}}{\sum_j e^{-\lambda E_j}} = e$$

Note that the last equation has a unique solution if $E_1 < e < E_m$, and the distribution [4] is now known as the discrete Maxwell–Boltzmann law.

Let $p_1, p_2, \ldots, p_n$ be the probabilities of different outcomes of a random experiment. According to Shannon, the expression [1] is a measure of our ignorance prior to the experiment. Hence it is also the amount of information gained by performing the experiment. The quantity [1] is maximum when all the $p_i$'s are equal. In information theory, logarithms with base 2 are used and the unit of information is called bit (from binary digit). As will be seen below, an extra factor equal to Boltzmann's constant is included in the physical definition of entropy.

The comprehensive mathematical formalism of quantum mechanics was first presented in the famous book *Mathematische Grundlagen der Quantenmechanik* published in 1932 by Johann von Neumann. In the traditional approach to quantum mechanics, a physical system is described in a Hilbert space: observables correspond to self-adjoint operators and statistical operators are associated with the states. In fact, a statistical operator describes a mixture of pure states. Pure states are really the physical states and they are given by rank-1 statistical operators, or equivalently by rays of the Hilbert space.

von Neumann associated an entropy quantity to a statistical operator in 1927 and the discussion was extended in his book (von Neumann 1932). His argument was a gedanken experiment on the grounds of phenomenological thermodynamics. Let us consider a gas of $N(\gg 1)$ molecules in a box. Suppose that the gas behaves like a quantum system and is described by a statistical operator $\omega$ which is a mixture $\sum_i \lambda_i |\varphi_i\rangle\langle\varphi_i|$, where $|\varphi_i\rangle \equiv \varphi_i$ are orthogonal state vectors. We may take $\lambda_i N$ molecules in the pure state $\varphi_i$ for every $i$. The gedanken experiment gave

$$S\left(\sum_i \lambda_i |\varphi_i\rangle\langle\varphi_i|\right) = \sum_i \lambda_i S(|\varphi_i\rangle\langle\varphi_i|) - \kappa \sum_i \lambda_i \log \lambda_i \qquad [5]$$

where $\kappa$ is Boltzmann's constant and $S$ is certain thermodynamical entropy quantity (relative to the fixed temperature and molecule density).

After this, von Neumann showed that $S(|\varphi\rangle\langle\varphi|)$ is independent of the state vector $|\varphi\rangle$, so that

$$S\left(\sum_i \lambda_i |\varphi_i\rangle\langle\varphi_i|\right) = -\kappa \sum_i \lambda_i \log \lambda_i \qquad [6]$$

up to an additive constant, which could be chosen to be 0 as a matter of normalization. Equation [6] is von Neumann's celebrated entropy formula; it has a more elegant form

$$S(\omega) = \kappa \operatorname{tr} \eta(\omega) \qquad [7]$$

where the state $\omega$ is identified with the corresponding statistical operator, and $\eta : \mathbb{R}^+ \to \mathbb{R}$ is the continuous function $\eta(t) = -t \log t$.

von Neumann solved the maximization problem for $S(\omega)$ under the constraint $\operatorname{tr} \omega H = e$. This means the determination of the ensemble of maximal entropy when the expectation of the energy operator $H$ is a prescribed value $e$. It is convenient to rephrase his argument in terms of conditional expectations. $H = H^*$ is assumed to have a discrete spectrum and we have a conditional expectation $E$ determined by the eigenbasis of $H$. If we pass from an arbitrary statistical operator $\omega$ with $\operatorname{tr} \omega H = e$ to $E(\omega)$, then the entropy is increasing, on the one hand, and the expectation of the energy does not change, on the other, so the maximizer should be searched among the operators commuting with $H$. In this way we are (and von Neumann was) back to the classical problem of statistical mechanics treated at the beginning of this article. In terms of operators, the solution is in the form

$$\frac{\exp(-\beta H)}{\operatorname{tr} \exp(-\beta H)} \qquad [8]$$

which is called Gibbs state today.

## The von Neumann Entropy

von Neumann was aware of the fact that statistical operators form a convex set whose extreme points are exactly the pure states. He also knew that entropy is a concave functional, so

$$S\left(\sum_i \lambda_i \omega_i\right) \geq \sum_i \lambda S(\omega_i) \qquad [9]$$

for any convex combination. To determine the entropy of a statistical operator, he used the Schatten decomposition, which is an orthogonal extremal decomposition in our present language. For a statistical operator $\omega$ there are many ways to write it in the form

$$\omega = \sum_i \lambda_i |\psi_i\rangle\langle\psi_i|$$

if we do not require the state vectors to be orthogonal. The geometry of the statistical operators, that is, the state space, allows many extremal decompositions and among them there is a unique orthogonal one if the spectrum of $\omega$ is not

degenerate. Nonorthogonal pure states are essentially nonclassical. They are between identical and completely different. Jaynes recognized in 1956 that from the point of view of information the Schatten decomposition is optimal. He proved that

$$S(\omega) = \sup\left\{-\sum_i \lambda_i \log \lambda_i\colon\ \omega = \sum_i \lambda_i \omega_i\right\} \qquad [10]$$

where the supremum is over all convex combinations $\omega = \sum_i \lambda_i \omega_i$ statistical operators. This is Jaynes contribution to the von Neumann entropy. By the way, formula [10] may be used to define von Neumann entropy for states of an arbitrary $C^*$-algebra whose states cannot be described by statistical operators.

Certainly the highlight of quantum entropy theory in the 1970s was the discovery of subadditivity. This property is formulated in a tripartite system whose Hilbert space $\mathcal{H}$ is a tensor product $\mathcal{H}_A \otimes \mathcal{H}_B \otimes \mathcal{H}_C$. A statistical operator $\omega_{ABC}$ admits several reduced densities, $\omega_{AB}, \omega_B, \omega_{BC}$, and others. The strong subadditivity is the inequality due to Lieb and Ruskai in 1973:

**Theorem 1**

$$S(\omega_{ABC}) + S(\omega_B) \le S(\omega_{AB}) + S(\omega_{BC}) \qquad [11]$$

The strong subadditivity inequality [11] is conveniently rewritten in terms of the relative entropy. For statistical operators $\rho$ and $\omega$,

$$S(\rho \| \omega) = \operatorname{tr} \rho(\log \rho - \log \omega) \qquad [12]$$

if $\operatorname{supp} \rho \le \operatorname{supp} \omega$, otherwise $S(\rho\|\omega) = +\infty$. The relative entropy expresses statistical distinguishability and therefore it decreases under stochastic mappings:

$$S(\rho\|\omega) \ge S(\mathcal{E}(\rho)\|\mathcal{E}(\omega)) \qquad [13]$$

for a completely positive trace-preserving mapping $\mathcal{E}$.

The strong subadditivity is equivalent to

$$S(\omega_{AB}, \varphi \otimes \omega_B) \le S(\omega_{ABC}, \varphi \otimes \omega_{BC}) \qquad [14]$$

where $\varphi$ is any state on $B(\mathcal{H}_A)$ of finite entropy. This inequality is a consequence of monotonicity of the relative entropy, since $\omega_{AB} = \mathcal{E}(\omega_{ABC})$ and $\varphi \otimes \omega_B = \mathcal{E}(\varphi \otimes \omega_{BC})$, where $\mathcal{E}$ is the partial trace over $\mathcal{H}_C$. Clearly, the equality in [11] is equivalent to equality in [14].

**Theorem 2** *The equality holds in [11] if and only if there is an orthogonal decomposition* $p_B \mathcal{H}_B = \bigoplus_n \mathcal{H}^{\mathrm{L}}_{nB} \otimes \mathcal{H}^{\mathrm{R}}_{nB}, p_B = \operatorname{supp} \omega_B$, *such that the density operator of* $\omega_{ABC}$ *satisfies*

$$\omega_{ABC} = \sum_n \omega_B(p_n) \omega^{\mathrm{L}}_n \otimes \omega^{\mathrm{R}}_n \qquad [15]$$

*where* $\omega^{\mathrm{L}}_n \in B(\mathcal{H}_A) \otimes B(\mathcal{H}^{\mathrm{L}}_{nB})$ *and* $\omega^{\mathrm{R}}_n \in B(\mathcal{H}^{\mathrm{R}}_{nB}) \otimes B(\mathcal{H}_C)$ *are density operators and* $p_n \in B(\mathcal{H}_B)$ *are the orthogonal projections* $\mathcal{H}_B \to \mathcal{H}^{\mathrm{L}}_{nB} \otimes \mathcal{H}^{\mathrm{R}}_{nB}$.

## Quantum Relative Entropy

The quantum relative entropy is an information measure representing the uncertainty of a state with respect to another state. Hence it indicates a kind of distance between the two states. The formal definition [12] is due to Umegaki.

Now we approach quantum relative entropy axiomatically. Our crucial postulate includes the notion of conditional expectation. Let us recall that in the setting of operator algebras conditional expectation (or projection of norm 1) is defined as a positive unital idempotent linear mapping onto a subalgebra.

Now we list the properties of the relative entropy functional which will be used in an axiomatic characterization:

1. *Conditional expectation property*. Assume that $\mathcal{A}$ is a subalgebra of $\mathcal{B}$ and there exists a projection of norm 1 $E$ of $\mathcal{B}$ onto $\mathcal{A}$, such that $\varphi \circ E = \varphi$. Then for every state $\omega$ of $\mathcal{B}$ $S(\omega, \varphi) = S(\omega|\mathcal{A}, \varphi|\mathcal{A}) + S(\omega, \omega \circ E)$ holds.
2. *Invariance property*. For every automorphism $\alpha$ of $\mathcal{B}$ we have $S(\omega, \varphi) = S(\omega \circ \alpha, \varphi \circ \alpha)$.
3. *Direct sum property*. Assume that $\mathcal{B} = \mathcal{B}_1 \oplus \mathcal{B}_2$. Let $\varphi_{12}(a \oplus b) = \lambda\varphi_1(a) + (1-\lambda)\varphi_2(b)$ and $\omega_{12}(a \oplus b) = \lambda\omega_1(a) + (1-\lambda)\omega_2(b)$ for every $a \in \mathcal{B}_1$, $b \in \mathcal{B}_2$ and some $0 < \lambda < 1$. Then $S(\omega_{12}, \varphi_{12}) = \lambda S\ (\omega_1, \varphi_1) + (1-\lambda)S(\omega_2, \varphi_2)$.
4. *Nilpotence property*. $S(\varphi, \varphi) = 0$.
5. *Measurability property*. The function $(\omega, \varphi) \mapsto S(\omega, \varphi)$ is measurable on the state space of the finite dimensional $C^*$-algebra $\mathcal{B}$ (when $\varphi$ is assumed to be faithful).

**Theorem 3** *If a real valued functional* $R(\omega, \varphi)$ *defined for faithful states* $\varphi$ *and arbitrary states* $\omega$ *of finite quantum systems shares the properties [1]–[5], then there exists a constant* $c \in \mathbb{R}$ *such that*

$$R(\omega, \varphi) = c \operatorname{Tr} D_\omega(\log D_\omega - \log D_\varphi)$$

The relative entropy may be defined for linear functionals of an arbitrary $C^*$-algebra. The general definition may go through von Neumann algebras, normal states and the relative modular operator. Another possibility is based on the monotonicity. Let $\omega$ and $\varphi$ be states of a $C^*$-algebra $\mathcal{A}$. Consider finite-dimensional algebras $\mathcal{B}$ and completely positive unital mappings $\alpha: \mathcal{B} \to \mathcal{A}$. Then the supremum

of the relative entropies $S(\omega \circ \alpha \| \varphi \circ \alpha)$ (over all $\alpha$) can be defined as $S(\omega \| \varphi)$.

**Theorem 4** *The relative entropy of states of $C^*$-algebras shares the following properties.*

(i) $(\omega, \varphi) \mapsto S(\omega \| \varphi)$ *is convex and weakly lower-semicontinuous.*
(ii) $\|\varphi - \omega\|^2 \leq 2S(\omega, \varphi)$.
(iii) *For a unital Schwarz map* $\alpha : \mathcal{A}_0 \to \mathcal{A}_1$ *the relation* $S(\omega \circ \alpha \| \varphi \circ \alpha) \leq S(\omega \| \varphi)$ *holds.*

Property (iii) is Uhlmann's monotonicity theorem, which we have already applied above.

The relative entropy appears in many concepts and problems in the area of quantum information theory (Nielsen and Chuang 2000, Schumacher and Westmoreland 2002).

## Statistical Thermodynamics

Let an infinitely extended system of quantum spins be considered in the simple cubic lattice $L = \mathbb{Z}^\nu$, where $\nu$ is a positive integer. The observables confined to a lattice site $x \in \mathbb{Z}^\nu$ form the self-adjoint part of a finite-dimensional $C^*$-algebra $\mathcal{A}_x$ which is a copy of the matrix algebra $M_d(\mathbb{C})$. It is assumed that the local observables in any bounded region $\Lambda \subset \mathbb{Z}^\nu$ are those of the finite quantum system

$$\mathcal{A}_\Lambda = \bigotimes_{x \in \Lambda} \mathcal{A}_x$$

It follows from the definition that for $\Lambda \subset \Lambda'$ we have $\mathcal{A}_{\Lambda'} = \mathcal{A}_\Lambda \otimes \mathcal{A}_{\Lambda' \setminus \Lambda}$, where $\Lambda' \setminus \Lambda$ is the complement of $\Lambda$ in $\Lambda'$. The algebra $\mathcal{A}_\Lambda$ and the subalgebra $\mathcal{A}_\Lambda \otimes \mathbb{C} I_{\Lambda' \setminus \Lambda}$ of $\mathcal{A}_{\Lambda'}$ have identical structure and we identify the element $A \in \mathcal{A}_\Lambda$ with $A \otimes I_{\Lambda' \setminus \Lambda}$ in $\mathcal{A}_{\Lambda'}$. If $\Lambda \subset \Lambda'$ then $\mathcal{A}_\Lambda \subset \mathcal{A}_{\Lambda'}$ and it is said that $\mathcal{A}_\Lambda$ is isotonic with respect to $\Lambda$. The definition also implies that if $\Lambda_1$ and $\Lambda_2$ are disjoint then elements of $\mathcal{A}_{\Lambda_1}$ commute with those of $\mathcal{A}_{\Lambda_2}$. The quasilocal $C^*$-algebra $\mathcal{A}$ is the norm completion of the normed algebra $\mathcal{A}_\infty = \cup_\Lambda \mathcal{A}_\Lambda$, the union of all local algebras $\mathcal{A}_\Lambda$ associated with bounded (finite) regions $\Lambda \subset \mathbb{Z}^\nu$.

We denote by $a_x$ the element of $\mathcal{A}_x$ corresponding to $a \in \mathcal{A}_0 (x \in \mathbb{Z}^\nu)$. It follows from the definition that the algebra $\mathcal{A}_\infty$ consists of linear combinations of terms $a^{(1)}_{x_1} \cdots a^{(k)}_{x_k}$ where $x_1, \ldots, x_k$ and $a^{(1)}, \ldots, a^{(k)}$ run through $\mathbb{Z}^\nu$ and $\mathcal{A}_0$, respectively. We define $\gamma_x$ to be the linear transformation

$$a^{(1)}_{x_1} \cdots a^{(k)}_{x_k} \longmapsto a^{(1)}_{x_1+x} \cdots a^{(k)}_{x_k+x}$$

$\gamma_x$ corresponds to the space translation by $x \in \mathbb{Z}^\nu$ and it extends to an automorphism of $\mathcal{A}$. Hence $\gamma$ is a representation of the abelian group $\mathbb{Z}^\nu$ by automorphisms of the quasilocal algebra $\mathcal{A}$. Clearly, the covariance condition

$$\gamma_x(\mathcal{A}_\Lambda) = \mathcal{A}_{\Lambda+x}$$

holds, where $\Lambda + x$ is the space-translate of the region $\Lambda$ by the displacement $x$.

Having described the kinematical structure of lattice systems, we turn to the dynamics. The local Hamiltonian $H(\Lambda)$ is taken to be the total potential energy between the particles confined to $\Lambda$. This energy may come from many-body interactions of various orders. Most generally, we assume that there exists a global function $\Phi$ such that for any finite subsystem $\Lambda$ the local Hamiltonian takes the form

$$H(\Lambda) = \sum_{X \subset \Lambda} \Phi(X) \qquad [16]$$

Each $\Phi(X)$ represents the interaction energy of the particles in $X$. Mathematically, $\Phi(X)$ is a self-adjoint element of $\mathcal{A}_X$ and $H(\Lambda)$ will be a self-adjoint operator in $\mathcal{A}_\Lambda$. We restrict our discussion to translation-invariant interactions, which satisfy the additional requirement

$$\gamma_x(\Phi(X)) = \Phi(X + x)$$

for every $x \in \mathbb{Z}^\nu$ and every region $X \subset \mathbb{Z}^\nu$. An interaction $\Phi$ is said to be of finite range if $\Phi(\Lambda) = 0$ when the cardinality (or diameter) of $\Lambda$ is large enough, $d(\Lambda) \geq d_\Phi$. The infimum of such numbers is called the range of $\Phi$.

If $\varphi$ is a state of the quasilocal algebra $\mathcal{A}$ then it will induce a state $\varphi_\Lambda$ on $\mathcal{A}(\Lambda)$, the finite system comprising the spin in the bounded region $\Lambda$ of $\mathbb{Z}^\nu$. The (local) energy, entropy, and free energy of this finite system are given by the following formulas:

$$\begin{aligned} E_\Lambda(\varphi) &:= \mathrm{tr}_\Lambda \omega_\Lambda H(\Lambda) \\ S_\Lambda(\varphi) &:= -\mathrm{tr}_\Lambda \omega_\Lambda \log \omega_\Lambda \\ F^\beta_\Lambda(\varphi) &:= E_\Lambda(\varphi) - \frac{1}{\beta} S_\Lambda(\varphi) \end{aligned} \qquad [17]$$

Here $\omega_\Lambda$ denotes the density of $\varphi_\Lambda$ with respect to the trace $\mathrm{tr}_\Lambda$ of $\mathcal{A}_\Lambda$, and $\beta$ denotes the inverse temperature. The functionals $E_\Lambda$, $S_\Lambda$, and $F^\beta_\Lambda$ are termed local. It is rather obvious that all three local functionals are continuous if the weak* topology is considered on the state space of the quasilocal algebra. The energy is affine, the entropy is concave and consequently, the free energy is a convex functional.

The free energy functional $F^\beta_\Lambda$ is minimized by the Gibbs state (see [8] with $H = H(\Lambda)$), and the minimum value is given by

$$-\frac{1}{\beta} \log \mathrm{tr}_\Lambda e^{-\beta H(\Lambda)} \qquad [18]$$

Our aim is to explain this variational principle after the thermodynamic limit is performed.

The thermodynamic limit "$\Lambda$ tends to infinity" may be taken along lattice parallelepipeds. Let $a \in \mathbb{Z}^\nu$ with positive coordinates and define

$$\Lambda(a) = \{x \in \mathbb{Z}^\nu:\ 0 \le x_i < a_i,\ i = 1, 2, \ldots, \nu\} \quad [19]$$

When $a \to \infty$, $\Lambda(a)$ tends to infinity in a manner suitable for the study of thermodynamic limit: the boundary of the parallelepipeds is getting more and more negligible compared with the volume. The notion of limit in the sense of van Hove makes this idea more precise and physically more satisfactory. For the sake of simplicity, we restrict ourselves to thermodynamic limit along parallelepipeds.

Denoting by $|\Lambda|$ the volume of $\Lambda$ (or the number of points in $\Lambda$), we may define the global energy, entropy, and free energy functionals of translationally invariant states to be

$$e(\varphi) := \lim_{\Lambda \to \infty} E_\Lambda(\varphi)/|\Lambda| \quad [20]$$

$$s(\varphi) := \lim_{\Lambda \to \infty} S_\Lambda(\varphi)/|\Lambda| \quad [21]$$

$$f^\beta(\varphi) := \lim_{\Lambda \to \infty} F^\beta_\Lambda(\varphi)/|\Lambda| \quad [22]$$

The existence of the limit in [21] is guaranteed by the strong subadditivity of entropy, while that of the limits in [20] and [22] is assumed if the interaction is suitably tempered, as it certainly does if the interaction is of finite range.

**Theorem 5** *If $\varphi$ is a translationally invariant state of the quasilocal algebra $\mathcal{A}$, then the limit [21] exists and*

$$s(\varphi) = \inf\{S_{\Lambda(a)}(\varphi)/|\Lambda(a)|:\ a \in \mathbb{Z}^\nu_+\} \quad [23]$$

*Moreover, the von Neumann entropy density functional $\varphi \mapsto s(\varphi)$ is affine and upper-semicontinuous when the state space is endowed with the weak* topology.*

*Let $\Phi$ be an interaction of finite range. Then the thermodynamic limit [20] exists and the energy density is given by*

$$e(\varphi) = \varphi(E_\Phi) \quad \text{and} \quad E_\Phi = \sum_{0 \in \Lambda} \frac{\Phi(\Lambda)}{|\Lambda|}$$

*Furthermore, $e(\varphi)$ is an affine weak* continuous functional of $\varphi$.*

*It follows that the free energy density $f(\varphi)$ exists and it is an affine lower-semicontinuous function of the translation-invariant state $\varphi$.*

*For $0 < \beta < \infty$ the thermodynamic limit*

$$\lim_{\Lambda \to \infty} \frac{1}{|\Lambda|} \log \mathrm{tr}_\Lambda \mathrm{e}^{-\beta H(\Lambda)} \equiv p(\beta, \Phi)$$

*exists.*

In accordance with the lattice-gas interpretation of our model, the global quantity $p$ is termed pressure.

In the treatment of quantum spin systems, the set $\mathfrak{S}_\gamma$ of all translation-invariant states is essential. The global entropy functional $s$ is a continuous affine function on $\mathfrak{S}_\gamma$ and physically it is a macroscopic quantity which does not have microscopic (i.e., local) counterpart. Indeed, the local entropy functional is not an observable because it is not affine on the (local) state space. The local internal energy $E_\Lambda(\varphi)$ is microscopic observable and the energy density functional $e$ of $\mathfrak{S}_\gamma$ is the corresponding global extensive quantity.

As an analog of the variational principle for finite quantum systems, the global free-energy functional $f_\beta$ attains an absolute minimum at a translationally invariant state, and the minimum value of $f^\beta$ is equal to the thermodynamic limit of the canonical free-energy densities of the local finite systems. In the next theorem, this global variational principle will be formulated in a slightly different but equivalent way.

**Theorem 6** *When $\Phi$ is an interaction of finite range, then*

$$p(\beta, \Phi) = \sup\{s(\omega) - \beta e(\omega)\}$$

*holds, when the supremum is over all translationally invariant states $\omega$ on $\mathcal{A}$.*

The minimizers of the right-hand side are called *equilibrium states* and they have several different characterizations.

## Asymptotical Properties

We keep the notation of the previous section but we consider one-dimensional chains, $\nu = 1$. Let $\omega$ be translation-invariant state on $\mathcal{A}$ and we fix a positive number $\varepsilon < 1$. We have in our mind that $\varepsilon$ is small and say that a sequence of projection $Q_n \in \mathcal{A}_{[1,n]}$ is of high probability if $\omega(Q_n) \ge 1 - \varepsilon$. The size of $Q_n$, the cardinality of a maximal pairwise orthogonal family of projections contained in $Q_n$, is given by $\mathrm{tr}_n Q_n$. (The subscript $n$ in $\mathrm{tr}_n$ indicates that the algebraic trace functional on $\mathcal{A}_n$ is meant here.) The theorem below says that the entropy density of $\omega$ governs asymptotically the rank of the high-probability projections.

**Theorem 7** *Assume that $\omega$ is an ergodic translation-invariant state of $\mathcal{A}$. Then the limit relation*

$$\lim_{n \to \infty} \frac{1}{n} \inf\{\log \mathrm{tr}_n Q_n\} = s(\omega)$$

*holds, when the infimum is over all projections $Q_n \in \mathcal{A}_{[1,n]}$ such that $\omega_n(Q_n) \ge 1 - \varepsilon$.*

This result is strongly related to data compression. When $\omega$ is interpreted as a stationary quantum source (with possible memory), then efficient and reliable data compression needs a subspace of small dimension and the range of $Q_n$ can play this role. The entropy density is the maximal rate of reliable compression.

It is interesting that one can impose further requirements on the high-probability projections and the statement of the theorem remains true.

1. The partial trace of $Q_{n+1}$ over $\mathcal{A}_{n+1}$ is $Q_n$;
2. $e^{n(s-\varepsilon)} \le \operatorname{tr} Q_n \le e^{n(s+\varepsilon)}$ if $n$ is large enough; and
3. if $q \le Q_n$ is a minimal projection (in $\mathcal{A}_{[1,n]}$), then $\omega(q) \le e^{-n(s-\varepsilon)}$ if $n$ is large enough.

In (2) and (3) $s$ stands for $s(\omega)$. Let $D_n$ be the density matrix of the restriction of $\omega$ to $\mathcal{A}_{[1,n]}$. It follows that for an eigenvalue $\lambda$ of $Q_n D_n Q_n$ the inequality

$$s - \varepsilon \le -\frac{\log \lambda}{n}$$

holds.

From the point of view of data compression, it is important if the sequence $Q_n \in \mathcal{A}_{[1,n]}$ works universally for many states. Indeed, in this case the compression algorithm can be universal for several quantum sources.

**Theorem 8** *Let* $R > 0$. *There is a projection* $Q_n \in \mathcal{A}_{[1,n]}$ *such that*

$$\limsup_n \frac{1}{n} \log \operatorname{tr} Q_n \le R \qquad [24]$$

*and for any ergodic state* $\omega$ *on* $\mathcal{A}$ *such that* $s(\omega) < R$ *the relation*

$$\lim_n \omega(Q_n) = 1 \qquad [25]$$

*holds.*

In the simplest quantum hypothesis testing problem, one has to decide between two states of a system. The state $\rho_0$ is the null hypothesis and $\rho_1$ is the alternative hypothesis. The problem is to decide which hypothesis is true. The decision is performed by a two-valued measurement $\{T, I - T\}$, where $0 \le T \le I$ is an observable. $T$ corresponds to the acceptance of $\rho_0$ and $I - T$ corresponds to the acceptance of $\rho_1$. $T$ is called a test. When the measurement value is 0, the hypothesis $\rho_0$ is accepted, otherwise the alternative hypothesis $\rho_1$ is accepted. The quantity $\alpha[T] = \operatorname{tr}\rho_0(I - T)$ is interpreted as the probability that the null hypothesis is true but the alternative hypothesis is accepted. This is the error of the first kind. Similarly, $\beta[T] = \operatorname{tr}\rho_1 T$ is the probability that the alternative hypothesis is true but the null hypothesis is accepted. It is called the error of the second kind.

Now we fix a formalism for an asymptotic theory of the hypothesis testing. Suppose that a sequence $(\mathcal{H}_n)$ of Hilbert spaces is given, $(\rho_0^{(n)})$ and $(\rho_1^{(n)})$ are density matrices on $\mathcal{H}_n$. The typical example we have in mind is $\rho_0^{(n)} = \rho_0 \otimes \rho_0 \otimes \cdots \otimes \rho_0$ and $\rho_1^{(n)} = \rho_1 \otimes \rho_1 \otimes \cdots \otimes \rho_1$. A positive contraction $T_n \in \mathcal{B}(\mathcal{H}_n)$ is considered as a test on a composite system. Now the errors of the first and second kind depend on $n$: $\alpha_n[T_n] = \operatorname{tr}\rho_0^{(n)}(I - T_n)$ and $\beta_n[T_n] = \operatorname{tr}\rho_1^{(n)} T_n$.

Set

$$\beta^*(n, \varepsilon) = \inf\{\operatorname{tr}\rho_1^{(n)} A_n\} \qquad [26]$$

where the infimum is over all $A_n \in \mathcal{B}(\mathcal{H}_n)$ such that $0 \le A_n \le I$ and $\operatorname{tr}\rho_0^{(n)}(I - A_n) \le \varepsilon$. In other words, this is the infimum of the error of the second kind when the error of the first kind is at most $\varepsilon$. The importance of this quantity is in the customary approach to hypothesis testing.

The following result is the quantum Stein lemma.

**Theorem 9** *In the above setting, the relation*

$$\lim_{n\to\infty} \frac{1}{n} \log \beta^*(n, \varepsilon) = -S(\rho_0 \| \rho_1)$$

*holds for every* $0 < \varepsilon < 1$.

## Bibliographic Notes

A book about entropy in several contexts is Greven *et al.* (2003). The role of von Neumann in the mathematization of the quantum entropy is described in Petz *et al.* (2001); this work contains also his gedanken experiment.

The first proof of the strong subadditivity appeared in Lieb and Ruskai (1973) and a didactical elementary approach is in Nielsen and Petz (2005). The structure of the case of equality was obtained in Hayden *et al.* (2004). The quantum relative entropy was introduced by Umegaki in 1962 and their properties and its axiomatization are contained in the monograph by Ohya and Petz (1993). The monotonicity of the relative entropy is called Uhlmann's theorem, see Uhlmann (1977) and Ohya and Petz (1993).

The rigorous and comprehensive treatment of quantum lattice systems was one of the early successes of the algebraic approach to quantum statistical thermodynamics. The subject is well summarized in Bratteli and Robinson (1981). The book by Sewell (1986) contains more physics and has less in mathematical technicalities. For many interesting entropy results concerning mean field systems, see, for example, Ragio and Werner (1991).

The high probability subspace theorem is due to Ohya and Petz – Petz (1992) and Ohya and Petz (1993) for product states – and was extended to

some algebraic and Gibbs states by Hiai and Petz. The application to data compression was first observed by Schumacher (1995). The chained property of the high-probability subspaces was studied in Bjelaković *et al.* (2003) and the universality is from Kaltchenko and Yang (2003).

A weak form of the quantum Stein lemma was proved in Hiai and Petz (1991) and the stated form is due to Nagaoka and Ogawa (2000). An extension to the case where $\rho_0^{(n)}$ is not a product was given in Bjelaković and Siegmund-Schultze (2004).

Other surveys about quantum entropy are Petz (1992) and Schumacher and Westmoreland (2002).

# Quantum Ergodicity and Mixing of Eigenfunctions

**S Zelditch**, Johns Hopkins University, Baltimore, MD, USA

Quantum ergodicity and mixing belong to the field of quantum chaos, which studies quantizations of "chaotic" classical Hamiltonian systems. The basic question is: how does the chaos of the classical dynamics impact on the eigenvalues/eigenfunctions of the quantum Hamiltonian $\hat{H}$ and on long-time dynamics generated by $\hat{H}$?

These problems lie at the foundations of the semiclassical limit, that is, the limit as the Planck constant $\hbar \to 0$ or the energy $E \to \infty$. More generally, one could ask what impact any dynamical feature of a classical mechanical system (e.g., complete integrability, KAM, and ergodicity) has on the eigenfunctions and eigenvalues of the quantization.

Over the last 30 years or so, these questions have been studied rather systematically by both mathematicians and physicists. There is an extensive literature comparing classical and quantum dynamics of model systems, such as comparing the geodesic flow and wave group on a compact (or finite-volume) hyperbolic surface, or comparing classical and quantum billiards on the Sinai billiard or the Bunimovich stadium, or comparing the

discrete dynamical system generated by a hyperbolic torus automorphism and its quantization by the metaplectic representation. As these models indicate, the basic problems and phenomena are richly embodied in simple, low-dimensional examples in much the same way that two-dimensional toy statistical mechanical models already illustrate complex problems on phase transitions. The principles established for simple models should apply to far more complex systems such as atoms and molecules in strong magnetic fields.

The conjectural picture which has emerged from many computer experiments and heuristic arguments on these simple model systems is roughly that there exists a length scale in which quantum chaotic systems exhibit universal behavior. At this length scale, the eigenvalues resemble eigenvalues of random matrices of large size and the eigenfunctions resemble random waves. A small sample of the original physics articles suggesting this picture is Berry (1977), Bohigas *et al.* (1984), Feingold and Peres (1986), and Heller (1984).

This article reviews some of the rigorous mathematical results in quantum chaos, particularly those on eigenfunctions of quantizations of classically ergodic or mixing systems. They support the conjectural picture of random waves up to two moments, that is, on the level of means and variances. A few results also exist on higher moments in very special cases. But from the mathematical point of view, the conjectural links to random matrices or random waves remain very much open at this time. A key difficulty is that the length scale on which universal behavior should occur is far below the resolving power of any known mathematical techniques, even in the simplest model problems. The main evidence for the random matrix and random wave connections comes from numerous computer experiments of model cases in the physics literature. We will not review numerical results here, but to get a well-rounded view of the field, it is important to understand the computer experiments (see, e.g., Bäcker *et al.* (1998a, b) and Barnett (2005)).

The model quantum systems that have been most intensively studied in mathematical quantum chaos are Laplacians or Schrödinger operators on compact (or finite-volume) Riemannian manifolds, with or without boundary, and quantizations of symplectic maps on compact Kähler manifolds. Similar techniques and results apply in both settings, so for the sake of coherence we concentrate on the Laplacian on a compact Riemannian manifold with "chaotic" geodesic flow and only briefly allude to the setting of "quantum maps." Additionally, two main kinds of methods are in use: (1) methods of semiclassical (or microlocal) analysis, which apply to general Laplacians (and more general Schrödinger operators), and (2) methods of number theory and automorphic forms, which apply to arithmetic models such as arithmetic hyperbolic manifolds or quantum cat maps. Arithmetic models are far more "explicitly solvable" than general chaotic systems, and the results obtained for them are far sharper than the results of semiclassical analysis. This article is primarily devoted to the general results on Laplacians obtained by semiclassical analysis; *see* Arithmetic Quantum Chaos for results by J Marklov. For background on semiclassical analysis, see Heller (1984).

## Wave Group and Geodesic Flow

The model quantum Hamiltonians we will discuss are Laplacians $\Delta$ on compact Riemannian manifolds $(M, g)$ (with or without boundary). The classical phase space in this setting is the cotangent bundle $T^*M$ of $M$, equipped with its canonical symplectic form $\sum_i \mathrm{d}x_i \wedge \mathrm{d}\xi_i$. The metric defines the Hamiltonian

$$H(x, \xi) = |\xi|_g = \sqrt{\sum_{ij=1}^{n} g^{ij}(x)\xi_i\xi_j}$$

on $T^*M$, where

$$g_{ij} = g\left(\frac{\partial}{\partial x_i}, \frac{\partial}{\partial x_j}\right)$$

$[g^{ij}]$ is the inverse matrix to $[g_{ij}]$. We denote the volume density of $(M, g)$ by dVol and the corresponding inner product on $L^2(M)$ by $\langle f, g\rangle$. The unit (co-) ball bundle is denoted $B^*M = \{(x, \xi) : |\xi| \leq 1\}$.

The Hamiltonian flow $\Phi^t$ of $H$ is the geodesic flow. By definition, $\Phi^t(x, \xi) = (x_t, \xi_t)$, where $(x_t, \xi_t)$ is the terminal tangent vector at time $t$ of the unit speed geodesic starting at $x$ in the direction $\xi$. Here and below, we often identify $T^*M$ with the tangent bundle $TM$ using the metric to simplify the geometric description. The geodesic flow preserves the energy surfaces $\{H = E\}$ which are the co-sphere bundles $S^*_E M$. Due to the homogeneity of $H$, the flow on any energy surface $\{H = E\}$ is equivalent to that on the co-sphere bundle $S^*M = \{H = 1\}$. (This homogeneity could be broken by adding a potential $V \in C^\infty(M)$ to form a semiclassical Schrödinger operator $-\hbar^2\Delta + V$, whose underlying Hamiltonian flow is generated by $|\xi|_g^2 + V(x)$.) *See* h-Pseudodifferential Operators and Applications.

The quantization of the Hamiltonian $H$ is the square root $\sqrt{\Delta}$ of the positive Laplacian

$$\Delta = -\frac{1}{\sqrt{g}}\sum_{i,j=1}^{n}\frac{\partial}{\partial x_i}g^{ij}g\frac{\partial}{\partial x_j}$$

of $(M,g)$. Here, $g = \det[g_{ij}]$. We choose to work with $\sqrt{\Delta}$ rather than $\Delta$ since the former generates the wave

$$U_t = \mathrm{e}^{\mathrm{i}t\sqrt{\Delta}}$$

which is the quantization of the geodesic flow $\Phi^t$.

By the last statement we mean that $U_t$ is related to $\Phi^t$ in several essentially equivalent ways:

1. singularities of waves, that is, solutions $U_t\psi$ of the wave equation, propagate along geodesics;
2. $U_t$ is a Fourier integral operator (= quantum map) associated to the canonical relation defined by the graph of $\Phi^t$ in $T^*M \times T^*M$; and
3. Egorov's theorem holds.

We only define the latter since it plays an important role in studying eigenfunctions. As with any quantum theory, there is an algebra of observables on the Hilbert space $L^2(M, \mathrm{dvol}_g)$ which quantizes $T^*M$. Here, $\mathrm{dvol}_g$ is the volume form of the metric. The algebra is that $\Psi^*(M)$ of pseudodifferential operators $\psi DO$'s of all orders, though we often restrict to the subalgebra $\Psi^0$ of $\psi\, DO$'s of order zero. We denote by $\Psi^m(M)$ the subspace of pseudodifferential operators of order $m$. The algebra is defined by constructing a quantization Op from an algebra of symbols $a \in S^m(T^*M)$ of order $m$ (polyhomogeneous functions on $T^*M\backslash 0$) to $\Psi^m$. The map Op is not unique. In the reverse direction is the symbol map $\sigma_A : \Psi^m \to S^m(T^*M)$ which takes an operator $\mathrm{Op}(a)$ to the homogeneous term $a_m$ of order $m$ in $a$.

Egorov's theorem for the wave group concerns the conjugations

$$\alpha_t(A) := U_t A U_t^*, \quad A \in \Psi^m(M) \qquad [1]$$

Such a conjugation defines the quantum evolution of observables in the Heisenberg picture, and, since the early days of quantum mechanics, it was known to correspond to the classical evolution

$$V_t(a) := a \circ \Phi^t \qquad [2]$$

of observables $a \in C^\infty(S^*M)$. Egorov's theorem is the rigorous version of this correspondence: it states that $\alpha_t$ defines an order-preserving automorphism of $\Psi^*(M)$, that is, $\alpha_t(A) \in \Psi^m(M)$ if $A \in \Psi^m(M)$, and that

$$\sigma_{U_t A U_t^*}(x,\xi) = \sigma_A(\Phi^t(x,\xi)) := V_t(\sigma_A), \quad (x,\xi) \in T^*M\backslash 0 \qquad [3]$$

This formula is almost universally taken to be the definition of quantization of a flow or map in the physics literature.

The key difficulty in quantum chaos is that it involves a comparison between long-time dynamical properties of $\Phi^t$ and $U_t$ through the symbol map and similar classical limits. The classical dynamics defines the "principal symbol" behavior of $U_t$ and the "error" $U_t A U_t^* - Op(\sigma_A \circ \Phi^t)$ typically grows exponentially in time. This is just the first example of a ubiquitous "exponential barrier" in the subject.

## Eigenvalues and Eigenfunctions of $\Delta$

The eigenvalue problem on a compact Riemannian manifold

$$\Delta\varphi_j = \lambda_j^2\varphi_j, \quad \langle\varphi_j, \varphi_k\rangle = \delta_{jk}$$

is dual under the Fourier transform to the wave equation. Here, $\{\varphi_j\}$ is a choice of orthonormal basis of eigenfunctions, which is not unique if the eigenvalues have multiplicities $>1$. The individual eigenfunctions are difficult to study directly, and so one generally forms the spectral projections kernel,

$$E(\lambda, x, y) = \sum_{j:\lambda_j \le \lambda}\varphi_j(x)\varphi_j(y) \qquad [4]$$

Semiclassical asymptotics is the study of the $\lambda \to \infty$ limit of the spectral data $\{\varphi_j, \lambda_j\}$ or of $E(\lambda, x, y)$. The (Schwartz) kernel of the wave group can be represented in terms of the spectral data by

$$U_t(x,y) = \sum_j \mathrm{e}^{\mathrm{i}t\lambda_j}\varphi_j(x)\varphi_j(y)$$

or equivalently as the Fourier transform $\int_{\mathbb{R}} \mathrm{e}^{\mathrm{i}t\lambda}\,\mathrm{d}E(\lambda, x, y)$ of the spectral projections. Hence, spectral asymptotics is often studied through the large-time behavior of the wave group.

The link between spectral theory and geometry, and the source of Egorov's theorem for the wave group, is the construction of a parametrix (or WKB formula) for the wave kernel. For small times $t$, the simplest is the Hadamard parametrix,

$$U_t(x,y) \sim \int_0^\infty \mathrm{e}^{\mathrm{i}\theta(r^2(x,y)-t^2)}\sum_{k=0}^\infty U_k(x,y)\theta^{((d-3)/2)-k}\,\mathrm{d}\theta \quad (t < \mathrm{inj}(M,g)) \qquad [5]$$

where $r(x,y)$ is the distance between points, $U_0(x,y) = \Theta^{-1/2}(x,y)$ is the volume 1/2-density, $\mathrm{inj}(M,g)$ is the injectivity radius, and the higher Hadamard coefficients are obtained by solving transport equations along geodesics. The parametrix is asymptotic to the wave kernel in the sense of

smoothness, that is, the difference of the two sides of [5] is smooth. The relation [5] may be iterated using $U_{tm} = U_t^m$ to obtain a parametrix for long times. This is obviously complicated and not necessarily the best long-time parametrix construction, but it illustrates again the difficulty of a long-time analysis.

### Weyl Law and Local Weyl Law

A fundamental and classical result in spectral asymptotics is Weyl's law on counting eigenvalues:

$$N(\lambda) = \#\{j : \lambda_j \leq \lambda\} = \frac{|B_n|}{(2\pi)^n}\mathrm{Vol}(M, g)\lambda^n + O(\lambda^{n-1}) \qquad [6]$$

Here, $|B_n|$ is the Euclidean volume of the unit ball and $\mathrm{Vol}(M, g)$ is the volume of $M$ with respect to the metric $g$. An equivalent formula which emphasizes the correspondence between classical and quantum mechanics is

$$\mathrm{tr}E_\lambda = \frac{\mathrm{Vol}(|\xi|_g \leq \lambda)}{(2\pi)^n} \qquad [7]$$

where Vol is the symplectic volume measure relative to the natural symplectic form $\sum_{j=1}^n \mathrm{d}x_j \wedge \mathrm{d}\xi_j$ on $T^*M$. Thus, the dimension of the space where $H = \sqrt{\Delta}$ is $\leq \lambda$ is asymptotically the volume where its symbol $|\xi|_g \leq \lambda$.

The remainder term in Weyl's law is sharp on the standard sphere, where all geodesics are periodic, but is not sharp on $(M, g)$ for which the set of periodic geodesics has measure zero (Duistermaat–Guillemin, Ivrii) (*see* Semiclassical Spectra and Closed Orbits). When the set of periodic geodesics has measure zero (as is the case for ergodic systems), one has

$$N(\lambda) = \#\{j : \lambda_j \leq \lambda\} = \frac{|B_n|}{(2\pi)^n}\mathrm{Vol}(M, g)\lambda^n + o(\lambda^{n-1}) \qquad [8]$$

The remainder is then of smaller order than the derivative of the principal term, and one then has asymptotics in shorter intervals:

$$N([\lambda, \lambda+1]) = \#\{j : \lambda_j \in [\lambda, \lambda+1]\} = n\frac{|B_n|}{(2\pi)^n}\mathrm{Vol}(M, g)\lambda^{n-1} + o(\lambda^{n-1}) \qquad [9]$$

Physicists tend to write $\lambda \sim \hbar^{-1}$ and to average over intervals of this width. Then mean spacing between the eigenvalues in this interval is $\sim C_n \mathrm{Vol}(M, g)^{-1} \times \lambda^{-(n-1)}$, where $C_n$ is a constant depending on the dimension.

An important generalization is the "local Weyl law" concerning the traces $\mathrm{tr}AE(\lambda)$, where $A \in \Psi^m(M)$. It asserts that

$$\sum_{\lambda_j \leq \lambda} \langle A\varphi_j, \varphi_j \rangle = \frac{1}{(2\pi)^n}\int_{B^*M} \sigma_A \mathrm{d}x\, \mathrm{d}\xi\ \lambda^n + O(\lambda^{n-1}) \qquad [10]$$

There is also a pointwise local Weyl law:

$$\sum_{\lambda_j \leq \lambda} |\varphi_j(x)|^2 = \frac{1}{(2\pi)^n}|B^n|\lambda^n + R(\lambda, x) \qquad [11]$$

where $R(\lambda, x) = O(\lambda^{n-1})$ uniformly in $x$. Again, when the periodic geodesics form a set of measure zero in $S^*M$, one could average over the shorter interval $[\lambda, \lambda+1]$. Combining the Weyl and local Weyl law, we find the surface average of $\sigma_A$ is a limit of traces:

$$\omega(A) := \frac{1}{\mu(S^*M)}\int_{S^*M} \sigma_A\, \mathrm{d}\mu = \lim_{\lambda \to \infty} \frac{1}{N(\lambda)} \sum_{\lambda_j \leq \lambda} \langle A\varphi_j, \varphi_j \rangle \qquad [12]$$

Here, $\mu$ is the "Liouville measure" on $S^*M$, that is, the surface measure $\mathrm{d}\mu = \mathrm{d}x\, \mathrm{d}\xi / \mathrm{d}H$ induced by the Hamiltonian $H = |\xi|_g$ and by the symplectic volume measure $\mathrm{d}x\, \mathrm{d}\xi$ on $T^*M$.

### Problems on Asymptotics Eigenfunctions

Eigenfunctions arise in quantum mechanics as stationary states, that is, states $\psi$ for which the probability measure $|\psi(t, x)|^2 \mathrm{dvol}$ is constant in time where $\psi(t, x) = U_t \psi(x)$ is the evolving state. This follows from the fact that

$$U_t \varphi_k = \mathrm{e}^{\mathrm{i}t\lambda_k} \varphi_k \qquad [13]$$

and that $|\mathrm{e}^{\mathrm{i}t\lambda_k}| = 1$. They are the basic modes of the quantum system. One would like to know the behavior as $\lambda_j \to \infty$ (or $\hbar \to 0$ in the semiclassical setting) of invariants such as:

1. matrix elements $\langle A\varphi_j, \varphi_j \rangle$ of observables in this state;
2. transition elements $\langle A\varphi_i, \varphi_j \rangle$ between states;
3. size properties as measured by $L^p$ norms $\|\varphi_j\|_{L^p}$;
4. value distribution as measured by the distribution function $\mathrm{Vol}\{x \in M : |\varphi_j(x)|^2 > t\}$; and
5. shape properties, for example, distribution of zeros and critical points of $\varphi_j$.

Let us introduce some problems which have motivated much of the work in this area.

**Problem 1** Let $\mathcal{Q}$ denote the set of "quantum limits," that is, weak* limit points of the sequence $\{\Phi_k\}$ of distributions on the classical phase space $S^*M$, defined by

$$\int_X a\, \mathrm{d}\Phi_k := \langle Op(a)\varphi_k, \varphi_k\rangle$$

where $a \in C^\infty(S^*M)$.

The set $\mathcal{Q}$ is independent of the definition of Op. It follows almost immediately from Egorov's theorem that $\mathcal{Q} \subset \mathcal{M}_I$, where $\mathcal{M}_I$ is the convex set of invariant probability measures for the geodesic flow. Furthermore, they are time-reversal invariant, that is, invariant under $(x, \xi) \to (x, -\xi)$ since the eigenfunctions are real valued.

To see this, it is helpful to introduce the linear functionals on $\Psi^0$:

$$\rho_k(A) = \langle Op(a)\varphi_k, \varphi_k\rangle \qquad [14]$$

We observe that $\rho_k(I) = 1$, $\rho_k(A) \geq 0$ if $A \geq 0$, and that

$$\rho_k\left(U_t A U_t^*\right) = \rho_k(A) \qquad [15]$$

Indeed, if $A \geq 0$ then $A = B^*B$ for some $B \in \Psi^0$ and we can move $B^*$ to the right-hand side. Similarly, [15] is proved by moving $U_t$ to the right-hand side and using [13]. These properties mean that $\rho_j$ is an "invariant state" on the algebra $\Psi^0$. More precisely, one should take the closure of $\Psi^0$ in the operator norm. An invariant state is the analog in quantum statistical mechanics of an invariant probability measure.

The next important fact about the states $\rho_k$ is that any weak limit of the sequence $\{\rho_k\}$ on $\Psi^0$ is an invariant probability measure on $C(S^*M)$, that is, a positive linear functional on $C(S^*M)$ rather than just a state on $\Psi^0$. This follows from the fact that $\langle K\varphi_j, \varphi_j\rangle \to 0$ for any compact operator $K$, and so any limit of $\langle A\varphi_k, \varphi_k\rangle$ is equally a limit of $\langle (A+K)\varphi_k, \varphi_k\rangle$. Hence, any limit is bounded by $\inf_K \|A+K\|$ (the infimum taken over compact operators), and for any $A \in \Psi^0, \|\sigma_A\|_{L^\infty} = \inf_K \|A+K\|$. Hence, any weak limit is bounded by a constant times $\|\sigma_A\|_{L^\infty}$ and is therefore continuous on $C(S^*M)$. It is a positive functional since each $\rho_j$, and hence any limit, is a probability measure. By Egorov's theorem and the invariance of the $\rho_k$, any limit of $\rho_k(A)$ is a limit of $\rho_k(Op(\sigma_A \circ \Phi^t))$ and hence the limit measure is invariant.

Problem 1 is thus to identify which invariant measures in $\mathcal{M}_I$ show up as weak limits of the functionals $\rho_k$ or equivalently the distributions $\mathrm{d}\Phi_k$. The weak limits reflect the concentration and oscillation properties of eigenfunctions. Here are some possibilities:

1. Normalized Liouville measure. In fact, the functional $\omega$ of [12] is also a state on $\Psi^0$ for the reason explained above. A subsequence $\{\varphi_{k_j}\}$ of eigenfunctions is considered diffuse if $\rho_{k_j} \to \omega$.
2. A periodic orbit measure $\mu_\gamma$ defined by

$$\mu_\gamma(A) = \frac{1}{L_\gamma}\int_\gamma \sigma_A\, \mathrm{d}s$$

where $L_\gamma$ is the length of $\gamma$. A sequence of eigenfunctions for which $\rho_{k_j} \to \mu_\gamma$ obviously concentrates (or strongly "scars") on the closed geodesic.
3. A finite sum of periodic orbit measures.
4. A delta-function along an invariant Lagrangian manifold $\Lambda \subset S^*M$. The associated eigenfunctions are viewed as "localizing" along $\Lambda$.
5. A more general invariant measure which is singular with respect to $\mathrm{d}\mu$.

All of these possibilities can and do happen in different examples. If $\mathrm{d}\Phi_{k_j} \to \omega$, then in particular we have

$$\frac{1}{\mathrm{Vol}(M)}\int_E |\varphi_{k_j}(x)|^2 \mathrm{dVol} \to \frac{\mathrm{Vol}(E)}{\mathrm{Vol}(M)}$$

for any measurable set $E$ whose boundary has measure zero. Interpreting $|\varphi_{k_j}(x)|^2\mathrm{dVol}$ as the probability density of finding a particle of energy $\lambda_k^2$ at $x$, this result means that the sequence of probabilities tends to uniform measure.

However, $\mathrm{d}\Phi_{k_j} \to \omega$ is much stronger since it says that the eigenfunctions become diffuse on the energy surface $S^*M$ and not just on the configuration space $M$. As an example, consider the flat torus $\mathbb{R}^n/\mathbb{Z}^n$. An orthonormal basis of eigenfunctions is furnished by the standard exponentials $\mathrm{e}^{2\pi\mathrm{i}\langle k, x\rangle}$ with $k \in \mathbb{Z}^n$. Obviously, $|\mathrm{e}^{2\pi\mathrm{i}\langle k, x\rangle}|^2 = 1$, so the eigenfunctions are already diffuse in configuration space. On the other hand, they are far from diffuse in phase space, and localize on invariant Lagrangian tori in $S^*M$. Indeed, by definition of pseudodifferential operator, $A\mathrm{e}^{2\pi\mathrm{i}\langle k, x\rangle} = a(x,k)\,\mathrm{e}^{2\pi\mathrm{i}\langle k, x\rangle}$, where $a(x,k)$ is the complete symbol. Thus,

$$\langle A\mathrm{e}^{2\pi\mathrm{i}\langle k,x\rangle}, \mathrm{e}^{2\pi\mathrm{i}\langle k,x\rangle}\rangle = \int_{\mathbb{R}^n/\mathbb{Z}^n} a(x,k)\,\mathrm{d}x \sim \int_{\mathbb{R}^n/\mathbb{Z}^n} \sigma_A\left(x, \frac{k}{|k|}\right)\mathrm{d}x$$

A subsequence $\mathrm{e}^{2\pi\mathrm{i}\langle k_j, x\rangle}$ of eigenfunctions has a weak limit if and only if $k_j/|k_j|$ tends to a limit vector $\xi_0$ in the unit sphere in $\mathbb{R}^n$. In this case, the associated

weak* limit is $\int_{\mathbb{R}^n/\mathbb{Z}^n} \sigma_A(x, \xi_0)\mathrm{d}x$, that is, the delta-function on the invariant torus $T_{\xi_0} \subset S^*M$ defined by the constant momentum condition $\xi = \xi_0$. The eigenfunctions are said to localize on this invariant torus for $\Phi^t$.

The flat torus is a model of a completely integrable system on both the classical and quantum levels. Another example is that of the standard round sphere $S^n$. In this case, the author and D Jakobson showed that absolutely any invariant measure $\nu \in \mathcal{M}_I$ can arise as a weak limit of a sequence of eigenfunctions. This reflects the huge degeneracy (multiplicities) of the eigenvalues.

On the other hand, if the geodesic flow is ergodic, one would expect the eigenfunctions to be diffuse in phase space. In the next section, we will discuss the rigorous results on this problem.

Off-diagonal matrix elements

$$\rho_{jk}(A) = \langle A\varphi_i, \varphi_j \rangle \qquad [16]$$

are also important as transition amplitudes between states. They no longer define states since $\rho_{jk}(I) = 0$, are positive, or invariant. Indeed, $\rho_{jk}(U_t A U_t^*) = \mathrm{e}^{\mathrm{i}t(\lambda_j - \lambda_k)}\rho_{jk}(A)$, so they are eigenvectors of the automorphism $\alpha_t$ of [1]. A sequence of such matrix elements cannot have a weak limit unless the spectral gap $\lambda_j - \lambda_k$ tends to a limit $\tau \in \mathbb{R}$. In this case, by the same discussion as above, any weak limit of the functionals $\rho_{jk}$ will be an eigenmeasure of the geodesic flow which transforms by $\mathrm{e}^{\mathrm{i}\tau t}$ under the action of $\Phi^t$. Examples of such eigenmeasures are orbital Fourier coefficients

$$\frac{1}{L_\gamma} \int_0^{L_\gamma} \mathrm{e}^{-\mathrm{i}\tau t} \sigma_A(\Phi^t(x, \xi))\,\mathrm{d}t$$

along a periodic orbit. Here, $\tau \in (2\pi/L_\gamma)\mathbb{Z}$. We denote by $\mathcal{Q}_\tau$ such eigenmeasures of the geodesic flow. Problem 1 has the following extension to off-diagonal elements:

**Problem 2** Determine the set $\mathcal{Q}_\tau$ of "quantum limits," that is, weak* limit points of the sequence $\{\Phi_{kj}\}$ of distributions on the classical phase space $S^*M$, defined by

$$\int_X a\,\mathrm{d}\Phi_{kj} := \langle \mathrm{O}p(a)\varphi_k, \varphi_j \rangle$$

where $\lambda_j - \lambda_k = \tau + o(1)$ and where $a \in C^\infty(S^*M)$, or equivalently of the functionals $\rho_{jk}$.

As will be discussed in the section "Quantum weak mixing," the asymptotics of off-diagonal elements depends on the weak mixing properties of the geodesic flow and not just its ergodicity.

Matrix elements of eigenfunctions are quadratic forms. More "nonlinear" problems involve the $L^p$-norms or the distribution functions of eigenfunctions. Estimates of the $L^\infty$-norms can be obtained from the local Weyl law [10]. Since the jump in the left-hand side at $\lambda$ is $\sum_{j:\lambda_j=\lambda} |\varphi_j(x)|^2$ and the jump in the right-hand side is the jump of $R(\lambda, x)$, this implies

$$\sum_{j:\lambda_j=\lambda} |\varphi_j(x)|^2 = \mathrm{O}(\lambda^{n-1}) \Longrightarrow \|\varphi_j\|_{L^\infty} = \mathrm{O}(\lambda^{\frac{n-1}{2}}) \quad [17]$$

For general $L^p$-norms, the following bounds were proved by C Sogge for any compact Riemannian manifold:

$$\frac{\|\varphi_j\|_p}{\|\varphi\|_2} = \mathrm{O}(\lambda^{\delta(p)}), \quad 2 \le p \le \infty \qquad [18]$$

where

$$\delta(p) = \begin{cases} n\left(\dfrac{1}{2} - \dfrac{1}{p}\right) - \dfrac{1}{2}, & \dfrac{2(n+1)}{n-1} \le p \le \infty \\[2ex] \dfrac{n-1}{2}\left(\dfrac{1}{2} - \dfrac{1}{p}\right), & 2 \le p \le \dfrac{2(n+1)}{n-1} \end{cases} \qquad [19]$$

These estimates are sharp on the unit sphere $S^n \subset \mathbb{R}^{n+1}$. The extremal eigenfunctions are the zonal spherical harmonics, which are the $L^2$-normalized spectral projection kernels $\Pi_N(x, x_0)/\|\Pi_N(\cdot, x_0)\|$ centered at any $x_0$. However, they are not sharp for generic $(M, g)$, and it is natural to ask how "chaotic dynamics" might influence $L^p$-norms.

**Problem 3** Improve the estimates $\|\varphi_j\|_p/\|\varphi\|_2 = O(\lambda^{\delta(p)})$ for $(M, g)$ with ergodic or mixing geodesic flow.

C Sogge and the author have proved that if a sequence of eigenfunctions attains the bounds in [17], then there must exist a point $x_0$ so that a positive measure of geodesics starting at $x_0$ in $S^*_{x_0}M$ returns to $x_0$ at a fixed time $T$. In the real analytic case, all return so $x_0$ is a perfect recurrent point. In dimension 2, such a perfect recurrent point cannot occur if the geodesic flow is ergodic; hence $\|\varphi_j\|_{L^\infty} = o(\lambda^{(n-1)/2})$ on any real analytic surface with ergodic geodesic flow. This shows that none of the $L^p$-estimates above the critical index are sharp for real analytic surfaces with ergodic geodesic flow, and the problem is the extent to which they can be improved.

The random wave model (see the section "Random waves and orthonormal bases") predicts that eigenfunctions of Riemannian manifolds with chaotic geodesic flow should have the bounds $\|\varphi_\lambda\|_{L^p} = O(1)$ for $p < \infty$ and that $\|\varphi_\lambda\|_{L^\infty} < \sqrt{\log \lambda}$. But there are

no rigorous estimates at this time close to such predictions. The best general estimate to date on negatively curved compact manifolds (which are models of chaotic geodesic flow) is just the logarithmic improvement

$$||\varphi_j||_{L^\infty} = O\left(\frac{\lambda^{n-1}}{\log \lambda}\right)$$

on the standard remainder term in the local Weyl law. This was known for compact hyperbolic manifolds from the Selberg trace formula, and similar estimates hold manifolds without conjugate points (P Bérard). The exponential growth of the geodesic flow again causes a barrier in improving the estimate beyond the logarithm. In the analogous setting of quantum "cat maps," which are models of chaotic classical dynamics, there exist arbitrarily large eigenvalues with multiplicities of the order $O(\lambda^{n-1}/\log \lambda)$; the $L^\infty$-norm of the $L^2$-normalized projection kernel onto an eigenspace of this multiplicity is of order of the square root of the multiplicity (Faure *et al.* 2003). This raises doubt that the logarithmic estimate can be improved by general dynamical arguments. Further discussion of $L^\infty$-norms, as well as zeros, will be given at the end of the next section for ergodic systems.

## Quantum Ergodicity

In this section, we discuss results on the problems stated above when the geodesic flow of $(M, g)$ is assumed to be ergodic. Let us recall that this means that Liouville measure is an ergodic measure for $\Phi^t$. This is a spectral property of the operator $V_t$ of [2] on $L^2(S^*M, \mathrm{d}\mu)$, namely that $V_t$ has 1 as an eigenvalue of multiplicity 1. That is, the only invariant $L^2$-functions (with respect to Liouville measure) are the constant functions. This implies that the only invariant sets have Liouville measure 0 or 1 and (Birkhoff's ergodic theorem) that time averages of functions are constant almost everywhere (equal to the space average).

In this case, there is a general result which originated in the work of Schnirelman and was developed into the following theorem by Zelditch, Colin de Verdière, and Sunada (manifolds without boundary), and Gérard–Leichtnam and Zelditch–Zworski (manifolds with boundary). The following discussion is based on the articles (Zelditch 1996b, c, Zelditch and Zworski 1996), which contain further references to the literature.

**Theorem 1** *Let $(M, g)$ be a compact Riemannian manifold (possibly with boundary), and let $\{\lambda_j, \varphi_j\}$ be the spectral data of its Laplacian $\Delta$. Then the geodesic flow $G^t$ is ergodic on $(S^*M, \mathrm{d}\mu)$ if and only if, for every $A \in \Psi^o(M)$, we have:*

(i) $\lim_{\lambda \to \infty} \frac{1}{N(\lambda)} \sum_{\lambda_j \le \lambda} |(A\varphi_j, \varphi_j) - \omega(A)|^2 = 0.$

(ii) $(\forall \epsilon)(\exists \delta) \limsup_{\lambda \to \infty} \frac{1}{N(\lambda)} \sum_{j \ne k : \lambda_j, \lambda_k \le \lambda |\lambda_j - \lambda_k| < \delta} |(A\varphi_j, \varphi_k)|^2 < \epsilon.$

This implies that there exists a subsequence $\{\varphi_{j_k}\}$ of eigenfunctions whose indices $j_k$ have counting density 1 for which $\langle A\varphi_{j_k}, \varphi_{j_k}\rangle \to \omega(A)$. We will call the eigenfunctions in such a sequence "ergodic eigenfunctions." One can sharpen the results by averaging over eigenvalues in the shorter interval $[\lambda, \lambda + 1]$ rather than in $[0, \lambda]$.

There is also an ergodicity result for boundary values of eigenfunctions on domains with boundary and with Dirichlet, Neumann, or Robin boundary conditions (Gérard–Leichtnam, Hassell–Zelditch, Burq). This corresponds to the fact that the billiard map on $B^*\partial M$ is ergodic.

The first statement (i) is essentially a convexity result. It remains true if one replaces the square by any convex function $\varphi$ on the spectrum of $A$,

$$\frac{1}{N(E)} \sum_{\lambda_j \le E} \varphi(\langle A\varphi_k, \varphi_k\rangle - \omega(A)) \to 0 \qquad [20]$$

Before sketching a proof, we point out a somewhat heuristic "picture proof" of the theorem. Namely, ergodicity of the geodesic flow is equivalent to the statement that Liouville measure is an extreme point of the compact convex set $\mathcal{M}_I$. In fact, it further implies that $\omega$ is an extreme point of the compact convex set $\mathcal{E}_{\mathbb{R}}$ of invariant states for $\alpha_t$ of eqn [1]; see Ruelle (1969) for background. But the local Weyl law says that $\omega$ is also the limit of the convex combination

$$\frac{1}{N(E)} \sum_{\lambda_j \le E} \rho_j$$

An extreme point cannot be written as a convex combination of other states unless all the states in the combination are equal to it. In our case, $\omega$ is only a limit of convex combinations so it need not (and does not) equal each term. However, almost all terms in the sequence must tend to $\omega$, and that is equivalent to [1].

**Sketch of Proof of Theorem 1(i)** As mentioned above, this is a convexity result and with no additional effort we can consider more general sums of the form. We then have

$$\sum_{\lambda_j \le E} \varphi(\langle A\varphi_k, \varphi_k\rangle - \omega(A)) = \sum_{\lambda_j \le E} \varphi(\langle\langle A\rangle_T - \omega(A)\varphi_k, \varphi_k\rangle) \qquad [21]$$

where

$$\langle A\rangle_T = \frac{1}{2T}\int_{-T}^{T} U_t A U_t^* \, \mathrm{d}t$$

We then apply the Peierls–Bogoliubov inequality

$$\sum_{j=1}^{n} \varphi((B\varphi_j, \varphi_j)) \le \operatorname{tr} \varphi(B)$$

with $B = \Pi_E[\langle A\rangle_T - \omega(A)]\Pi_E$ to get

$$\sum_{\lambda_j \le E} \varphi(\langle\langle A\rangle_T - \omega(A)\varphi_k, \varphi_k\rangle) \le \operatorname{tr} \varphi(\Pi_E[\langle A\rangle_T - \omega(A)]\Pi_E) \qquad [22]$$

Here, $\Pi_E$ is the spectral projection for $\hat{H}$ corresponding to the interval $[0, E]$. From the Berezin inequality we then have (if $\varphi(0) = 0$):

$$\begin{aligned}\frac{1}{N(E)} &\operatorname{tr} \varphi(\Pi_E[\langle A\rangle_T - \omega(A)]\Pi_E) \\ &\le \frac{1}{N(E)} \operatorname{tr} \Pi_E \varphi([\langle A\rangle_T - \omega(A)])\Pi_E \\ &\to \omega_E(\varphi(\langle A\rangle_T - \omega(A))), \text{ as } E \to \infty\end{aligned}$$

As long as $\varphi$ is smooth, $\varphi(\langle A\rangle_T - \omega(A))$ is a pseudodifferential operator of order zero with principal symbol $\varphi(\langle\sigma_A\rangle_T - \omega(A))$. By the assumption that $\omega_E \to \omega$ we get

$$\begin{aligned}\lim_{E\to\infty} \frac{1}{N(E)} &\sum_{\lambda_j \le E} \varphi(\langle A\varphi_k, \varphi_k\rangle - \omega(A)) \\ &\le \int_{\{H=1\}} \varphi(\langle\sigma_A\rangle_T - \omega(A)) \, \mathrm{d}\mu\end{aligned}$$

where

$$\langle\sigma_A\rangle_T = \frac{1}{2T}\int_{-T}^{T} \sigma_A \circ \Phi^t \, \mathrm{d}t$$

As $T \to \infty$ the right-hand side approaches $\varphi(0) = 0$ by the dominated convergence theorem and by Birkhoff's ergodic theorem. Since the left-hand side is independent of $T$, this implies that

$$\lim_{E\to\infty} \frac{1}{N(E)} \sum_{\lambda_j \le E} \varphi(\langle A\varphi_k, \varphi_k\rangle - \omega(A)) = 0$$

for any smooth convex $\varphi$ on Spec$(A)$ with $\varphi(0) = 0$. □

As mentioned above, the statement of Theorem 1(i) is equivalent to saying that there is a subsequence $\{\varphi_{j_k}\}$ of counting density 1 for which $\rho_{j_k} \to \omega$. The above proof does not and cannot settle the question whether there exist exceptional sparse subsequences of eigenfunctions of density zero tending to other invariant measures. To see this, we observe that the proof is so general that it applies to seemingly very different situations. In place of the distributions $\{\Phi_j\}$ we may consider the set $\mu_\gamma$ of periodic orbit measures for a hyperbolic flow on a compact manifold $X$. That is,

$$\mu_\gamma(f) = \frac{1}{T_\gamma}\int_\gamma f \quad \text{for } f \in C(X)$$

where $\gamma$ is a closed orbit and $T_\gamma$ is its period. According to the Bowen–Margulis equidistribution theorem for closed orbits of hyperbolic flows, we have

$$\frac{1}{\Pi(T)} \sum_{\gamma: T_\gamma \le T} \frac{1}{|\det(I - P_\gamma)|} \mu_\gamma \to \mu$$

where as above $\mu$ is the Liouville measure, where $P_\gamma$ is the linear Poincaré map and where $\Pi(T)$ is the normalizing factor which makes the left side a probability measure, that is, defined by the integral of 1 against the sum. An exact repetition of the previous argument shows that up to a sparse subsequence of $\gamma$'s, $\mu_\gamma \to \mu$ individually. Yet clearly, the whole sequence does not tend to $\mathrm{d}\mu$: for instance, one could choose the sequence of iterates $\gamma^k$ of a fixed closed orbit.

### Quantum Ergodicity in Terms of Operator Time and Space Averages

The first part of the result above may be reformulated as a relation between operator time and space averages.

**Definition** Let $A \in \Psi^0$ be an observable and define its time average to be:

$$\langle A\rangle := \lim_{T\to\infty} \frac{1}{2T}\int_{-T}^{T} U_t^* A U_t \, \mathrm{d}t$$

and its space average to be scalar operator

$$\omega(A) \cdot I$$

Here, the limit is taken in the weak operator topology (i.e., one matrix element at a time). To see what is involved, we consider matrix elements with respect to the eigenfunctions. We have

$$\left(\frac{1}{2T}\int_{-T}^{T} U_t^* A U_t \, \mathrm{d}t \varphi_i, \varphi_j\right) = \frac{\sin T(\lambda_i - \lambda_j)}{T(\lambda_i - \lambda_j)} (A\varphi_i, \varphi_j)$$

from which it is clear that the matrix element tends to zero as $T \to \infty$ unless $\lambda_i = \lambda_j$. However, there is no uniformity in the rate at which it goes to zero since the spacing $\lambda_i - \lambda_j$ could be uncontrollably small.

In these terms, Theorem 1(i) states that

$$\langle A \rangle = \omega(A)I + K, \quad \text{where} \lim_{\lambda\to\infty} \omega_\lambda(K^*K) \to 0 \qquad [23]$$

where $\omega_\lambda(A) = \operatorname{tr} E(\lambda)A$. Thus, the time average equals the space average plus a term $K$ which is semiclassically small in the sense that its Hilbert–Schmidt norm square $\|E_\lambda K\|^2_{\mathrm{HS}}$ in the span of the eigenfunctions of eigenvalue $\leq \lambda$ is $o(N(\lambda))$.

This is not exactly equivalent to Theorem 1(i) since it is independent of the choice of orthonormal basis, while the previous result depends on the choice of basis. However, when all eigenvalues have multiplicity 1, then the two are equivalent. To see the equivalence, note that $\langle A \rangle$ commutes with $\sqrt{\Delta}$ and hence is diagonal in the basis $\{\varphi_j\}$ of joint eigenfunctions of $\langle A \rangle$ and of $U_t$. Hence, $K$ is the diagonal matrix with entries $\langle A\varphi_k, \varphi_k\rangle - \omega(A)$. The condition is therefore equivalent to

$$\lim_{E\to\infty} \frac{1}{N(E)} \sum_{\lambda_j \leq E} |\langle A\varphi_k, \varphi_k\rangle - \omega(A)|^2 = 0$$

Since all the terms are positive, no cancellation is possible and this condition is equivalent to the existence of a subset $\mathcal{S} \subset \mathbb{N}$ of density 1 such that $\mathcal{Q}_\mathcal{S} := \{\mathrm{d}\Phi_k : k \in \mathcal{S}\}$ has only $\omega$ as a weak$^*$ limit point. As above, one says that the sequence of eigenfunctions is ergodic.

One could take this restatement of Theorem 1(i) as a semiclassical definition of quantum ergodicity. Two natural questions arise. First:

**Problem 4** Suppose the geodesic flow $\Phi^t$ of $(M, g)$ is ergodic on $S^*M$. Is the operator $K$ in

$$\langle A \rangle = \omega(A) + K$$

a compact operator? In this case, $\sqrt{\Delta}$ is said to be quantum uniquely ergodic (QUE). If ergodicity is not sufficient for the QUE property, what extra conditions need to be added?

Compactness would imply that $\langle K\varphi_k, \varphi_k\rangle \to 0$, hence $\langle A\varphi_k, \varphi_k\rangle \to \omega(A)$ along the entire sequence. Quite a lot of attention has been focused on this problem in the last decade. It is probable that ergodicity is not by itself sufficient for the QUE property of general Riemann manifold. For instance, it is believed that there exist modes of asymptotic bouncing ball type which concentrate on the invariant Lagrangian cylinder (with boundary) formed by bouncing ball orbits of the Bunimovich stadium (see e.g., Heller (1984) for more on such "scarring"). Further, Faure *et al.* (2003) have shown that QUE does not hold for the hyperbolic system defined by a quantum cat map on the torus. Since the methods applicable to eigenfunctions of quantum maps and of Laplacians have much in common, this negative result shows that there cannot exist a universal structural proof of QUE.

The principal positive result available at this time is the recent proof by Lindenstrauss of the QUE property for the orthonormal basis of Laplace–Hecke eigenfunctions on arithmetic hyperbolic surfaces. It is generally believed that the spectrum of the Laplace eigenvalues is of multiplicity 1 for such surfaces, so this should imply QUE completely for these surfaces. Earlier partial results on Hecke eigenfunctions are due to Rudnick–Sarnak, Wolpert, and others. For references and further discussion onf Hecke eigenfunctions, see Rudnick and Sarnak (1994) (*see* Arithmetic Quantum Chaos).

So far we have not mentioned Theorem 1(ii). In the next section, we will describe a similar but more general result for mixing systems and the relevance of (ii) will become clear. An interesting open problem is the extent to which (ii) is actually necessary for the equivalence to classical ergodicity.

**Problem 5** Converse QE: What can be said of the classical limit of a quantum ergodic system, that is, a system for which $\langle A \rangle = \omega(A) + K$, where $K$ is compact? Is it necessarily ergodic?

Very little is known on this converse problem at present. It is known that if there exists an open set in $S^*M$ filled by periodic orbits, then the Laplacian cannot be quantum ergodic (see Marklof and O'Keefe (2005) for recent results and references). But no proof exists at this time that KAM systems, which have Cantor-like positive measure invariant sets, are not quantum ergodic. It is known that there exists a positive proportion of approximate eigenfunctions (quasimodes) which localize on the invariant tori, but it has not been proved that a positive proportion of actual eigenfunctions has this localization property.

## Further Problems and Results on Ergodic Eigenfunctions

Ergodicity is also known to have an impact on the distribution of zeros. The complex zeros in Kähler phase spaces of ergodic eigenfunctions of quantum ergodic maps become uniformly distributed with respect to the Kähler volume form (Nonnenmacher–Voros, Shiffman–Zelditch). An interesting problem is whether the real analog is true:

**Problem 6** Ergodicity and equidistribution of nodal sets. Let $\mathcal{N}_{\varphi_j} \subset M$ denote the nodal set (zero set) of $\varphi_j$, and equip it with its hypersurface volume form $\mathrm{d}\mathcal{H}^{n-1}$ induced by $g$. Let $(M, g)$ have ergodic geodesic flow, and suppose that $\{\varphi_j\}$ is an ergodic

sequence of eigenfunctions. Are the following asymptotics valid?

$$\int_{\mathcal{N}_{\varphi_j}} f\, \mathrm{d}\mathcal{H}^{n-1} \sim \lambda_j \frac{1}{\mathrm{Vol}(M,g)} \int_M f\, \mathrm{dVol}$$

This is predicted by the random wave model of the section "Random waves and orthonormal bases." An equidistribution law for the complex zeros is known which gives some evidence for the validity of this limit formula. Let $(M,g)$ be a compact real analytic Riemannian manifold and let $\varphi_j^{\mathbb{C}}$ be the holomorphic extension of the real analytic eigenfunction $\varphi_j$ to the complexification $M_{\mathbb{C}}$ of $M$ (its Grauert tube). Then, if the geodesic flow is ergodic and if $\varphi_j$ is an ergodic sequence of eigenfunctions, the normalized current of integration $(1/\lambda_j)Z_{\varphi_j^{\mathbb{C}}}$ over the complex zero set of $\varphi_j^{\mathbb{C}}$ tends weakly to $(\mathrm{i}/\pi)\bar{\partial}\partial|\xi_g|$. This current is singular along the zero section.

Finally, we mention some results on $L^\infty$-norms of eigenfunctions on arithmetic hyperbolic manifolds of dimensions 2 and 3. It was proved by Iwaniec–Sarnak that the joint eigenfunctions of $\Delta$ and the Hecke operators on arithmetic hyperbolic surfaces have the upper bound $\|\varphi_j\|_\infty = O_\epsilon(\lambda_j^{5/48+\epsilon})$ for all $j$ and $\epsilon > 0$, and the lower bound $\|\varphi_j\|_\infty \geq c\sqrt{\log\log \lambda_j}$ for some constant $c > 0$ and infinitely many $j$. Rudnick and Sarnak (1994) proved that there exists an arithmetic hyperbolic manifold and a subsequence $\varphi_{j_k}$ of eigenfunctions with $\|\varphi_{j_k}\|_{L^\infty} \gg \lambda_{j_k}^{1/4}$, contradicting the random wave model predictions.

## Quantum Weak Mixing

There are parallel results on quantizations of weak-mixing geodesic flows which are the subject of this section. First we recall the classical definition: the geodesic flow of $(M,g)$ is weak mixing if the operator $V_t$ has purely continuous spectrum on the orthogonal complement of the constant functions in $L^2(S^*M, \mathrm{d}\mu)$. Hence, like ergodicity, it is a spectral property of the geodesic flow.

We have:

**Theorem 2** (Zelditch 1996c). *The geodesic flow $\Phi^t$ of $(M,g)$ is weak mixing if and only if the conditions (i) and (ii) of Theorem 1 hold and additionally, for any $A \in \Psi^o(M)$,*

$$(\forall\epsilon)(\exists\delta) \limsup_{\lambda\to\infty} \frac{1}{N(\lambda)} \sum_{\substack{j\neq k:\lambda_j,\lambda_k\leq\lambda \\ |\lambda_j-\lambda_k-\tau|<\delta}} |(A\varphi_j,\varphi_k)|^2 < \epsilon$$

$$(\forall\tau\in\mathbb{R})$$

The restriction $j \neq k$ is of course redundant unless $\tau = 0$, in which case the statement coincides with quantum ergodicity. This result follows from the general asymptotic formula, valid for any compact Riemannian manifold $(M,g)$, that

$$\frac{1}{N(\lambda)} \sum_{i\neq j,\lambda_i,\lambda_j\leq\lambda} |\langle A\varphi_i,\varphi_j\rangle|^2 \left|\frac{\sin T(\lambda_i-\lambda_j-\tau)}{T(\lambda_i-\lambda_j-\tau)}\right|^2 \sim \left\|\frac{1}{2T}\int_{-T}^{T} \mathrm{e}^{\mathrm{i}t\tau} V_t(\sigma_A)\right\|_2^2 - \left|\frac{\sin T\tau}{T\tau}\right|^2 \omega(A)^2 \qquad [24]$$

In the case of weak-mixing geodesic flows, the right-hand side tends to 0 as $T\to\infty$. As with diagonal sums, the sharper result is true where one averages over the short intervals $[\lambda, \lambda+1]$.

### Spectral Measures and Matrix Elements

Theorem 2 is based on expressing the spectral measures of the geodesic flow in terms of matrix elements. The main limit formula is

$$\int_{\tau-\varepsilon}^{\tau+\varepsilon} \mathrm{d}\mu_{\sigma_A} := \lim_{\lambda\to\infty} \frac{1}{N(\lambda)} \sum_{\substack{i,j:\ \lambda_j\leq\lambda, \\ |\lambda_i-\lambda_j-\tau|<\varepsilon}} |\langle A\varphi_i,\varphi_j\rangle|^2 \qquad [25]$$

where $\mathrm{d}\mu_{\sigma_A}$ is the spectral measure for the geodesic flow corresponding to the principal symbol of $A$, $\sigma_A \in C^\infty(S^*M, \mathrm{d}\mu)$. Recall that the spectral measure of $V_t$ corresponding to $f \in L^2$ is the measure $\mathrm{d}\mu_f$ defined by

$$\langle V_t f, f\rangle_{L^2(S^*M)} = \int_{\mathbb{R}} \mathrm{e}^{\mathrm{i}t\tau}\, \mathrm{d}\mu_f(\tau)$$

The limit formula [25] is equivalent to the dual formula (under the Fourier transform):

$$\lim_{\lambda\to\infty} \frac{1}{N(\lambda)} \sum_{i,j:\lambda_j\leq\lambda} \mathrm{e}^{\mathrm{i}t(\lambda_i-\lambda_j)} |\langle A\varphi_i,\varphi_j\rangle|^2 = \langle V_t\sigma_A, \sigma_A\rangle_{L^2(S^*M)} \qquad [26]$$

The proof of [26] is to consider, for $A \in \Psi^\circ$, the operator $A_t^*A \in \Psi^\circ$ with $A_t = U_t^* A U_t$. By the local Weyl law,

$$\lim_{\lambda\to\infty} \frac{1}{N(\lambda)} \mathrm{tr}\, E(\lambda) A_t^* A = \langle V_t\sigma_A, \sigma_A\rangle_{L^2(S^*M)}$$

The right-hand-side of [25] defines a measure $\mathrm{d}m_A$ on $\mathbb{R}$ and [26] says

$$\int_{\mathbb{R}} \mathrm{e}^{\mathrm{i}t\tau}\, \mathrm{d}m_A(\tau) = \langle V_t\sigma_A, \sigma_A\rangle_{L^2(S^*M)} = \int_{\mathbb{R}} \mathrm{e}^{\mathrm{i}t\tau}\, \mathrm{d}\mu_{\sigma_A}(\tau)$$

Since weak-mixing systems are ergodic, it is not necessary to average in both indices along an ergodic subsequence:

$$\lim_{\lambda_j\to\infty}\langle A_t^* A\varphi_j,\varphi_j\rangle = \sum_j e^{it(\lambda_i-\lambda_j)}|\langle A\varphi_i,\varphi_j\rangle|^2 = \langle V_t\sigma_A,\sigma_A\rangle_{L^2(S^*M)} \qquad [27]$$

Dually, one has

$$\lim_{\lambda_j\to\infty}\sum_{i:|\lambda_i-\lambda_j-\tau|<\varepsilon}|\langle A\varphi_i,\varphi_j\rangle|^2 = \int_{\tau-\varepsilon}^{\tau+\varepsilon} d\mu_{\sigma_A} \qquad [28]$$

For QUE systems, these limit formulas are valid for the full sequence of eigenfunctions.

## Rate of Quantum Ergodicity and Mixing

A quantitative refinement of quantum ergodicity is to ask at what rate the sums in Theorem 1(i) tend to zero, that is, to establish a rate of quantum ergodicity. More generally, we consider "variances" of matrix elements. For diagonal matrix elements, we define

$$V_A(\lambda) := \frac{1}{N(\lambda)}\sum_{j:\lambda_j\le\lambda}|\langle A\varphi_j,\varphi_j\rangle-\omega(A)|^2 \qquad [29]$$

In the off-diagonal case, one may view $|\langle A\varphi_i,\varphi_j\rangle|^2$ as analogous to $|\langle A\varphi_j,\varphi_j\rangle-\omega(A)|^2$. However, the sums in [25] are double sums while those of [29] are single. One may also average over the shorter intervals $[\lambda,\lambda+1]$.

### Quantum Chaos Conjectures

First, consider off-diagonal matrix elements. One conjecture is that it is not necessary to sum in $j$ in [28]: each individual term has the asymptotics consistent with [28]. This is implicitly conjectured by Feingold–Peres (1986) (see [11]) in the form

$$|\langle A\varphi_i,\varphi_j\rangle|^2 \simeq \frac{C_A\left(\frac{E_i-E_j}{\hbar}\right)}{2\pi\rho(E)} \qquad [30]$$

where

$$C_A(\tau)=\int_{-\infty}^{\infty} e^{-i\tau t}\langle V_t\sigma_A,\sigma_A\rangle\, dt$$

In our notation, $\lambda_j=\hbar^{-1}E_j$ and $\rho(E)\,dE\sim dN(\lambda)$. There are $\sim C\lambda^{n-1}$ eigenvalues $\lambda_i$ in the interval $[\lambda_j-\tau-\epsilon,\lambda_j-\tau+\epsilon]$, so [30] states that individual terms have the asymptotics of [28].

On the basis of the analogy between $|\langle A\varphi_i,\varphi_j\rangle|^2$ and $|\langle A\varphi_j,\varphi_j\rangle-\omega(A)|^2$, it is conjectured in Feingold and Peres (1986) that

$$V_A(\lambda)\sim\frac{C_{A-\omega(A)I}(0)}{\lambda^{n-1}\operatorname{vol}(\Omega)}$$

The idea is that $\varphi_\pm=(1/\sqrt{2})(\varphi_i\pm\varphi_j)$ have the same matrix element asymptotics as eigenfunctions when $\lambda_i-\lambda_j$ is sufficiently small. But then $2\langle A\varphi_+,\varphi_-\rangle=\langle A\varphi_i,\varphi_i\rangle-\langle A\varphi_j,\varphi_j\rangle$ when $A^*=A$. Since we are taking a difference, we may replace each matrix element $\langle A\varphi_i,\varphi_i\rangle$ by $\langle A\varphi_i,\varphi_i\rangle-\omega(A)$ (and also for $\varphi_j$). The conjecture then assumes that $\langle A\varphi_i,\varphi_i\rangle-\omega(A)$ has the same order of magnitude as $\langle A\varphi_i,\varphi_i\rangle-\langle A\varphi_j,\varphi_j\rangle$. Dynamical grounds for this conjecture are given in Eckhardt *et al.* (1995). The order of magnitude is predicted by some natural random wave models, as discussed in the next section.

### Rigorous results

At this time, the strongest variance result is an asymptotic formula for the diagonal variance proved by Luo and Sarnak (2004) for special Hecke eigenfunctions on the quotient $\boldsymbol{H}^2/\mathrm{SL}(2,\mathbb{Z})$ of the upper half plane by the modular group. Their result pertains to holomorphic Hecke eigenforms, but the analogous statement for smooth Maass–Hecke eigenfunctions is expected to hold by similar methods, so we state the result as a theorem/conjecture. Note that $\boldsymbol{H}^2/\mathrm{SL}(2,\mathbb{Z})$ is a noncompact finite-area surface whose Laplacian $\Delta$ has both a discrete and a continuous spectrum. The discrete Hecke eigenfunctions are joint eigenfunctions of $\Delta$ and the Hecke operators $T_p$.

**Theorem/Conjecture 1** (Luo and Sarnak 2004). *Let $\{\varphi_k\}$ denote the orthonormal basis of Hecke eigenfunctions for $\boldsymbol{H}^2/\mathrm{SL}(2,\mathbb{Z})$. Then there exists a quadratic form $B(f)$ on $C_0^\infty(\boldsymbol{H}^2/\mathrm{SL}(2,\mathbb{Z}))$ such that*

$$\frac{1}{N(\lambda)}\sum_{\lambda_j\le\lambda}\left|\int_X f|\varphi_j|^2 d\mathrm{vol}-\frac{1}{\mathrm{Vol}(X)}\int_X f d\mathrm{Vol}\right|^2 = \frac{B(f,f)}{\lambda}+o\left(\frac{1}{\lambda}\right)$$

When the multiplier $f=\varphi_\lambda$ is itself an eigenfunction, Luo–Sarnak have shown that

$$B(\varphi_\lambda,\varphi_\lambda)=C_{\varphi_\lambda}(0)L(\tfrac12,\varphi_\lambda)$$

where $L(\frac12,\varphi_\lambda)$ is a certain $L$-function. Thus, the conjectured classical variance is multiplied by an arithmetic factor depending on the multiplier. A crucial fact in the proof is that the quadratic form B is diagonalized by the $\varphi_\lambda$.

The only rigorous result to date which is valid on general Riemannian manifolds with hyperbolic geodesic flow is the logarithmic decay:

**Theorem 3** (*Zelditch*). *For any* $(M, g)$ *with hyperbolic geodesic flow,*

$$\frac{1}{N(\lambda)}\sum_{\lambda_j\leq\lambda}|(A\varphi_j,\varphi_j)-\omega(A)|^{2p}=\frac{1}{(\log\lambda)^p}$$

The logarithm reflects the exponential blow-up in time of remainder estimates for traces involving the wave group associated to hyperbolic flows. It would be surprising if the logarithmic decay is sharp for Laplacians. However, a recent result of R Schubert shows that the estimate is sharp in the case of two-dimensional hyperbolic quantum cat maps. Hence, the estimate cannot be improved by semiclassical arguments that hold in both settings.

## Random Waves and Orthonormal Bases

We have mentioned that the random wave model provides a kind of guideline for what to conjecture about eigenfunctions of quantum chaotic system. In this final section, we briefly discuss random wave models and what they predict.

By a random wave model, one means a probability measure on a space of functions. To deal with orthonormal bases rather than individual functions, one sets a probability measure on a space of orthonormal bases, that is, on a unitary group. We denote expected values relative to a given probability measure by $\boldsymbol{E}$. We now consider some specific Gaussian models and what they predict about variances.

As a model for quantum chaotic eigenfunctions in plane domains, Berry (1977) suggested using the Euclidean random wave model at fixed energy. A rigorous version of such a model is as follows: let $\mathcal{E}_\lambda$ denote the space of (tempered) eigenfunctions of eigenvalue $\lambda^2$ of the Euclidean Laplacian $\Delta$ on $\mathbb{R}^n$. It is spanned by exponentials $e^{i\langle k,x\rangle}$ with $k\in\mathbb{R}^n, |k|=\lambda$. The infinite-dimensional space $\mathcal{E}_\lambda$ is a unitary representation of the Euclidean motion group and carries an invariant inner product. The inner product defines an associated Gaussian measure whose covariance kernel $C_\lambda(x,y)=\boldsymbol{E}f(x)\bar{f}(y)$ is the derivative at $\lambda$ of the spectral function

$$E(\lambda,x,y)=(2\pi)^{-n}\int_{|\xi|\leq\lambda}e^{i\langle x-y,\xi\rangle}\,d\xi,\quad \xi\in\mathbb{R}^n \quad [31]$$

Thus,

$$\begin{aligned}C_\lambda(x,y)&=\frac{d}{d\lambda}E(\lambda,x,y)\\&=(2\pi)^{-n}\int_{|\xi|=\lambda}e^{i\langle x-y,\xi\rangle}dS\\&=(2\pi)^{-n}\lambda^{n-1}\int_{|\xi|=1}e^{i\lambda\langle x-y,\xi\rangle}\,dS \quad [32]\end{aligned}$$

where $dS$ is the usual surface measure. With this definition, $C_\lambda(x,x)\sim\lambda^{n-1}$. In order to make $\mathbf{E}(f(x)^2)=1$ consistent with normalized eigenfunctions, we divide by $\lambda^{n-1}$ to define

$$\hat{C}_\lambda(x,y)=(2\pi)^{-n}\int_{|\xi|=1}e^{i\lambda\langle x-y,\xi\rangle}dS$$

One could express the integral as a Bessel function to rewrite this as

$$\Gamma\left(\frac{n-1}{2}\right)|\lambda|x-y||^{-(n-2)/2}J_{(n-2)/2}(\lambda|x-y|)$$

Wick's formula in this ensemble gives

$$\boldsymbol{E}\varphi(x)^2\varphi(y)^2=\frac{1}{\mathrm{Vol}(\Omega)^2}[1+2C_\lambda(x,y)^2]$$

Thus, in dimension $n$ we have

$$\begin{aligned}&\boldsymbol{E}\left[\int\!\!\int V(x)V(y)\varphi(x)^2\varphi(y)^2dxdy-\bar{V}^2\right]\\&=\frac{2}{\mathrm{Vol}(\Omega)^2}\int_\Omega\int_\Omega\hat{C}_\lambda(x,y)^2V(x)V(y)dx\,dy\\&\sim\frac{1}{\lambda^{n-1}\mathrm{Vol}(\Omega)^2}\int_\Omega\int_\Omega\frac{V(x)V(y)}{|x-y|^{n-1}}\cos(|x-y|\lambda)^2dx\,dy\end{aligned}$$

In the last line, we used the stationary-phase asymptotics

$$\begin{aligned}&(2\pi)^{-n}\lambda^{n-1}\int_{|\xi|=1}e^{i\lambda\langle x-y,\xi\rangle}dS\\&\quad\sim C_n(\lambda|x-y|)^{-(n-1)/2}\cos(|x-y|\lambda) \quad [33]\end{aligned}$$

Thus, the variances have order $\lambda^{-(n-1)}$ in dimension $n$, consistent with the conjectures in Feingold and Peres (1986) and Eckhardt *et al.* (1995).

This model is often used to obtain predictions on eigenfunctions of chaotic systems. By construction, it is tied to Euclidean geometry and only pertains directly to individual eigenfunctions of a fixed eigenvalue. It is based on the infinite-dimensional multiplicity of eigenfunctions of fixed eigenvalue of the Euclidean Laplacian on $\mathbb{R}^n$. There also exist random wave models on a curved Riemannian manifold $(M,g)$, which model individual eigenfunctions and also random orthonormal bases

(Zelditch 1996a). Thus, one can compare the behavior of sums over eigenvalues of the orthonormal basis of eigenfunctions of $\Delta$ with that of a random orthonormal basis. Instead of taking Gaussian random combinations of Euclidean plane waves of a fixed eigenvalue, one takes Gaussian random combinations $\sum_{j:\lambda_j\in[\lambda,\lambda+1]} c_j\varphi_j$ of the eigenfunctions of $(M,g)$ with eigenvalues in a short interval in the sense above. Equivalently, one takes random combinations with $\sum_j |c_j|^2 = 1$. These random waves are globally adapted to $(M,g)$. The statistical results depend on the measure of the set of periodic geodesics of $(M,g)$; thus, as discussed in Kaplan and Heller (1998), different random wave models make different predictions about off-diagonal variances.

Fix a compact Riemannian manifold $(M,g)$ and partition the spectrum of $\sqrt{\Delta}$ into the intervals $I_k = [k, k+1]$. Let $\Pi_k = E(k+1) - E(k)$ be the kernel of the spectral projections for $\sqrt{\Delta}$ corresponding to the interval $I_k$. Its kernel $\Pi_k(x,y)$ is the covariance kernel of Gaussian random combinations $\sum_{j:\lambda_j\in I_k} c_j\varphi_j$ and is analogous to $C_\lambda(x,y)$ in the Euclidean case; it is of course not the derivative $\mathrm{d}E(\lambda,x,y)$ but the difference of the spectral projector over $I_k$. We denote by $N(k)$ the number of eigenvalues in $I_k$ and put $\mathcal{H}_k = \mathrm{ran}\Pi_k$ (the range of $\Pi_k$). We define a "random" orthonormal basis of $\mathcal{H}_k$ by changing the basis of eigenfunctions $\{\varphi_j\}$ of $\Delta$ in $\mathcal{H}_k$ by a random element of the unitary group $U(\mathcal{H}_k)$ of the finite-dimensional Hilbert space $\mathcal{H}_k$. We then define a random orthonormal basis of $L^2(M)$ by taking the product over all the spectral intervals in our partition. More precisely, we define the infinite-dimensional unitary group

$$U(\infty) = \prod_{k=1}^{\infty} U(\mathcal{H}_k)$$

of sequences $(U_1, U_2, \ldots)$, with $U_k \in U(\mathcal{H}_k)$. We equip $U(\infty)$ with the product

$$\mathrm{d}\nu_\infty = \prod_{k=1}^{\infty} \mathrm{d}\nu_k$$

of the unit mass Haar measures $\mathrm{d}\nu_k$ on $U(\mathcal{H}_k)$: we then define a random orthonormal basis of $L^2(M)$ to be obtained by applying a random element $U \in U(\infty)$ to the orthonormal basis $\Phi = \{\varphi_j\}$ of eigenfunctions of $\sqrt{\Delta}$.

Assuming the set of periodic geodesics of $(M,g)$ has measure zero, the Weyl remainder results [8] and strong Szegö limit asymptotics of Guillemin–Okikiolu and Laptev–Robert–Safarov give two term asymptotics for the traces $\Pi_k A \Pi_k, (\Pi_k A \Pi_k)^2$ for any pseudodifferential operator $A$. Combining the strong Szegö asymptotics with the arguments of Zelditch (1996a), random orthonormal bases can be proved to satisfy the following variance asymptotics:

1. $\boldsymbol{E}(\sum_{j:\lambda_j\in I_k} |(AU\varphi_j, U\varphi_j) - \omega(A)|^2$
   $\sim (\omega(A^*A) - \omega(A)^2)$;

2. $\boldsymbol{E}(\sum_{i\neq j:\lambda_j,\lambda_i\in I_k} \left|\frac{\sin T(\lambda_i-\lambda_j-\tau)}{T(\lambda_i-\lambda_j-\tau)}\right|^2 |(AU\varphi_j, U\varphi_i)|^2$
   $\sim \left\{ 2\left|\frac{\sin\tau T}{\tau T}\right|^2 + \frac{1}{N(k)}\sum_{i\neq j}\left|\frac{\sin T(\lambda_i-\lambda_j-\tau)}{T(\lambda_i-\lambda_j-\tau)}\right|^2 \right\}$
   $\times(\omega(A^*A) - \omega(A)^2)$

# Quantum Error Correction and Fault Tolerance

**D Gottesman**, Perimeter Institute, Waterloo, ON, Canada

## Quantum Error Correction

Building a quantum computer or a quantum communications device in the real world means having to deal with errors. Any qubit stored unprotected or one transmitted through a communications channel will inevitably come out at least slightly changed. The theory of quantum error-correcting codes (QECCs) has been developed to counteract noise introduced in this way. By adding extra qubits and carefully encoding the quantum state we wish to protect, a quantum system can be insulated to a great extent against errors.

To build a quantum computer, we face an even more daunting task: if our quantum gates are imperfect, everything we do will add to the error. The theory of fault-tolerant quantum computation tells us how to perform operations on states encoded in a QECC without compromising the code's ability to protect against errors.

In general, a QECC is a subspace of a Hilbert space designed so that any of a set of possible errors can be corrected by an appropriate quantum operation. Specifically:

**Definition 1** Let $\mathcal{H}_n$ be a $2^n$-dimensional Hilbert space ($n$ qubits), and let $C$ be a $K$-dimensional subspace of $\mathcal{H}_n$. Then $C$ is an $((n, K))$ (binary) QECC correcting the set of errors $\mathcal{E} = \{E_a\}$ iff $\exists \mathcal{R}$ s.t. $\mathcal{R}$ is a quantum operation and $(\mathcal{R} \circ E_a)(|\psi\rangle) = |\psi\rangle$ for all $E_a \in \mathcal{E}, |\psi\rangle \in C$.

$\mathcal{R}$ is called the "recovery" or "decoding" operation and serves to actually perform the correction of the state. The decoder is sometimes also taken to map $\mathcal{H}_n$ into an unencoded Hilbert space $\mathcal{H}_{\log K}$ isomorphic to $C$. This should be distinguished from the "encoding" operation which maps $\mathcal{H}_{\log K}$ into $\mathcal{H}_n$, determining the imbedding of $C$. The computational complexity of the encoder is frequently a great deal lower than that of the decoder. In particular, the task of determining what error has occurred can be computationally difficult (NP-hard, in fact), and designing codes with efficient decoding algorithms is an important task in quantum error correction, as in classical error correction.

This article will cover only binary quantum codes, built with qubits as registers, but all of the techniques discussed here can be generalized to higher-dimensional registers, or "qudits."

To determine whether a given subspace is able to correct a given set of errors, we can apply the quantum error-correction conditions (Bennett *et al.* 1996, Knill and Laflamme 1997):

**Theorem 1** *A QECC C corrects the set of errors $\mathcal{E}$ iff*

$$\langle \psi_i | E_a^\dagger E_b | \psi_j \rangle = C_{ab} \delta_{ij} \qquad [1]$$

*where $E_a, E_b \in \mathcal{E}$ and $\{|\psi_i\rangle\}$ form an orthonormal basis for C.*

The salient point in these error-correction conditions is that the matrix element $C_{ab}$ does not depend on the encoded basis states $i$ and $j$, which, roughly speaking, indicates that neither the environment nor the decoding operation learns any information about the encoded state. We can imagine the various possible errors taking the subspace $C$ into other subspaces of $\mathcal{H}_n$, and we want those subspaces to be isomorphic to $C$, and to be distinguishable from each other by an appropriate measurement. For instance, if $C_{ab} = \delta_{ab}$, then the various erroneous subspaces are orthogonal to each other.

Because of the linearity of quantum mechanics, we can always take the set of errors $\mathcal{E}$ to be a linear space: if a QECC corrects $E_a$ and $E_b$, it will also correct $\alpha E_a + \beta E_b$ using the same recovery operation. In addition, if we write any superoperator $\mathcal{S}$ in terms of its operator-sum representation $\mathcal{S}(\rho) \mapsto \sum A_k \rho A_k^\dagger$, a QECC that corrects the set of errors $\{A_k\}$ automatically corrects $\mathcal{S}$ as well. Thus, it is sufficient in general to check that the error-correction conditions hold for a basis of errors.

Frequently, we are interested in codes that correct any error affecting $t$ or fewer physical qubits. In that case, let us consider tensor products of the Pauli matrices

$$I = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}, \quad X = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$$
$$Y = \begin{pmatrix} 0 & -\mathrm{i} \\ \mathrm{i} & 0 \end{pmatrix}, \quad Z = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} \qquad [2]$$

Define the Pauli group $\mathcal{P}_n$ as the group consisting of tensor products of $I$, $X$, $Y$, and $Z$ on $n$ qubits, with an overall phase of $\pm 1$ or $\pm \mathrm{i}$. The weight $\mathrm{wt}(P)$ of a Pauli operator $P \in \mathcal{P}_n$ is the number of qubits on which it acts as $X$, $Y$, or $Z$ (i.e., not as the identity). Then the Pauli operators of weight $t$ or less form a basis for the set of all errors acting on $t$ or fewer qubits, so a QECC which corrects these Pauli operators corrects all errors acting on up to $t$ qubits. If we have a channel which causes errors independently with probability $O(\epsilon)$ on each qubit in the QECC, then the code will allow us to decode a correct state except with probability $O(\epsilon^{t+1})$, which is the probability of having more than $t$ errors. We get a similar result in the case where the noise is a general quantum operation on each qubit which differs from the identity by something of size $O(\epsilon)$.

**Definition 2** The distance $d$ of an $((n, K))$ QECC is the smallest weight of a nontrivial Pauli operator $E \in \mathcal{P}_n$ s.t. the equation

$$\langle \psi_i | E | \psi_j \rangle = C(E)\delta_{ij} \qquad [3]$$

fails.

We use the notation $((n, K, d))$ to refer to an $((n, K))$ QECC with distance $d$. Note that for $P, Q \in \mathcal{P}_n, \mathrm{wt}(PQ) \le \mathrm{wt}(P) + \mathrm{wt}(Q)$. Then by comparing the definition of distance with the quantum error-correction conditions, we immediately see that a QECC corrects $t$ general errors iff its distance $d > 2t$. If we are instead interested in "erasure" errors, when the location of the error is known but not its precise nature, a distance $d$ code corrects $d-1$ erasure errors. If we only wish to detect errors, a distance $d$ code can detect errors on up to $d-1$ qubits.

One of the central problems in the theory of quantum error correction is to find codes which maximize the ratios $(\log K)/n$ and $d/n$, so they can encode as many qubits as possible and correct as many errors as possible. Conversely, we are also interested in the problem of setting upper bounds on achievable values of $(\log K)/n$ and $d/n$. The quantum Singleton bound (or Knill–Laflamme (1997) bound) states that any $((n, K, d))$ QECC must satisfy

$$n - \log K \ge 2d - 2 \qquad [4]$$

We can set a lower bound on the existence of QECCs using the quantum Gilbert–Varshamov bound, which states that, for large $n$, an $((n, 2^k, d))$ QECC exists provided that

$$k/n \le 1 - (d/n)\log 3 - h(d/n) \qquad [5]$$

where $h(x) = -x\log x - (1-x)\log(1-x)$ is the binary Hamming entropy. Note that the Gilbert–Varshamov bound simply states that codes at least this good exist; it does not suggest that better codes cannot exist.

## Stabilizer Codes

In order to better manipulate and discover QECCs, it is helpful to have a more detailed mathematical structure to work with. The most widely used structure gives a class of codes known as "stabilizer codes" (Calderbank *et al.* 1998, Gottesman 1996). They are less general than arbitrary quantum codes, but have a number of useful properties that make them easier to work with than the general QECC.

**Definition 3** Let $S \subset \mathcal{P}_n$ be an abelian subgroup of the Pauli group that does not contain $-1$ or $\pm\mathrm{i}$, and let $C(S) = \{|\psi\rangle \text{ s.t. } P|\psi\rangle = |\psi\rangle \forall P \in S\}$. Then $C(S)$ is a stabilizer code and $S$ is its stabilizer.

Because of the simple structure of the Pauli group, any abelian subgroup has order $2^{n-k}$ for some $k$ and can easily be specified by giving a set of $n-k$ commuting generators.

The code words of the QECC are by definition in the +1-eigenspace of all elements of the stabilizer, but an error $E$ acting on a code word will move the state into the $-1$-eigenspace of any stabilizer element $M$ which anticommutes with $E$:

$$M(E|\psi\rangle) = -EM|\psi\rangle = -E|\psi\rangle \qquad [6]$$

Thus, measuring the eigenvalues of the generators of $S$ tells us information about the error that has occurred. The set of such eigenvalues can be represented as an $(n-k)$-dimensional binary vector known as the "error syndrome." Note that the error syndrome does not tell us anything about the encoded state, only about the error that has occurred.

**Theorem 2** *Let $S$ be a stabilizer with $n-k$ generators, and let $S^{\perp} = \{E \in \mathcal{P}_n \text{ s.t. } [E, M] = 0\ \forall M \in S\}$. Then $S$ encodes $k$ qubits and has distance $d$, where $d$ is the smallest weight of an operator in $S^{\perp} \backslash S$.*

We use the notation $[[n, k, d]]$ to a refer to such a stabilizer code. Note that the square brackets specify that the code is a stabilizer code, and that the middle term $k$ refers to the number of encoded qubits, and not the dimension $2^k$ of the encoded subspace, as for the general QECC (whose dimension might not be a power of 2).

$S^\perp$ is the set of Pauli operators that commute with all elements of the stabilizer. They would therefore appear to be those errors which cannot be detected by the code. However, the theorem specifies the distance of the code by considering $S^\perp \backslash S$. A Pauli operator $P \in S$ cannot be detected by the code, but there is in fact no need to detect it, since all code words remain fixed under $P$, making it equivalent to the identity operation. A distance $d$ stabilizer code which has nontrivial $P \in S$ with $\mathrm{wt}(P) < d$ is called degenerate, whereas one which does not is nondegenerate. The phenomenon of degeneracy has no analog for classical error-correcting codes, and makes the study of quantum codes substantially more difficult than the study of classical error correction. For instance, a standard bound on classical error correction is the Hamming bound (or sphere-packing bound), but the analogous quantum Hamming bound

$$k/n \leq 1 - (t/n)\log 3 - h(t/n) \qquad [7]$$

for $[[n, k, 2t+1]]$ codes (when $n$ is large) is only known to apply to nondegenerate quantum codes (though in fact we do not know of any degenerate QECCs that violate the quantum Hamming bound).

An example of a stabilizer code is the 5-qubit code, a [[5,1,3]] code whose stabilizer can be generated by

$$\begin{array}{c} X\otimes Z\otimes Z\otimes X\otimes I \\ I\otimes X\otimes Z\otimes Z\otimes X \\ X\otimes I\otimes X\otimes Z\otimes Z \\ Z\otimes X\otimes I\otimes X\otimes Z \end{array}$$

The 5-qubit code is a nondegenerate code, and is the smallest possible QECC which corrects 1 error (as one can see from the quantum Singleton bound).

It is frequently useful to consider other representations of stabilizer codes. For instance, $P \in \mathcal{P}_n$ can be represented by a pair of $n$-bit binary vectors $(p_X \mid p_Z)$, where $p_X$ is 1 for any location where $P$ has an $X$ or $Y$ tensor factor and is 0 elsewhere, and $p_Z$ is 1 for any location where $P$ has a $Y$ or $Z$ tensor factor. Two Pauli operators $P = (p_X|p_Z)$ and $Q = (q_X|q_Z)$ commute iff $p_X \cdot q_Z + p_Z \cdot q_X = 0$. Then the stabilizer for a code becomes a pair of $(n-k) \times n$ binary matrices, and most interesting properties can be determined by an appropriate linear algebra exercise. Another useful representation is to map the single-qubit Pauli operators $I$, $X$, $Y$, $Z$ to the finite field GF(4), which sets up a connection between stabilizer codes and a subset of classical codes on four-dimensional registers.

## CSS Codes

CSS codes are a very useful class of stabilizer codes invented by Calderbank and Shor (1996), and by Steane (1996). The construction takes two binary classical linear codes and produces a quantum code, and can therefore take advantage of much existing knowledge from classical coding theory. In addition, CSS codes have some very useful properties which make them excellent choices for fault-tolerant quantum computation.

A classical $[n, k, d]$ linear code ($n$ physical bits, $k$ logical bits, classical distance $d$) can be defined in terms of an $(n-k) \times n$ binary "parity check" matrix $H$ – every classical code word $v$ must satisfy $Hv = 0$. Each row of the parity check matrix can be converted into a Pauli operator by replacing each 0 with an $I$ operator and each 1 with a $Z$ operator. Then the stabilizer code generated by these operators is precisely a quantum version of the classical error-correcting code given by $H$. If the classical distance $d = 2t+1$, the quantum code can correct $t$ bit flip ($X$) errors, just as could the classical code.

If we want to make a QECC that can also correct phase ($Z$) errors, we should choose two classical codes $C_1$ and $C_2$, with parity check matrices $H_1$ and $H_2$. Let $C_1$ be an $[n, k_1, d_1]$ code and let $C_2$ be an $[n, k_2, d_2]$ code. We convert $H_1$ into stabilizer generators as above, replacing each 0 with $I$ and each 1 with $Z$. For $H_2$, we perform the same procedure, but each 1 is instead replaced by $X$. The code will be able to correct bit flip ($X$) errors as if it had a distance $d_1$ and to correct phase ($Z$) errors as if it had a distance $d_2$. Since these two operations are completely separate, it can also correct $Y$ errors as both a bit flip and a phase error. Thus, the distance of the quantum code is at least $\min(d_1, d_2)$, but might be higher because of the possibility of degeneracy.

However, in order to have a stabilizer code at all, the generators produced by the above procedure must commute. Define the dual $C^\perp$ of a classical code $C$ as the set of vectors $w$ s.t. $w \cdot v = 0$ for all $v \in C$. Then the $Z$ generators from $H_1$ will all commute with the $X$ generators from $H_2$ iff $C_2^\perp \subseteq C_1$ (or equivalently, $C_1^\perp \subseteq C_2$). When this is true, $C_1$ and $C_2$ define an $[[n, k_1 + k_2 - n, d]]$ stabilizer code, where $d \geq \min(d_1, d_2)$.

The smallest distance-3 CSS code is the 7-qubit code, a [[7, 1, 3]] QECC created from the classical Hamming code (consisting of all sums of classical strings 1111000, 1100110, 1010101, and 1111111). The encoded $|\bar{0}\rangle$ for this code consists of the superposition of all even-weight classical code words and the encoded $|\bar{1}\rangle$ is the superposition of all odd-weight classical code words. The 7-qubit code is much studied because its properties make it particularly well suited to fault-tolerant quantum computation.

## Fault Tolerance

Given a QECC, we can attempt to supplement it with protocols for performing fault-tolerant operations. The basic design principle of a fault-tolerant protocol is that an error in a single location – either a faulty gate or noise on a quiescent qubit – should not be able to alter more than a single qubit in each block of the QECC. If this condition is satisfied, $t$ separate single-qubit or single-gate failures are required for a distance $2t + 1$ code to fail.

Particular caution is necessary, as computational gates can cause errors to propagate from their original location onto qubits that were previously correct. In general, a gate coupling pairs of qubits allows errors to spread in both directions across the coupling.

The solution is to use transversal gates whenever possible (Shor 1996). A transversal operation is one in which the $i$th qubit in each block of a QECC interacts only with the $i$th qubit of other blocks of the code or of special ancilla states. An operation consisting only of single-qubit gates is automatically transversal. A transversal operation has the virtue that an error occurring on the third qubit in a block, say, can only ever propagate to the third qubit of other blocks of the code, no matter what other sequence of gates we perform before a complete error-correction procedure.

In the case of certain codes, such as the 7-qubit code, a number of different gates can be performed transversally. Unfortunately, it does not appear to be possible to perform universal quantum computations using just transversal gates. We therefore have to resort to more complicated techniques. First we create special encoded ancilla states in a non-fault-tolerant way, but perform some sort of check on them (in addition to error correction) to make sure they are not too far off from the goal. Then we interact the ancilla with the encoded data qubits using gates from our stock of transversal gates and perform a fault-tolerant measurement. Then we complete the operation with a further transversal gate which depends on the outcome of the measurement.

## Fault-Tolerant Gates

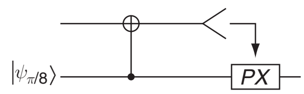
We will focus on stabilizer codes. Universal fault tolerance is known to be possible for any stabilizer code, but in most cases the more complicated type of construction is needed for all but a few gates. The Pauli group $\mathcal{P}_k$, however, can be performed transversally on any stabilizer code. Indeed, the set $S^{\perp}\backslash S$ of undetectable errors is a boon in this case, as it allows us to perform these gates. In particular, each coset $S^{\perp}/S$ corresponds to a different logical Pauli operator (with $S$ itself corresponding to the identity). On a stabilizer code, therefore, logical Pauli operations can be performed via a transversal Pauli operation on the physical qubits.

Stabilizer codes have a special relationship to a finite subgroup $\mathcal{C}_n$ of the unitary group $U(2^n)$ frequently called the "Clifford group." The Clifford group on $n$ qubits is defined as the set of unitary operations which conjugate the Pauli group $\mathcal{P}_n$ into itself; $\mathcal{C}_n$ can be generated by the Hadamard transform, the controlled-NOT (CNOT), and the single-qubit $\pi/4$ phase rotation diag(1, i). The set of stabilizer codes is exactly the set of codes which can be created by a Clifford group encoder circuit using $|0\rangle$ ancilla states.

Some stabilizer codes have interesting symmetries under the action of certain Clifford group elements, and these symmetries result in transversal gate operations. A particularly useful fact is that a transversal CNOT gate (i.e., CNOT acting between the $i$th qubit of one block of the QECC and the $i$th qubit of a second block for all $i$) acts as a logical CNOT gate on the encoded qubits for any CSS code. Furthermore, for the 7-qubit code, transversal Hadamard performs a logical Hadamard, and the transversal $\pi/4$ rotation performs a logical $-\pi/4$ rotation. Thus, for the 7-qubit code, the full logical Clifford group is accessible via transversal operations.

Unfortunately, the Clifford group by itself does not have much computational power: it can be efficiently simulated on a classical computer. We need to add some additional gate outside the Clifford group to allow universal quantum computation; a single gate will suffice, such as the single-qubit $\pi/8$ phase rotation diag(1, $\exp(i\pi/4)$). Note that this gives us a finite generating set of gates. However, by taking appropriate products, we get an infinite set of gates, one that is dense in the unitary group $U(2^n)$, allowing universal quantum computation.

The following circuit performs a $\pi/8$ rotation, given an ancilla state $|\psi_{\pi/8}\rangle = |0\rangle + \exp(i\pi/4)|1\rangle$:



Here $P$ is the $\pi/4$ phase rotation diag(1, i), and $X$ is the bit flip. The product is in the Clifford group, and is only performed if the measurement outcome is 1. Therefore, given the ability to perform fault-tolerant Clifford group operations, fault-tolerant measurements, and to prepare the encoded $|\psi_{\pi/8}\rangle$ state, we have universal fault-tolerant quantum computation. A slight generalization of the fault-tolerant measurement procedure below can be used to fault-tolerantly verify the $|\psi_{\pi/8}\rangle$ state, which is a +1 eigenstate of $PX$. Using this or another verification procedure, we can check a non-fault-tolerant construction.

## Fault-Tolerant Measurement and Error Correction

Since all our gates are unreliable, including those used to correct errors, we will need some sort of fault-tolerant quantum error-correction procedure. A number of different techniques have been developed. All of them share some basic features: they involve creation and verification of specialized ancilla states, and use transversal gates which interact the data block with the ancilla state.

The simplest method, due to Shor, is very general but also requires the most overhead and is frequently the most susceptible to noise. Note that the following procedure can be used to measure (non-fault-tolerantly) the eigenvalue of any (possibly multiqubit) Pauli operator $M$: produce an ancilla qubit in the state $|+\rangle = |0\rangle + |1\rangle$. Perform a controlled-$M$ operation from the ancilla to the state being measured. In the case where $M$ is a multiqubit Pauli operator, this can be broken down into a sequence of controlled-$X$, controlled-$Y$, and controlled-$Z$ operations. Then measure the ancilla in the basis of $|+\rangle$ and $|-\rangle = |0\rangle - |1\rangle$. If the state is a +1 eigenvector of $M$, the ancilla will be $|+\rangle$, and if the state is a –1 eigenvector, the ancilla will be $|-\rangle$.

The advantage of this procedure is that it measures just $M$ and nothing more. The disadvantage is that it is not transversal, and thus not fault tolerant. Instead of the unencoded $|+\rangle$ state, we must use a more complex ancilla state $|00\ldots0\rangle + |11\ldots1\rangle$ known as a "cat" state. The cat state contains as many qubits as the operator $M$ to be measured, and we perform the controlled-$X$, -$Y$, or -$Z$ operations transversally from the appropriate qubits of the cat state to the appropriate qubits in the data block. Since, assuming the cat state is correct, all of its qubits are either $|0\rangle$ or $|1\rangle$, the procedure either leaves the data state alone or performs $M$ on it uniformly. A +1 eigenstate in the data therefore leaves us with $|00\ldots0\rangle + |11\ldots1\rangle$ in the ancilla and a –1 eigenstate leaves us with $|00\ldots0\rangle - |11\ldots1\rangle$. In either case, the final state still tells us nothing about the data beyond the eigenvalue of $M$. If we perform a Hadamard transform and then measure each qubit in the ancilla, we get either a random even-weight string (for eigenvalue +1) or an odd-weight string (for eigenvalue –1).

The procedure is transversal, so an error on a single qubit in the initial cat state or in a single gate during the interaction will only produce one error in the data. However, the initial construction of the cat state is not fault tolerant, so a single-gate error then could eventually produce two errors in the data block. Therefore, we must be careful and use some sort of technique to verify the cat state, for instance, by checking if random pairs of qubits are the same. Also, note that a single phase error in the cat state will cause the final measurement outcome to be wrong (even and odd switch places), so we should repeat the measurement procedure multiple times for greater reliability.

We can then make a full fault-tolerant error-correction procedure by performing the above measurement technique for each generator of the stabilizer. Each measurement gives us one bit of the error syndrome, which we then decipher classically to determine the actual error.

More sophisticated techniques for fault-tolerant error correction involve less interaction with the data but at the cost of more complicated ancilla states. A procedure due to Steane uses (for CSS codes) one ancilla in a logical $|\bar{0}\rangle$ state of the same code and one ancilla in a logical $|\bar{0}\rangle + |\bar{1}\rangle$ state. A procedure due to Knill (for any stabilizer code) teleports the data qubit through an ancilla consisting of two blocks of the QECC containing an encoded Bell state $|\overline{00}\rangle + |\overline{11}\rangle$. Because the ancillas in Steane and Knill error correction are more complicated than the cat state, it is especially important to verify the ancillas before using them.

## The Threshold for Fault Tolerance

In an unencoded protocol, even one error can destroy the computation, but a fully fault-tolerant protocol will give the right answer unless multiple

errors occur before they can be corrected. On the other hand, the fault-tolerant protocol is larger, requiring more qubits and more time to do each operation, and therefore providing more opportunities for errors. If errors occur on the physical qubits independently at random with probability $p$ per gate or time step, the fault-tolerant protocol has probability of logical error for a single logical gate or time step at most $Cp^2$, where $C$ is a constant that depends on the design of the fault-tolerant circuitry (assume the QECC has distance 3, as for the 7-qubit code). When $p < p_t = 1/C$, the fault tolerance helps, decreasing the logical error rate. $p_t$ is the "threshold" for fault-tolerant quantum computation. If the error rate is higher than the threshold, the extra overhead means that errors will occur faster than they can be reliably corrected, and we are better off with an unencoded system.

To further lower the logical error rate, we turn to a family of codes known as "concatenated codes" (Aharonov and Ben-Or, Kitaev 1997, Knill *et al.* 1998). Given a code word of a particular $[[n, 1]]$ QECC, we can take each physical qubit and again encode it using the same code, producing an $[[n^2, 1]]$ QECC. We could repeat this procedure to get an $n^3$-qubit code, and so forth. The fault-tolerant procedures concatenate as well, and after $L$ levels of concatenation, the effective logical error rate is $p_t(p/p_t)^{2^L}$ (for a base code correcting 1 error). Therefore, if $p$ is below the threshold $p_t$, we can achieve an arbitrarily good error rate $\epsilon$ per logical gate or time step using only poly$(\log \epsilon)$ resources, which is excellent theoretical scaling.

Unfortunately, the practical requirements for this result are not nearly so good. The best rigorous proofs of the threshold to date show that the threshold is at least $2 \times 10^{-5}$ (meaning one error per 50,000 operations). Optimized simulations of fault-tolerant protocols suggest that the true threshold may be as high as 5%, but to tolerate this much error, existing protocols require enormous overhead, perhaps increasing the number of gates and qubits by a factor of a million or more for typical computations. For lower physical error rates, overhead requirements are more modest, particularly if we only attempt to optimize for calculations of a given size, but are still larger than one would like.

Furthermore, these calculations make a number of assumptions about the physical properties of the computer. The errors are assumed to be independent and uncorrelated between qubits except when a gate connects them. It is assumed that measurements and classical computations can be performed quickly and reliably, and that quantum gates can be performed between arbitrary pairs of qubits in the computer, irrespective of their physical proximity. Of these, only the assumption of independent errors is at all necessary, and that can be considerably relaxed to allow short-range correlations and certain kinds of non-Markovian environments. However, the effects of relaxing these assumptions on the threshold value and overhead requirements have not been well studied.

# Quantum Field Theory in Curved Spacetime

**B S Kay**, University of York, York, UK

## Introduction and Preliminaries

Quantum Field Theory (QFT) in curved spacetime is a hybrid approximate theory in which quantum matter fields are assumed to propagate in a fixed classical background gravitational field. Its basic physical prediction is that strong gravitational fields can polarize the vacuum and, when time dependent, lead to pair creation just as a strong and/or time-dependent electromagnetic field can polarize the vacuum and/or give rise to pair creation of charged particles. One expects it to be a good approximation to full quantum gravity provided the typical frequencies of the gravitational background are very much less than the Planck frequency $(c^5/G\hbar)^{1/2} \sim 10^{43}\,\mathrm{s}^{-1}$ and provided, with a suitable measure for energy, the energy of created particles is very much less than the energy of the background gravitational field or of its matter sources. Undoubtedly, the most important prediction of the theory is the Hawking effect, according to which a, say spherically symmetric, classical black hole of mass $M$ will emit thermal radiation at the Hawking temperature $T = (8\pi M)^{-1}$ (here and from now on, we use Planck units where $G, c, \hbar$ and, $k$ (Boltzmann's constant) are all taken to be 1).

On the mathematical side, the need to formulate the laws and derive the general properties of QFT on nonflat spacetimes forces one to state and prove results in local terms and, as a byproduct, thereby leads to an improved perspective on flat-spacetime QFT too. It is also interesting to formulate QFT on idealized spacetimes with particular global geometrical features. Thus, QFT on spacetimes with bifurcate Killing horizons is intimately related to the Hawking effect; QFT on spacetimes with closed timelike curves is intimately related to the question whether the laws of physics permit the manufacture of a time machine.

As is standard in general relativity, a curved spacetime is modeled mathematically as a (paracompact, Hausdorff) manifold $\mathcal{M}$ equipped with a pseudo-Riemannian metric $g$ of signature $(-,+++)$ (we follow the conventions of the standard text by Misner *et al.* (1973)). We shall also assume, except where otherwise stated, our spacetime to be *globally hyperbolic*, that is, that $\mathcal{M}$ admits a *global time coordinate*, by which we mean a global coordinate $t$ such that each constant-$t$ surface is a smooth Cauchy surface, that is, a smooth spacelike 3-surface cut exactly once by each inextendible causal curve. (Without this default assumption, extra problems arise for QFT which we shall briefly mention in connection with the "time machine" question discussed later.) In view of this definition, globally hyperbolic spacetimes are clearly time-orientable and we shall assume a choice of time-orientation has been made so we can talk about the "future" and "past" directions. Modern formulations of the subject take, as the fundamental mathematical structure modeling the quantum field, a $*$-algebra $\mathcal{A}$ (with identity $I$) together with a family of local sub $*$-algebras $\mathcal{A}(\mathcal{O})$ labeled by bounded open regions $\mathcal{O}$ of the spacetime $(\mathcal{M}, g)$ and satisfying the *isotony* or *net* condition that $\mathcal{O}_1 \subset \mathcal{O}_2$ implies $\mathcal{A}(\mathcal{O}_1)$ is a subalgebra of $\mathcal{A}(\mathcal{O}_2)$ as well as the condition that whenever two bounded open regions $\mathcal{O}_1$ and $\mathcal{O}_2$ are spacelike separated, then $\mathcal{A}(\mathcal{O}_1)$ and $\mathcal{A}(\mathcal{O}_2)$ commute.

Standard concepts and techniques from algebraic quantum theory are then applicable: In particular, *states* are defined to be positive (this means $\omega(A^*A) \geq 0\ \forall A \in \mathcal{A}$) normalized (this means $\omega(I) = 1$) linear functionals on $\mathcal{A}$. One distinguishes between *pure* states and *mixed* states, only the latter being writable as nontrivial convex combinations of other states. To each state, $\omega$, the *GNS construction* associates a representation, $\rho_\omega$, of $\mathcal{A}$ on a Hilbert space $\mathcal{H}_\omega$ together with a cyclic vector $\Omega \in \mathcal{H}_\omega$ such that

$$\omega(A) = \langle \Omega | \rho_\omega(A) \Omega \rangle$$

(and the *GNS triple* $(\rho_\omega, \mathcal{H}, \Omega)$ is unique up to equivalence). There are often technical advantages in formulating things so that the $*$-algebra is a $C^*$-algebra. Then the GNS representation is as everywhere-defined bounded operators and is irreducible if and only if the state is pure. A useful concept, due to Haag, is the *folium* of a given state $\omega$ which may be defined to be the set of all states $\omega_\sigma$ which arise in the form $\mathrm{tr}(\sigma\rho_\omega(\cdot))$, where $\sigma$ ranges over the density operators (trace-class operators with unit trace) on $\mathcal{H}_\omega$.

Given a state, $\omega$, and an automorphism, $\alpha$, which preserves the state (i.e., $\omega \circ \alpha = \omega$) then there will be a unitary operator, $U$, on $H_\omega$ which *implements* $\alpha$ in the sense that $\rho_\omega(\alpha(A)) = U^{-1}\rho_\omega(A)U$ and $U$ is chosen uniquely by the condition $U\Omega = \Omega$.

On a *stationary* spacetime, that is, one which admits a one-parameter group of isometries whose integral curves are everywhere timelike, the algebra will inherit a one-parameter group (i.e., satisfying $\alpha(t_1) \circ \alpha(t_2) = \alpha(t_1 + t_2)$) of time-translation

automorphisms, $\alpha(t)$, and, given any stationary state (i.e., one which satisfies $\omega \circ \alpha(t) = \omega \ \forall t \in \boldsymbol{R}$), these will be implemented by a one-parameter group of unitaries, $U(t)$, on its GNS Hilbert space satisfying $U(t)\Omega = \Omega$. If $U(t)$ is strongly continuous so that it takes the form $e^{-iHt}$ and if the Hamiltonian, $H$, is positive, then $\omega$ is said to be a "ground state." Typically one expects *ground states* to exist and often be unique.

Another important class of stationary states for the algebra of a stationary spacetime is the class of *KMS states*, $\omega^\beta$, at inverse temperature $\beta$; these have the physical interpretation of thermal equilibrium states. In the GNS representation of one of these, the automorphisms are also implemented by a strongly continuous unitary group, $e^{-iHt}$, which preserves $\Omega$ but (in place of $H$ positive) there is a complex conjugation, $J$, on $H_\omega$ such that

$$e^{-\beta H/2}\rho_\omega(A)\Omega = J\rho_\omega(A^*)\Omega \qquad [1]$$

for all $A \in \mathcal{A}$. An attractive feature of the subject is that its main qualitative features are already present for linear field theories and, unusually in comparison with other questions in QFT, these are susceptible of a straightforward explicit and rigorous mathematical formulation. In fact, as our principal example, we give, in the next section a construction for the field algebra for the quantized real linear Klein–Gordon equation

$$(\Box_g - m^2 - V)\phi = 0 \qquad [2]$$

of mass $m$ on a globally hyperbolic spacetime $(\mathcal{M}, g)$. Here, $\Box_g$ denotes the Laplace–Beltrami operator $g^{ab}\nabla_a\partial_b$ $(= (|\det(g)|)^{-1/2}\partial_a((|\det(g)|^{1/2}g^{ab}\partial_b))$. We include a scalar external background classical field, $V$, in addition to the external gravitational field represented by $g$. In case $m$ is zero, taking $V$ to equal $R/6$, where $R$ denotes the Riemann scalar, makes the equation *conformally invariant*.

The main new feature of QFT in curved spacetime (present already for linear field theories) is that, in a general (neither flat nor stationary) spacetime there will not be any single preferred state but rather a family of preferred states, members of which are best regarded as on an equal footing with one another. It is this feature which makes the above algebraic framework particularly suitable, indeed essential, to a clear formulation of the subject. Conceptually, it is this feature which takes the most getting used to. In particular, one must realize that, as we shall explain later, the interpretation of a state as having a particular "particle content" is in general problematic because it can only be relative to a particular choice of "vacuum" state and, depending on the spacetime of interest, there may be one state or several states or, frequently, no states at all which deserve the name "vacuum" and even when there are states which deserve this name, they will often only be defined in some approximate or asymptotic or transient sense or only on some subregion of the spacetime.

Concomitantly, one does not expect global observables such as the "particle number" or the quantum Hamiltonian of flat-spacetime free-field theory to generalize to a curved spacetime context, and for this reason local observables play a central role in the theory. The quantized stress–energy tensor is a particularly natural and important such local observable and the theory of this is central to the whole subject. A brief introduction to it is given in a later section.

This is followed by a further section on the Hawking and Unruh effects and then a brief section on the problems of extending the theory beyond the "default" setting, to nonglobally hyperbolic spacetimes. Finally, we briefly mention a number of other interesting and active areas of the subject as well as issuing a few *warnings* to be borne in mind when reading the literature.

## Construction of $*$-Algebra(s) for a Real Linear Scalar Field on Globally Hyperbolic Spacetimes and Some General Theorems

On a globally hyperbolic spacetime, the classical equation [2] admits well-defined *advanced* and *retarded Green* functions (strictly bidistributions) $\Delta^A$ and $\Delta^R$ and the standard covariant quantum free real (or "Hermitian") scalar field commutation relations familiar from Minkowski spacetime free-field theory naturally generalize to the (heuristic) equation

$$[\hat{\phi}(x), \hat{\phi}(y)] = i\Delta(x, y)I$$

where $\Delta$ is the *Lichnérowicz commutator function* $\Delta = \Delta^A - \Delta^R$. Here, the "$\hat{}$" on the quantum field $\hat{\phi}$ serves to distinguish it from a classical solution $\phi$. In mathematical work, one does not assign a meaning to the field at a point itself, but rather aims to assign meaning to *smeared fields* $\hat{\phi}(F)$ for all real-valued test functions $F \in C_0^\infty(\mathcal{M})$ which are then to be interpreted as standing for $\int_\mathcal{M} \hat{\phi}(x)f(x)|\det(g)|^{1/2}\, d^4x$. In fact, it is straightforward to define a *minimal field algebra* (see below) $\mathcal{A}_{\min}$ generated by such $\hat{\phi}(F)$ which satisfy the suitably smeared version

$$[\hat{\phi}(F), \hat{\phi}(G)] = i\Delta(F, G)I$$

of the above commutation relations together with Hermiticity (i.e., $\hat{\phi}(F)^* = \hat{\phi}(F)$), the property of being a weak solution of eqn [2] (i.e., $\hat{\phi}((\Box_g - m^2 - V)F) = 0 \ \forall F \in C_0^\infty(\mathcal{M})$) and linearity in test functions. There is a technically different alternative formulation of this minimal algebra, which is known as the *Weyl algebra*, which is constructed to be the C*-algebra generated by operators $W(F)$ (to be interpreted as standing for $\exp(\mathrm{i}\int_{\mathcal{M}} \hat{\phi}(x) f(x) |\det(g)|^{1/2} \mathrm{d}^4x)$ satisfying

$$W(F_1)W(F_2) = \exp(-\mathrm{i}\Delta(F_1, F_2)/2)W(F_1 + F_2)$$

together with $W(F)^* = W(-F)$ and $W((\Box_g - m^2 - V)F) = I$. With either the minimal algebra or the Weyl algebra one can define, for each bounded open region $\mathcal{O}$, subalgebras $A(\mathcal{O})$ as generated by the $\hat{\phi}(\cdot)$ (or the $W(\cdot)$) smeared with test functions supported in $\mathcal{O}$ and verify that they satisfy the above "net" condition and commutativity at spacelike separation.

Specifying a state, $\omega$, on $\mathcal{A}_{\min}$ is tantamount to specifying its collection of $n$-point distributions (i.e., smeared $n$-point functions) $\omega(\hat{\phi}(F_1)\ldots\hat{\phi}(F_n))$. (In the case of the Weyl algebra, one restricts attention to "regular" states for which the map $F \to \omega(W(F))$ is sufficiently often differentiable on finite-dimensional subspaces of $C_0^\infty(\mathcal{M})$ and defines the $n$-point distributions in terms of derivatives with respect to suitable parameters of expectation values of suitable Weyl algebra elements.) A particular role is played in the theory by the *quasifree* states for which all the *truncated* $n$-point distributions except for $n=2$ vanish. Thus, all the $n$-point distributions for odd $n$ vanish while the four-point distribution is made out of the two-point distribution according to

$$\begin{aligned}\omega(\hat{\phi}(F_1)\hat{\phi}(F_2)\hat{\phi}(F_3)\hat{\phi}(F_4)) \\ = \omega(\hat{\phi}(F_1)\hat{\phi}(F_2))\omega(\hat{\phi}(F_3)\hat{\phi}(F_4)) \\ + \omega(\hat{\phi}(F_1)\hat{\phi}(F_3))\omega(\hat{\phi}(F_2)\hat{\phi}(F_4)) \\ + \omega(\hat{\phi}(F_1)\hat{\phi}(F_4))\omega(\hat{\phi}(F_2)\hat{\phi}(F_3))\end{aligned}$$

etc. The anticommutator distribution

$$G(F_1, F_2) = \omega(\hat{\phi}(F_1)\hat{\phi}(F_2)) + \omega(\hat{\phi}(F_2)\hat{\phi}(F_1)) \qquad [3]$$

of a quasifree state (or indeed of any state) will satisfy the following conditions (for all test functions $F, F_1, F_2$, etc.):

C1. *Symmetry*

$$G(F_1, F_2) = G(F_2, F_1)$$

C2. *Weak bisolution property*

$$\begin{aligned}G((\Box_g - m^2 - V)F_1, F_2) = 0 \\ = G(F_1, (\Box_g - m^2 - V)F_2)\end{aligned}$$

C3. *Positivity*

$$\begin{aligned}G(F, F) \geq 0 \text{ and } G(F_1, F_1)^{1/2} G(F_2, F_2)^{1/2} \\ \geq |\Delta(F_1, F_2)|\end{aligned}$$

and it can be shown that, to every bilinear functional $G$ on $C_0^\infty(\mathcal{M})$ satisfying (C1)–(C3), there is a quasifree state with two-point distribution $(1/2)(G + \mathrm{i}\Delta)$. One further declares a quasifree state to be *physically admissible* only if (for pairs of points in sufficiently small convex neighborhoods)

C4. *Hadamard condition*

$$\text{“}G(x_1, x_2) = \frac{1}{2\pi^2}\left(u(x_1, x_2)\mathrm{P}\frac{1}{\sigma} + v(x_1, x_2)\log|\sigma| + w(x_1, x_2)\right)\text{”}$$

This last condition expresses the requirement that (locally) the two-point distribution actually "is" (in the usual sense in which one says that a distribution "is" a function) a smooth function for pairs of non-null-separated points. At the same time, it requires that the two-point distribution be singular at pairs of null-separated points and locally specifies the nature of the singularity for such pairs of points with a leading "principal part of $1/\sigma$" type singularity and a subleading "$\log|\sigma|$" singularity, where $\sigma$ denotes the square of the geodesic distance between $x_1$ and $x_2$. $u$ (which satisfies $u(x_1, x_2) = 1$ when $x_1 = x_2$) and $v$ are certain smooth two-point functions determined in terms of the local geometry and the local values of $V$ by something called the *Hadamard procedure* while the smooth two-point function $w$ depends on the state. We shall omit the details. The important point is that this Hadamard condition on the two-point distribution is believed to be the correct generalization to a curved spacetime of the well-known universal short-distance behavior shared by the truncated two-point distributions of all physically relevant states for the special case of our theory when the spacetime is flat (and $V$ vanishes). In the latter case, $u$ reduces to 1, and $v$ to a simple power series $\sum_{n=0}^{\infty} v_n \sigma^n$ with $v_0 = m^2/4$, etc.

Actually, it is known (this is the content of "Kay's conjecture" which was proved by M Radzikowski in 1992) that (C1)–(C4) together imply that the two-point distribution is nonsingular at all pairs of (not necessarily close together) spacelike separated points. More important than this result itself is a reformulation of the Hadamard condition in terms of the concepts of *microlocal analysis* which Radzikowski originally introduced as a tool towards its proof.

C4′. *Wave front set* (*or microlocal*) *spectrum condition*

$$\begin{aligned}&\mathrm{WF}(G+\mathrm{i}\Delta)\\&=\{(x_1,p_1;x_2,p_2)\in T^*(\mathcal{M}\times\mathcal{M})\setminus \mathbf{0}|x_1 \text{ and } x_2\\&\quad\text{lie on a single null geodesic, } p_1 \text{ is tangent to}\\&\quad\text{that null geodesic and future pointing, and}\\&\quad p_2 \text{ when parallel transported along that null}\\&\quad\text{geodesic from } x_2 \text{ to } x_1 \text{ equals } -p_1\}\end{aligned}$$

For the gist of what this means, it suffices to know that to say that an element $(x,p)$ of the cotangent bundle of a manifold (excluding the zero section $\mathbf{0}$) is in the *wave front set*, WF, of a given distribution on that manifold may be expressed informally by saying that that distribution is singular *at* the point $x$ *in the direction* $p$. (And here the notion is applied to $G+\mathrm{i}\Delta$, thought of as a distribution on the manifold $\mathcal{M}\times\mathcal{M}$.)

We remark that generically (and, e.g., always if the spatial sections are compact and $m^2+V(x)$ is everywhere positive) the Weyl algebra for eqn [2] on a given stationary spacetime will have a unique ground state and unique KMS states at each temperature and these will be quasifree and Hadamard.

Quasifree states are important also because of a theorem of R Verch (1994, in verification of another conjecture of Kay) that (in the Weyl algebra framework) on the algebra of any bounded open region, the folia of the quasifree Hadamard states coincide. With this result one can extend the notion of physical admissibility to not-necessarily-quasifree states by demanding that, to be admissible, a state belong to the resulting common folium when restricted to the algebra of each bounded open region; equivalently, that it be a *locally normal* state on the resulting natural extension of the net of local Weyl algebras to a net of local $W^*$-algebras.

## Particle Creation and the Limitations of the Particle Concept

Global hyperbolicity also entails that the Cauchy problem is well posed for the classical field equation [2] in the sense that for every Cauchy surface, $\mathcal{C}$, and every pair $(f,p)$ of Cauchy data in $C_0^\infty(\mathcal{C})$, there exists a unique solution $\phi$ in $C_0^\infty(\mathcal{M})$ such that $f=\phi|_{\mathcal{C}}$ and $p=|\det(g)|^{1/2}g^{ab}\partial_b\phi|_{\mathcal{C}}$. Moreover, $\phi$ has compact support on all other Cauchy surfaces. Given a global time coordinate $t$, increasing towards the future, foliating $\mathcal{M}$ into a family of constant-$t$ Cauchy surfaces, $\mathcal{C}_t$, and given a choice of global timelike vector field $\tau^a$ (e.g., $\tau^a=g^{ab}\partial_b t$) enabling one to identify all the $\mathcal{C}_t$, say with $\mathcal{C}_0$, by identifying points cut by the same integral curve of $\tau^a$, a single such classical solution $\phi$ may be pictured as a family $\{(f_t,p_t): t\in\boldsymbol{R}\}$ of time-evolving Cauchy data on $\mathcal{C}_0$. Moreover, since [2] implies, for each pair of classical solutions, $\phi_1,\phi_2$, the conservation (i.e., $\partial_a j^a=0$) of the current $j^a=|\det(g)|^{1/2}g^{ab}(\phi_1\partial_b\phi_2-\phi_2\partial_b\phi_1)$, the symplectic form (on $C_0^\infty(\mathcal{C})\times C_0^\infty(\mathcal{C})$)

$$\sigma((f_t^1,p_t^1);(f_t^2,p_t^2))=\int_{\mathcal{C}_0}(f_t^1p_t^2-p_t^1f_t^2)\mathrm{d}^3x$$

will be conserved in time.

Corresponding to this picture of classical dynamics, one expects there to be a description of quantum dynamics in terms of a family of sharp-time quantum fields $(\varphi_t,\pi_t)$ on $\mathcal{C}_0$, satisfying heuristic canonical commutation relations

$$\begin{aligned}[\varphi_t(\boldsymbol{x}),\varphi_t(\boldsymbol{y})]&=0\\ [\pi_t(\boldsymbol{x}),\pi_t(\boldsymbol{y})]&=0\\ [\varphi_t(\boldsymbol{x}),\pi_t(\boldsymbol{y})]&=\mathrm{i}\delta^3(\boldsymbol{x},\boldsymbol{y})I\end{aligned}$$

and evolving in time according to the same dynamics as the Cauchy data of a classical solution. (Both these expectations are correct because the field equation is linear.) An elegant way to make rigorous mathematical sense of these expectations is in terms of a $*$-algebra with identity generated by Hermitian objects "$\sigma((\varphi_0,\pi_0);(f,p))$" ("symplectically smeared sharp-time fields at $t=0$") satisfying linearity in $f$ and $p$ together with the commutation relations

$$\begin{aligned}&[\sigma((\varphi_0,\pi_0);(f^1,p^1)),\sigma((\varphi_0,\pi_0);(f^2,p^2))]\\&\quad=\mathrm{i}\sigma((f^1,p^1);(f^2,p^2))I\end{aligned}$$

and to define (symplectically smeared) time-$t$ sharp-time fields by demanding

$$\sigma((\varphi_t,\pi_t);(f_t,p_t))=\sigma((\varphi_0,\pi_0);(f_0,p_0))$$

where $(f_t,p_t)$ is the classical time-evolute of $(f_0,p_0)$. This $*$-algebra of sharp-time fields may be identified with the (minimal) field $*$-algebra of the previous section, the $\hat\phi(F)$ of the previous section being identified with $\sigma((\varphi_0,\pi_0);(f,p))$, where $(f,p)$ are the Cauchy data at $t=0$ of $\Delta * F$. (This identification is of course many–one since $\hat\phi(F)=0$ whenever $F$ arises as $(\Box_g-m^2-V)G$ for some test function $G\in C_0^\infty(\mathcal{M})$.)

Specializing momentarily to the case of the free scalar field $(\Box-m^2)\phi=0$ $(m\neq 0)$ in Minkowski space with a flat $t=0$ Cauchy surface, the "symplectically smeared" two-point function of the usual ground state ("Minkowski vacuum state"), $\omega_0$, is given, in this formalism, by

$$\begin{aligned}&\omega_0(\sigma((\varphi,\pi);(f^1,p^1))\sigma((\varphi,\pi);(f^2,p^2)))\\&\quad=\tfrac{1}{2}(\langle f^1|\mu f^2\rangle+\langle p^1|\mu^{-1}p^2\rangle\\&\qquad+\mathrm{i}\sigma((f^1,p^1);(f^2,p^2)))\end{aligned}\qquad[4]$$

where the inner products are in the *one-particle Hilbert space* $\mathcal{H} = L^2_{\mathrm{C}}(\boldsymbol{R}^3)$ and $\mu = (m^2 - \nabla^2)^{1/2}$. The GNS representation of this state may be concretely realized on the familiar *Fock space* $\mathcal{F}(\mathcal{H})$ over $\mathcal{H}$ by

$$\rho_0(\sigma((\varphi, \pi); (f, p))) = -\mathrm{i}(\hat{a}^\dagger(\mathrm{a}) - (\hat{a}^\dagger(\mathrm{a}))^*)$$

where a denotes the element of $\mathcal{H}$:

$$\mathrm{a} = \frac{(\mu^{1/2} f + \mathrm{i}\mu^{-1/2} p)}{\sqrt{2}}$$

(we note in passing that, if we equip $\mathcal{H}$ with the symplectic form $2\,\mathrm{Im}\langle\cdot|\cdot\rangle$, then $K:(f,p)\mapsto \mathrm{a}$ is a symplectic map) and $\hat{a}^\dagger(\mathrm{a})$ is the usual smeared *creation operator* (= "$\int \hat{a}^\dagger(\boldsymbol{x})\mathrm{a}(\boldsymbol{x})\mathrm{d}^3\boldsymbol{x}$") on $\mathcal{F}(\mathcal{H})$ satisfying

$$[(\hat{a}^\dagger(\mathrm{a}^1))^*, \hat{a}^\dagger(\mathrm{a}^2)] = \langle \mathrm{a}^1 | \mathrm{a}^2 \rangle_{\mathcal{H}} I$$

The usual (smeared) *annihilation operator*, $\hat{a}(\mathrm{a})$, is $(\hat{a}^\dagger(C\mathrm{a}))^*$, where $C$ is the natural complex conjugation, $\mathrm{a} \mapsto \mathrm{a}^*$ on $\mathcal{H}$. Both of these operators annihilate the *Fock vacuum vector* $\Omega^{\mathcal{F}}$. In this representation, the one-parameter group of time-translation automorphisms

$$\alpha(t): \sigma((\varphi_0, \pi_0); (f, p)) \mapsto \sigma((\varphi_t, \pi_t); (f, p)) \quad [5]$$

is implemented by $\exp(-\mathrm{i}Ht)$ where $H$ is the second quantization of $\mu$ (i.e., the operator otherwise known as $\int \mu(k)\hat{a}^\dagger(k)\hat{a}(k)\mathrm{d}^3 k$) on $\mathcal{F}(\mathcal{H})$.

The most straightforward (albeit physically artificial) situation involving "particle creation" in a curved spacetime concerns a globally hyperbolic spacetime which, outside of a compact region, is isometric to Minkowski space with a compact region removed – that is, to a globally hyperbolic spacetime which is flat except inside a localized "bump" of curvature (see Figure 1). (One could also allow the function $V$ in [2] to be nonzero inside the bump.) On the field algebra (defined as in the previous section) of such a spacetime, there will be an "in" vacuum state (which may be identified with the Minkowski vacuum to the past of the bump) and an "out" vacuum state (which may be identified with the Minkowski vacuum to the future of the bump) and one expects, for example, the "in vacuum" to arise as a many-particle state in the GNS representation of the "out vacuum" corresponding to the creation of particles out of the vacuum by the bump of curvature.

In the formalism of this section, if we choose our global time coordinate on such a spacetime so that, say, the $t = 0$ surface is to the past of the bump and the $t = T$ surface to its future, then the single automorphism $\alpha(T)$ (defined as in [5]) encodes the overall effect of the bump of curvature on the quantum field and one can ask whether it is implemented by a unitary operator in the GNS representation of the Minkowski vacuum state [4].

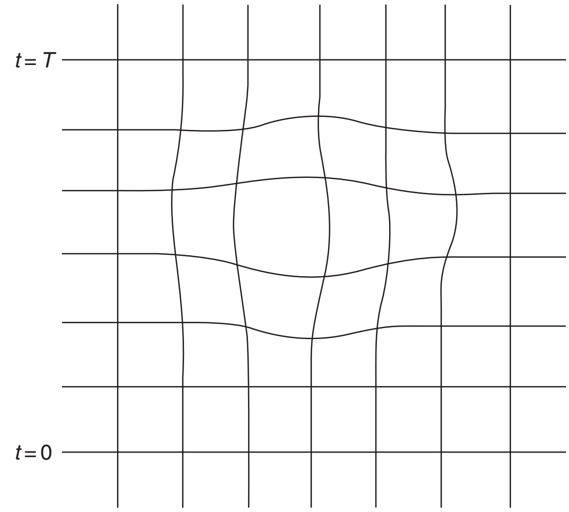

**Figure 1** A spacetime which is flat outside of a compact bump of curvature.

This question may be answered by referring to the real linear map $\mathcal{T}:\mathcal{H}\to\mathcal{H}$ which sends $\mathrm{a}_T = 2^{-1/2}(\mu^{1/2} f_T + \mathrm{i}\mu^{-1/2} p_T)$ to $\mathrm{a}_0 = 2^{-1/2}(\mu^{1/2} f_0 + \mathrm{i}\mu^{-1/2} p_0)$. By the conservation in time of $\sigma$ and the symplecticity, noted in passing above, of the map $K:(f,p)\mapsto \mathrm{a}$, this satisfies the defining relation

$$\mathrm{Im}\langle \mathcal{T}\mathrm{a}^1 | \mathcal{T}\mathrm{a}^2 \rangle = \mathrm{Im}\langle \mathrm{a}^1 | \mathrm{a}^2 \rangle$$

of a *classical Bogoliubov transformation*. Splitting $\mathcal{T}$ into its complex-linear and complex-antilinear parts by writing

$$\mathcal{T} = \alpha + \beta C$$

where $\alpha$ and $\beta$ are complex-linear operators, this relation may alternatively be expressed in terms of the pair of relations

$$\alpha^*\alpha - \bar{\beta}^*\bar{\beta} = I, \qquad \bar{\alpha}^*\bar{\beta} = \beta^*\alpha$$

where $\bar{\alpha} = C\alpha C$, $\bar{\beta} = C\beta C$.

We remark that there is an easy-to-visualize equivalent way of defining $\alpha$ and $\beta$ in terms of the analysis, to the past of the bump, into *positive- and negative-frequency parts* of complex solutions to [2] which are purely *positive frequency* to the future of the bump. In fact, if, for any element $\mathrm{a} \in \mathcal{H}$, we identify the positive-frequency solution to the Minkowski-space Klein–Gordon equation

$$\phi^{\mathrm{pos}}_{\mathrm{out}}(t, \boldsymbol{x}) = ((2\mu)^{-1/2} \exp(-\mathrm{i}\mu t)\mathrm{a})(\boldsymbol{x})$$

with a complex solution to [2] to the future of the bump, then (it may easily be seen) to the past of the bump, this same solution will be identifiable with

the (partly positive-frequency, partly negative-frequency) Minkowski-space Klein–Gordon solution

$$\phi_{\mathrm{in}}(t,\boldsymbol{x}) = \left((2\mu)^{-1/2}\exp(-\mathrm{i}\mu t)\alpha \mathrm{a}\right)(\boldsymbol{x}) + \left((2\mu)^{-1/2}\exp(\mathrm{i}\mu t)\bar{\beta}\mathrm{a}\right)(\boldsymbol{x})$$

and this could be taken to be the defining equation for the operators $\alpha$ and $\beta$.

It is then known (by a 1962 theorem of Shale) that the automorphism [5] (strictly, its Weyl algebra counterpart) will be unitarily implemented if and only if $\beta$ is a Hilbert–Schmidt operator on $\mathcal{H}$. Wald (1979, in case $m \geq 0$) and Dimock (1979, in case $m \neq 0$) have verified that this condition is satisfied in the case of our bump-of-curvature situation. In that case, if we denote the unitary implementor by $U$, we have the following results:

R1. The expectation value $\langle U\Omega | N(\mathrm{a})U\Omega\rangle_{\mathcal{F}(\mathcal{H})}$ of the number operator, $N(\mathrm{a}) = \hat{a}^{\dagger}(\mathrm{a})\hat{a}(\mathrm{a})$, where a is a normalized element of $\mathcal{H}$, is equal to $\langle \beta \mathrm{a} \mid \beta \mathrm{a}\rangle_{\mathcal{H}}$.

R2. First note that there exists an orthonormal basis of vectors, $e_i, (i = 1 \ldots \infty)$, in $\mathcal{H}$ such that the (Hilbert–Schmidt) operator $\bar{\beta}^{*}\bar{\alpha}^{*-1}$ has the canonical form $\sum_i \lambda_i \langle Ce_i | \cdot \rangle | e_i\rangle$. We then have (up to an undetermined phase)

$$U\Omega = N\exp\left(-\frac{1}{2}\sum_i \lambda_i \hat{a}^{\dagger}(e_i)\hat{a}^{\dagger}(e_i)\right)\Omega$$

where the normalization constant $N$ is chosen so that $\|U\Omega\| = 1$. This formula makes manifest that the particles are created in pairs.

We remark that, identifying elements, a, of $\mathcal{H}$ with positive-frequency solutions (below, we shall call them "modes") as explained above, result (R1) may alternatively be expressed by saying that the expectation value, $\omega_{\mathrm{in}}(N(\mathrm{a}))$, in the *in-vacuum state* of the occupation number, $N(\mathrm{a})$, of a *normalized mode*, a, to the future of the bump, is given by $\langle \beta \mathrm{a} | \beta \mathrm{a}\rangle_{\mathcal{H}}$.

This formalism and the results, (R1) and (R2) above, will generalize (at least heuristically, and sometimes rigorously – see especially the rigorous scattering-theoretic work in the 1980s by Dimock and Kay and more recently by A Bachelot and others) to more realistic spacetimes which are only asymptotically flat or asymptotically stationary. In favorable cases, one will still have notions of classical solutions which are positive frequency asymptotically towards the future/past, and, in consequence, one will have well-defined asymptotic notions of "vacuum" and "particles." Also, in, for example, cosmological, models where the background spacetime is slowly varying in time, one can define approximate *adiabatic* notions of classical positive-frequency solutions, and hence also of quantum "vacuum" and "particles" at each finite value of the cosmological time. But, at times where the gravitational field is rapidly varying, one does not expect there to be any sensible notion of "particles." And, in a rapidly time-varying background gravitational field which never settles down, one does not expect there to be any sensible particle interpretation of the theory at all. To understand these statements, it suffices to consider the $(1+0)$-dimensional Klein–Gordon equation with an external potential $V$:

$$\left(-\frac{\mathrm{d}^2}{\mathrm{d}t^2} - m^2 - V(t)\right)\phi = 0$$

which is of course a system of one degree of freedom, mathematically equivalent to the harmonic oscillator with a time-varying angular frequency $\varpi(t) = (m^2 + V(t))^{1/2}$. One could of course express its quantum theory in terms of a time-evolving Schrödinger wave function $\Psi(\varphi, t)$ and attempt to give this a particle interpretation at each time, $s$, by expanding $\Psi(\varphi, s)$ in terms of the harmonic oscillator wave functions for a harmonic oscillator with some particular choice of angular frequency. But the problem is, as is easy to convince oneself, that there is no such good choice. For example, one might think that a good choice would be to take, at time $s$, the set of harmonic oscillator wave functions with angular frequency $\varpi(s)$. (This is sometimes known as the method of "instantaneous diagonalization of the Hamiltonian.") But suppose we were to apply this prescription to the case of a smooth $V(\cdot)$ which is constant in time until time 0 and assume the initial state is the usual vacuum state. Then at some positive time $s$, the number of particles predicted to be present is the same as the number of particles predicted to be present on the same prescription at all times after $s$ for a $\hat{V}(\cdot)$ which is equal to $V(\cdot)$ up to time $s$ and then takes the constant value $V(s)$ for all later times (see Figure 2). But $\hat{V}(\cdot)$ will generically have a sharp corner in its graph (i.e., a

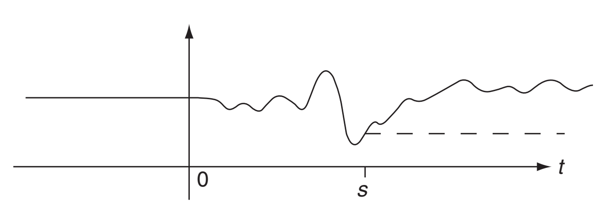

**Figure 2** Plots of $\varpi$ against $t$ for the two potentials $V$ (continuous line) and $\hat{V}$ (continuous line upto $s$ and then dashed line) which play a role in our critique of "instantaneous diagonalization."

discontinuity in its time derivative) at time $s$, and one would expect a large part of the particle production in the latter situation to be accounted for by the presence of this sharp corner – and therefore a large part of the predicted particle production in the case of $V(\cdot)$ to be spurious.

Back in $1+3$ dimensions, even where a good notion of particles is possible, it depends on the choice of time evolution, as is dramatically illustrated by the Unruh effect discussed in the relevant section.

## Theory of the Stress–Energy Tensor

To orient ideas, consider first the free (minimally coupled) scalar field, $(\Box - m^2)\phi = 0$, in Minkowski space. If one quantizes this system in the usual Minkowski-vacuum representation, then the expectation value of the *renormalized stress-energy tensor* (which in this case is the same thing as the *normal ordered stress–energy tensor*) in a vector state $\Psi$ in the Fock space will be given by the formal *point-splitting* expression

$$\begin{aligned}\langle\Psi|T_{ab}(x)\Psi\rangle &= \lim_{(x_1,x_2)\to(x,x)}\Big(\partial_a^1\partial_b^2 - \tfrac{1}{2}\eta_{ab}(\eta^{cd}\partial_c^1\partial_d^2 + m^2)\Big)\\ &\times(\langle\Psi|\rho_0(\phi(x_1)\phi(x_2))\Psi\rangle\\ &- \langle\Omega^{\mathcal{F}}|\rho_0(\phi(x_1)\phi(x_2))\Omega^{\mathcal{F}}\rangle)\end{aligned} \qquad [6]$$

where $\eta_{ab}$ is the usual Minkowski metric. A sufficient condition for the limit here to be finite and well defined would, for example, be for $\Psi$ to consist of a (normalized) finite superposition of $n$-particle vectors of form $\hat{a}^\dagger(\mathrm{a}_1),\ldots,\hat{a}^\dagger(\mathrm{a}_n)\Omega^{\mathcal{F}}$ where the smearing functions $\mathrm{a}_1,\ldots,\mathrm{a}_n$ are all $C^\infty$ elements of $\mathcal{H}$ (i.e., of $L^2_{\mathbb{C}}(\boldsymbol{R}^3)$. The reason this works is that the two-point function in such states shares the same short-distance singularity as the Minkowski-vacuum two-point function. For exactly the same reason, one obtains a well-defined finite limit if one defines the expectation value of the stress–energy tensor in any physically admissible quasifree state by the expression

$$\begin{aligned}\omega(T_{ab}(x)) &= \lim_{(x_1,x_2)\to(x,x)}\Big(\partial_a^1\partial_b^2 - \tfrac{1}{2}\eta_{ab}(\eta^{cd}\partial_c^1\partial_d^2 + m^2)\Big)\\ &\times(\omega(\phi(x_1)\phi(x_2)) - \omega_0(\phi(x_1)\phi(x_2)))\end{aligned} \qquad [7]$$

This latter point-splitting formula generalizes to a definition for the *expectation value of the renormalized stress–energy tensor* for an arbitrary physically admissible quasifree state (or indeed for an arbitrary state whose two-point function has *Hadamard form* – i.e., whose anticommutator function satisfies condition (C4)) on the minimal field algebra and to other linear field theories (including the stress tensor for a conformally coupled linear scalar field) on a general globally hyperbolic spacetime (and the result obtained agrees with that obtained by other methods, including *dimensional regularization* and *zeta-function regularization*). However, the generalization to a curved spacetime involves a number of important new features which we now briefly list (see Wald (1978) for details).

First, the subtraction term which replaces $\omega_0(\phi(x_1)\phi(x_2))$ is, in general, not the expectation value of $\phi(x_1)\phi(x_2)$ in any particular state, but rather a particular *locally constructed Hadamard two-point function* whose physical interpretation is more subtle; the renormalization is thus in general not to be regarded as a normal ordering. Second, the immediate result of the resulting limiting process will not be covariantly conserved and, in order to obtain a covariantly conserved quantity, one needs to add a particular *local geometrical correction term*. The upshot of this is that the resulting expected stress–energy tensor is covariantly conserved but possesses a (state-independent) *anomalous trace*. In particular, for a massless conformally coupled linear scalar field, one has (for all physically admissible quasifree states, $\omega$) the *trace anomaly formula*

$$\omega(T^a_a(x)) = (2880\pi^2)^{-1}\Big(C_{abcd}C^{abcd} + R_{ab}R^{ab} - \tfrac{1}{3}R^2\Big)$$

plus an arbitrary multiple of $\Box R$. In fact, in general, the thus-defined renormalized stress–energy tensor operator (see below) is only defined up to a *finite renormalization ambiguity* which consists of the addition of arbitrary multiples of the functional derivatives with respect to $g_{ab}$ of the quantities

$$I_n = \int_{\mathcal{M}} F_n(x)|\det(g)|^{1/2}\mathrm{d}^4x$$

where $n$ ranges from 1 to 4 with $F_1 = 1$, $F_2 = R$, $F_3 = R^2$, and $F_4 = R_{ab}R^{ab}$. In the Minkowski-space case, only the first of these ambiguities arises and it is implicitly resolved in the formulas [6], [7] inasmuch as these effectively incorporate the *renormalization condition* that $\omega_0(T_{ab}) = 0$. (For the same reason, the locally flat example we give below has no ambiguity.)

One expects, in both flat and curved cases, that, for test functions, $F \in C_0^\infty(\mathcal{M})$, there will exist operators $T_{ab}(F)$ which are *affiliated to* the net of

local $W^*$-algebras referred to earlier and that it is meaningful to write

$$\int_{\mathcal{M}} \omega(T_{ab}(x))F(x)|\det(g)|^{1/2}\mathrm{d}^4x = \omega(T_{ab}(F))$$

provided that, by $\omega$ on the right-hand side, we understand the extension of $\omega$ from the Weyl algebra to this net. ($T_{ab}(F)$ is however not expected to belong to the minimal algebra or be affiliated to the Weyl algebra.)

An interesting simple example of a renormalized stress–energy tensor calculation is the so-called *Casimir effect* calculation for a linear scalar field on a (for further simplicity, $(1+1)$-dimensional) timelike cylinder spacetime of radius $R$ (see Figure 3). This spacetime is globally hyperbolic and stationary and, while locally flat, globally distinct from Minkowski space. As a result, while – provided the regions $\mathcal{O}$ are sufficiently small (such as the diamond region in Figure 3) – elements $\mathcal{A}(\mathcal{O})$ of the minimal net of local algebras on this spacetime will be identifiable, in an obvious way, with elements of the minimal net of local algebras on Minkowski space, the stationary ground state $\omega_{\text{cylinder}}$ will, when restricted to such thus-identified regions, be distinct from the Minkowski vacuum state $\omega_0$. The resulting renormalized stress–energy tensor (as first pointed out in Kay (1979)), definable, once the above identification has been made, exactly as in [7]) turns out, in the massless case, to be nonzero and, interestingly, to have a (in the natural coordinates, constant) *negative energy-density* $T_{00}$. In fact, in this massless case,

$$\omega_{\text{cylinder}}(T_{ab}) = \frac{1}{24\pi R^2}\eta_{ab}$$

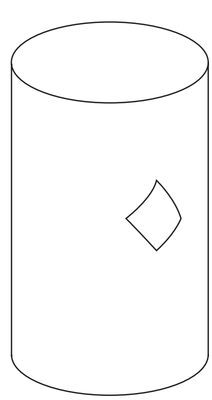

**Figure 3** The timelike cylinder spacetime of radius $R$ with a diamond region isometric to a piece of Minkowski space. See Kay (1979). Casimir effect in quantum field theory. ## Hawking and Unruh Effects

The original calculation by Hawking (1975) concerned a model spacetime for a star which collapses to a black hole. For simplicity, we shall only discuss the spherically symmetric case (see Figure 4). Adopting a similar "mode" viewpoint to that mentioned after results (R1) and (R2) discussed earlier, the result of the calculation may be stated as follows: For a real linear scalar field satisfying [2] with $m=0$ (and $V=0$) on this spacetime, the expectation value $\omega_{\text{in}}(N(\mathrm{a}_{\varpi,\ell}))$ of the occupation number of a one-particle outgoing mode $\mathrm{a}_{\varpi,\ell}$) localized (as far as a normalized mode can be) around $\varpi$ in angular-frequency space and about retarded time $v$, and with angular momentum "quantum number" $\ell$, in the in-vacuum state (i.e., on the minimal algebra for a real scalar field on this model spacetime) $\omega_{\text{in}}$ is, at late retarded times, given by the formula

$$\omega_{\text{in}}(N(\mathrm{a}_{\varpi,\ell})) = \frac{\Gamma(\varpi,\ell)}{\exp(8\pi M\varpi)-1}$$

where $M$ is the mass of the black hole and the *absorption factor* (alternatively known as *gray-body factor*) $\Gamma(\varpi,\ell)$ is equal to the norm-squared of that part of the one-particle mode $\mathrm{a}_{\varpi,\ell}$ which, viewed as a complex positive-frequency classical solution propagating backwards in time from late retarded times, would be absorbed by the black hole. (Note the independence of the right-hand side of this formula from the retarded time, $v$.) This calculation can be understood as an application of result (R1)

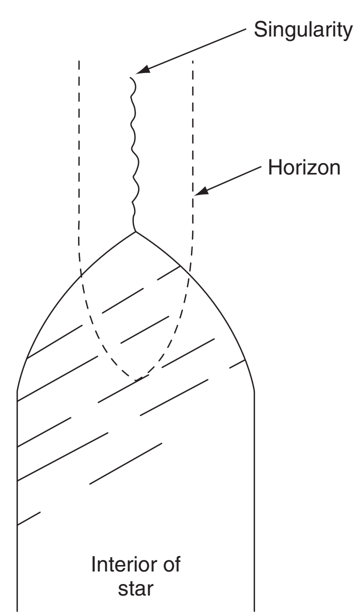

**Figure 4** The spacetime of a star collapsing to a spherical black hole.

(even though the spacetime is more complicated than one with a localized "bump of curvature" and even though the relevant overall time evolution will not be unitarily implemented, the result still applies when suitably interpreted) and the heart of the calculation is an asymptotic estimate of the relevant "$\beta$" Bogoliubov coefficient which turns out to be dependent on the geometrical optics of rays which pass through the star just before the formation of the horizon. This result suggests that the in-vacuum state is indistinguishable at late retarded times from a state of blackbody radiation at the *Hawking temperature*, $T_{\text{Hawking}} = 1/8\pi M$, in Minkowski space from a blackbody (gray body) with the same absorption factor. This was confirmed by further work by many authors. Much of that work, as well as the original result of Hawking was partially heuristic but later work by Dimock and Kay (1987), by Fredenhagen and Haag (1990), and by Bachelot (1999) and others has put different aspects of it on a rigorous mathematical footing. The result generalizes to nonzero mass and higher spin fields to interacting fields as well as to other types of black hole and the formula for the Hawking temperature generalizes to

$$T_{\text{Hawking}} = \kappa/2\pi$$

where $\kappa$ is the *surface gravity* of the black hole.

This result suggests that there is something fundamentally "thermal" about quantum fields on black-hole backgrounds and this is confirmed by a number of mathematical results. In particular, the theorems in the two papers Kay and Wald (1991) and Kay (1993), combined together, tell us that there is a unique state on the Weyl algebra for the *maximally extended Schwarzschild spacetime* (a.k.a. *Kruskal–Szekeres spacetime*) (see **Figure 5**) which is invariant under the *Schwarzschild isometry group* and whose two-point function has Hadamard form. Moreover, they tell us that this state, when restricted to a single wedge (i.e., the exterior Schwarzschild spacetime) is necessarily a KMS state at the Hawking temperature. This unique state is known as the *Hartle–Hawking–Israel state*. These results in fact apply more generally to a wide class of globally hyperbolic spacetimes with *bifurcate Killing horizons* including de Sitter space – where the unique state is sometimes called the *Euclidean* and sometimes the *Bunch–Davies* vacuum state – as well as to Minkowski space, in which case the unique state is the usual Minkowski vacuum state, the analog of the exterior Schwarzschild wedge is a so-called *Rindler wedge*, and the relevant isometry group is a one-parameter family of wedge-preserving Lorentz boosts. In the latter situation, the fact that the Minkowski vacuum state is a KMS state (at "temperature" $1/2\pi$)

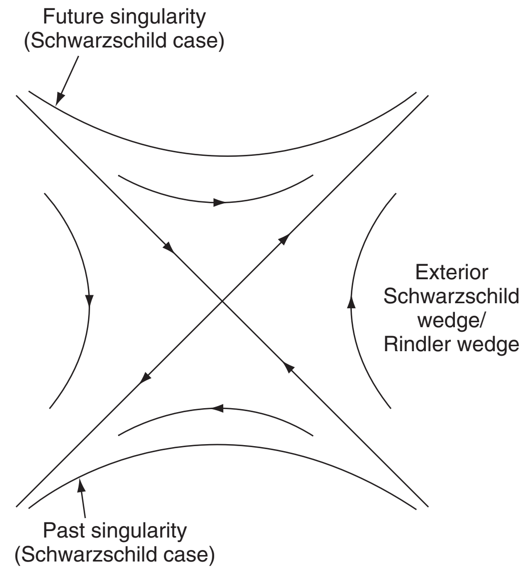

**Figure 5** The geometry of maximally extended Schwarzschild (/or Minkowski) spacetime. In the Schwarzschild case, every point represents a 2-sphere (/in the Minkowski case, a 2-plane). The curves with arrows on them indicate the Schwarzschild time evolution (/one-parameter family of Lorentz boosts). These curves include the (straight lines at right angles) event horizons (/Killing horizons).

when restricted to a Rindler wedge and regarded with respect to the time evolution consisting of the wedge-preserving one-parameter family of Lorentz boosts is known as the *Unruh effect* (1975). This latter property of the Minkowski vacuum in fact generalizes to general *Wightman QFTs* and is in fact an immediate consequence of a combination of the *Reeh–Schlieder theorem* (applied to a Rindler wedge) and the *Bisognano–Wichmann theorem* (1975). The latter theorem says that the defining relation [1] of a KMS state holds if, in [1], we identify the operator $J$ with the complex conjugation which implements wedge reflection and $H$ with the self-adjoint generator of the unitary implementor of Lorentz boosts. We remark that the Unruh effect illustrates how the concept of "vacuum" (when meaningful at all) is dependent on the choice of time evolution under consideration. Thus, the usual Minkowski vacuum is a ground state with respect to the usual Minkowski time evolution but not (when restricted to a Rindler wedge) with respect to a one-parameter family of Lorentz boosts; with respect to these, it is, instead, a KMS state.

## Nonglobally Hyperbolic Spacetimes and the "Time Machine" Question

Hawking (1992) argued that a spacetime in which a time machine gets manufactured should be modeled (see **Figure 6**) by a spacetime with an initial *globally*

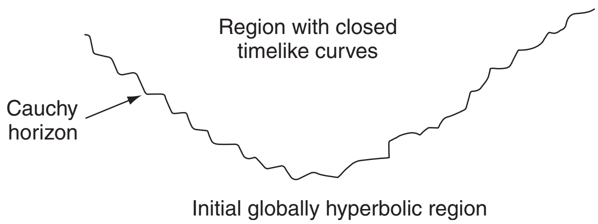

**Figure 6** The schematic geometry of a spacetime in which a time machine gets manufactured.

*hyperbolic region* with a region containing closed timelike curves to its future and such that the future boundary of the globally hyperbolic region is a *compactly generated Cauchy horizon*. On such a spacetime, Kay *et al.* (1997) proved that it is impossible for any distributional bisolution which satisfies (even a certain weakened version of) the Hadamard condition on the initial globally hyperbolic region to continue to satisfy that condition on the full spacetime – the (weakened) Hadamard condition being necessarily violated at at least one point *on* the Cauchy horizon. This result implies that, however one extends a state, satisfying our conditions (C1)–(C4), on the minimal algebra for [2] on the initial globally hyperbolic region, the expectation value of its stress–energy tensor must necessarily become singular on the Cauchy horizon. This result, together with many heuristic results and specific examples considered by many other authors appears to support the validity of the (Hawking 1992) *chronology protection conjecture* to the effect that it is impossible in principle to manufacture a time machine. However, there are potential loopholes in the physical interpretation of this result as pointed out by Visser (1997), as well as other claims by various authors that one can nevertheless violate the chronology protection conjecture. For a recent discussion on this question, we refer to Visser (2003).

## Other Related Topics and Some Warnings

There is a vast computational literature, calculating the expectation values of stress–energy tensors in states of interest for scalar and higher spin linear fields (and also some work for interacting fields) on interesting cosmological and black-hole backgrounds. QFT on de Sitter and anti-de Sitter space is a big subject area in its own right with recent renewed interest because of its relevance to *string theory* and *holography*. Also important on black-hole backgrounds is the calculation of gray-body factors, again with renewed interest because of relevance to string theory and to *brane-world* scenarios.

There are many further mathematically rigorous results on algebraic and axiomatic QFT in a curved spacetime setting, including versions of *PCT*, *spin-statistics* and *Reeh–Schlieder* theorems and also rigorous *energy inequalities* bounding the extent to which expected energy densities can be negative, etc.

There is much mathematical work controlling scattering theory on black holes, partly with a view to further elucidating the Hawking effect.

Perturbative renormalization theory of interacting quantum fields in curved spacetime is also now a highly developed subject.

Beyond QFT in a fixed curved spacetime is *semiclassical gravity* which takes into account the *back-reaction* of the expectation value of the stress–energy tensor on the classical gravitational background. There are also interesting condensed matter analogs of the Hawking effect such as *dumb holes*.

Readers exploring the wider literature, or doing further research on the subject should be aware that the word "vacuum" is sometimes used to mean "ground state" and sometimes just to mean "quasifree state." They should be cautious of attempts to define particles on Cauchy surfaces in *instantaneous diagonalization* schemes (cf. the remarks at the end of the section "Particle creation and the limitations of the particle concept"). When studying (or performing) calculations of the "expectation value of the stress–energy tensor" it is always important to ask oneself with respect to which state the expectation value is being taken. It is also important to remember to check that candidate two-point (anticommutator) functions satisfy the positivity condition (C3) discussed earlier. Typically, two-point distributions obtained via *mode sums* automatically satisfy condition (C3) (and condition (C4)), but those obtained via *image* methods do not always satisfy it. (When they do not, the presence of nonlocal spacelike singularities is often a tell-tale sign as can be inferred from Kay's conjecture/Radzikowski's theorem discussed earlier.) There are a number of apparent implicit assertions in the literature that some such two-point functions arise from "states" when of course they cannot. Some of these concern proposed analogs to the Hartle–Hawking–Israel state for the (appropriate maximal globally hyperbolic portion of the maximally extended) Kerr spacetime. That they cannot belong to states is clear from a theorem in Kay and Wald (1991) which states that there is no stationary Hadamard state on this spacetime at all. Others of them concern claimed "states" on spacetimes such as those discussed in the previous section which, if they really were states would seem to be in conflict with the chronology protection conjecture. Finally, beware states (such as the so-called $\alpha$-*vacua* of de Sitter spacetime) whose two-point

distributions violate the "Hadamard" condition (C4) and which therefore do not have a well-defined finite expectation value for the renormalized stress–energy tensor.

# Quantum Field Theory: A Brief Introduction

**L H Ryder**, University of Kent, Canterbury, UK

By any account quantum field theory occupies a prominent place in the history of mathematical physics. This article is, however, not intended to serve as an overview of this subject, but has the more modest aim of identifying a few areas which seem to me interesting and significant.

## Historical Remarks; Second Quantization

At the time when quantum field theory was at the forefront of theoretical physics its *raison d'être* was to complete the quantum description of the sub-atomic world. Quantum mechanics had been amazingly successful in solving almost the whole of atomic physics by making explicit the quantum (wave) nature of the electron, according to the formulations of Heisenberg and Schrödinger. The introduction of the quantum idea into physics, however, by Planck in 1900 closely followed by Einstein in 1905 was the proposal of a quantum (particular) aspect of the electromagnetic field – the photon. In the mid-1920s the only force in nature to be considered was the electromagnetic interaction; this was before the theories of Yukawa and Fermi, concerning the strong and weak nuclear forces. Dirac, Heisenberg, Jordan, and others then addressed themselves to finding a formulation of quantum electrodynamics (QED) comparable in mathematical sophistication to the Heisenberg–Schrödinger formulation of quantum mechanics – which Planck's and Einstein's theories were not.

The idea that was pursued, at least in the early stages, was that the Schrödinger wave function $\psi$, taken as a wave field, should be "quantized"; Dirac

seems to have taken this as a model for photons. Jordan further proposed that electrons should be treated as the quanta of an electron field, but recognized that their fermionic nature would modify the quantization procedure. This generic idea involved what was called "second quantization" – of a field into a particle.

One of the earliest quantization rules was Bohr's condition relating to the periodic orbits of electrons in atoms, $J = \int p\, \mathrm{d}q = nh$. At the hands of Heisenberg and Dirac this became upgraded to the commutation relation

$$[q, p] = \mathrm{i}\hbar$$

where the operators $p$ and $q$ are "observables." In their papers on quantum field theory, Dirac, Jordan and Wigner, and Heisenberg introduced creation and annihilation operators which had the function, as their name implied, of creating and destroying single particles – quanta of the field. These operators obeyed the commutation rules (with $[A, B] = AB - BA$)

$$[b_r, b_s^*] = \delta_{rs}, \quad [b_r, b_s] = [b_r^*, b_s^*] = 0$$

when the field quanta were bosons, and the anti-commutation rules

$$\{b_r, b_s^*\} = \delta_{rs}, \quad \{b_r, b_s\} = \{b_r^*, b_s^*\} = 0$$

(with $\{A, B\} = AB + BA$) when the field quanta were fermions (e.g., electrons). These steps constitute second quantization, but it may be noted that the creation and annihilation operators are not observables, as $p$ and $q$ are in the Heisenberg commutation relation. In addition, the second quantization conditions do not involve Planck's constant. "First" and "second" quantization are therefore not so similar as one might like to think.

The question of what exactly is being quantized was in fact the source of some confusion. In his paper of 1927, Dirac's attention is focussed on electromagnetic radiation, but he nevertheless discusses the difference between "a light-wave and the de Broglie or Schrödinger wave associated with the light-quanta." As Dirac points out, "their intensities are to be interpreted in different ways. The number of light quanta per unit volume associated with a monochromatic light-wave equals the energy per unit volume of the wave divided by the energy $(2\pi h)\nu$ of a single light quantum. On the other hand a monochromatic de Broglie wave of amplitude $a$ (multiplied into the imaginary exponential factor) must be interpreted as representing $a^2$ light quanta per unit volume for all frequencies." There are at least two problematic issues here. First, is the Schrödinger wave function $\psi$ to be considered as a "real" field, whose quanta result in "real" particles, or is it a probability field, whose significance lies in Born's probabilistic interpretation of quantum mechanics? Born wrote in 1926, "[Einstein said that] the waves are present only to show the corpuscular light quanta the way, and he spoke in the sense of a "ghost field". This determines the probability that a light quantum, the bearer of energy and momentum, takes a certain path; however, the field itself has no energy and no momentum." This is the first problem. The second one concerns the nature of the quantization itself. Is this a quantization of field energy, or a quantization of the field itself, as a substantial entity? If the field is real, the second of these does not imply the first.

Ambiguities surrounding the idea of second quantization survived into the 1960s. Wigner is recorded as saying, in an interview in 1963, "just as we get photons by quantising the electromagnetic fields, so we should be able to get material particles by quantising the Schrödinger field." And Rosenfeld, also in an interview in 1963, said, "in some sense or other, Jordan himself took the wave function, the probability amplitude, physically more seriously than most people [did]."

It would seem we are justified in concluding that the idea of second quantization contains flaws, but an even clearer indication of the need for rethinking is provided by the story of the Dirac equation. This is a wave equation for the electron, compatible with special relativity, and taking explicit account of its spin being $(1/2)\hbar$. The equation famously had both positive- and negative-energy solutions. This potential disaster was converted by Dirac into a triumph by reinterpreting the (absence of) negative-energy solutions as (positive-energy) antiparticles – positrons, particles with positive charge but the same mass and spin as the electron. Positrons were eventually discovered by Anderson. It was later shown that the existence of antiparticles is a general feature of quantum field theory, not just a peculiarity of spin-1/2 particles. The significance of this discovery, however, is that the twin requirements of relativity and quantum theory are not compatible with a single-particle state; rather, these requirements result in a two-particle state. Thus, in some sense the requirements of relativity and quantum mechanics already start to take us down the road to a quantum theory of fields.

Quantum field theory is then constructed on the following sort of framework: "classical" theories for fields with any spin may be written down and these are quantized by reinterpreting the field variables as operators and imposing Heisenberg-type commutation relations on the field and its corresponding

"momentum" variable. So, for example, for spinless fields we have the equal-time commutation relation

$$[\phi(\boldsymbol{x}, t), \pi(\boldsymbol{y}, t)] = \mathrm{i}\hbar\delta^{(3)}(\boldsymbol{x} - \boldsymbol{y})$$

where $\pi = \partial \mathrm{L}/\partial(\partial_0\phi)$ and L is the Lagrange density. The mass and spin of particles are defined with reference to the Poincaré group (thereby incorporating special relativity) and the quantum requirement is the familiar one that physical states are represented by vectors in Hilbert space. The rest follows: as Weinberg says, "quantum field theory is the way it is because (with certain qualifications) this is the only way to reconcile quantum mechanics with special relativity."

## Renormalization

A notorious problem in quantum field theory is the occurrence of infinities. In QED, for example, the electron acquires a self-energy – and therefore a contribution to its mass – by virtue of the emission and reabsorption of virtual photons. It turns out that this self-energy is infinite – it is given by a divergent integral – even in the lowest order of perturbation theory. In the early days, this was recognized as being a serious problem, and in fact it turns out to be a generic problem in quantum field theory. It was realized by Dyson, however, that in some field theories these divergences may be dealt with by redefining a small number of parameters (e.g., in QED, the electron mass, charge, and field amplitude) so that thereafter the theory is finite to all orders of perturbation theory. Such theories are called renormalizable, and QED is a renormalizable field theory.

Some important field theories, however, are not renormalizable; an example is Fermi's theory of weak interactions. To lowest order in perturbation theory, Fermi's theory works well (e.g., in accounting for the electron spectrum in neutron beta decay), but to higher orders divergent results are obtained, which cannot be waved away by redefining a finite number of parameters; that is to say, as the order of perturbation increases, so also does the number of parameters to be redefined. Nonrenormalizable theories of this type have traditionally been regarded as highly undesirable, not to say rather nasty.

The modern view of renormalization is, however, somewhat different. The problem with nonrenormalizable theories is that, in order to calculate a physical process to all orders in perturbation theory, an infinite number of parameters must be renormalized, so the theory has no predictive power. In practice, however, we do not need to calculate to all orders in perturbation theory, since any physical process (say a scattering process or a particle decay) will only be observed at a finite energy and comparison of theory and experiment therefore only requires calculation up to a finite order of perturbation theory. So even nonrenormalizable theories are perfectly acceptable as low-energy theories. This amounts to a philosophy of effective field theories; an effective field theory is a model which holds good up to a particular energy scale, or equivalently down to a particular length scale.

An important addition to the theoretical armoury is the renormalization group. Renormalization is implemented first of all by a scheme of regularization, which enables the divergences to be exhibited explicitly. The simplest type of regularization is the introduction of a cutoff in the momentum integrals, but in modern particle physics the favored scheme is dimensional regularization. The dimensionality of the integrals in momentum space is taken to be $d = 4 - \varepsilon$ and the divergent quantities have an explicit dependence on $\varepsilon$ (which, of course, as the "real" world is approached, approaches zero). At the same time, a mass parameter $\mu$ is introduced in order to define dimensionless quantities, for example, a dimensionless coupling constant. The renormalized quantities then depend on the "bare" (unrenormalized) quantities and on $\mu$ and $\varepsilon$. The arbitrariness of $\mu$ enables a differential equation, for scattering amplitudes, for example, to be written down. While at first sight this renormalization group equation might seem to have no physical importance, in fact it gives a powerful way of studying scattering behavior at large momenta.

Most interestingly, the concept of the renormalization group also arises in condensed matter physics. Here, rather than, for example, a cutoff in momentum space, the relevant parameter is a distance scale. In the Ising model in statistical mechanics, for example, in which spins are located on a lattice, the parameter is the lattice spacing. To construct a theory that describes the physics on the macroscopic scale involves integrating out the details on the microscopic scale and one way to do this is via the "block spin" transformation originally introduced by Kadanoff. In this way the renormalization group has had a large impact in condensed matter physics, for example, in the study of critical phenomena.

## Particle Physics and Cosmology

Probably the most spectacular success of quantum field theory in the twentieth century has been in particle physics. The "standard model" accounts for the strong, electromagnetic, and weak interactions

between elementary particles with outstanding success. The interactions are generalizations of Maxwell's electrodynamics, which is invariant under a symmetry group U(1) of gauge transformations. An enlargement of this group to $SU(2) \otimes U(1)$ accounts for the unified electroweak interaction (the unification resulting from the fact that the two U(1)'s above are not exactly the same; there is some on-diagonal mixing), and the strong interactions between quarks, which binds them into hadrons, are invariant under an SU(3) group of gauge transformations. The gauge fields are the photon $\gamma$, the $W$ and $Z$ bosons (both heavy; of the order of 100 times the proton mass), and the (massless) gluons mediating the force between quarks (quantum chromodynamics, QCD). An important feature of the standard model is spontaneous symmetry breaking, which is the mechanism by which the $W$ and $Z$ particles acquire a mass (but the photon does not, and neither do the gluons). This goes by the name of the Higgs mechanism.

The quantization of the standard model is most successfully carried out using the path-integral formalism, rather than canonical quantization, and the proof of the renormalizability of the model (of nonabelian gauge theories with spontaneous symmetry breaking) was given by 't Hooft. Details of these topics are now available in many textbooks.

Confidence that this is a realistic model of elementary particles – that is to say, of quarks and leptons – depends, of course, on particular experiments and their interpretation and an important milestone on this journey was Feynman's quark–parton model of deep inelastic electron–proton scattering. The interpretation of the data required a picture of an electron scattering from an individual quark in the proton, and this in turn required a negligible interaction between quarks; in other words, that at small distances (inside the proton) the quarks are (almost) free – despite the fact that at large distances they most certainly are not! The proof, by Gross, Politzer, and Wilczek, that nonabelian gauge are indeed asymptotically free (asymptotic in momentum space, that is) was therefore an important event in helping to establish the credibility of the standard model.

A characteristic contribution of quantum field theory to our view of the physical world is its picture of the vacuum, as being populated with virtual particle–antiparticle pairs. A consequence of this is the phenomenon of vacuum polarization – that the presence of an electric charge in free space polarizes these virtual pairs. This in turns leads to the phenomenon of screening in QED, and antiscreening in QCD, SU(3) having a more complicated structure than U(1). It also leads to a nonzero (in fact, quadratically divergent!) value for the energy of the vacuum. This is in effect the contribution of the zero-point energies of all the oscillators in the Fourier expansion of the scalar field operator. In any other interaction than gravity, this zero-point energy may be ignored, but in gravity it may be expected to have observable consequences, and indeed it turns out that it plays the same role as a cosmological constant $\Lambda$, and therefore acts as an agent of acceleration, rather than deceleration, of the universe.

A final topic worth noting is one whose existence would have been inconceivable in the early days of this subject. The nonlinearity of the (nonabelian) gauge field equations and the existence of a nontrivial group space allows new types of topologically nontrivial solutions to these equations: solitons, bounces, instantons, sphalerons, and so on. Effects such as fractional spin and nonconservation of fermion number also appear, and, on the cosmological scale, domain walls and cosmic strings. There is something here for theoretical physicists of many differing interests.

# Quantum Fields with Indefinite Metric: Non-Trivial Models

**S Albeverio and H Gottschalk**, Rheinische Friedrich-Wilhelms-Universität Bonn, Bonn, Germany

## Introduction

The nonperturbative construction of quantum field models with nontrivial scattering in arbitrary dimension $d$ of the underlying Minkowski spacetime is much simpler in the framework of quantum field theory with indefinite metric than in the positive-metric case. In particular, there exist a number of solutions in the physical dimension $d = 4$, where up to now no positive-metric solutions are known. The reasons why this is so are reviewed in this article, and some examples obtained by analytic continuation from the solutions of Euclidean covariant stochastic partial differential equations (SPDEs) driven by non-Gaussian white noise are discussed.

## The Hilbert Space Structure Condition

It has been proved by F Strocchi that a quantum gauge field in a local, covariant gauge cannot act on a Hilbert space with a positive-definite inner product. But it is possible to overcome this obstacle by passing from a Hilbert space representation of the algebra of the quantum field to Krein space representations in order to preserve locality and covariance under the Poincaré group.

A Krein space $\mathcal{K}$ is an inner-product space which also is a Hilbert space with respect to some auxiliary scalar product. The relation between the inner product $\langle .,. \rangle$ and the auxiliary scalar product $(.,.)$ is given by a self-adjoint linear operator $J:\mathcal{K}\to\mathcal{K}$ with $J^2 = \mathbf{1}_{\mathcal{K}}$ and $\langle .,. \rangle = (.,J.)$. $J$ is called the metric operator. A quantum field acting on such a space is called a quantum field with indefinite metric. The formal definition is as follows.

Let $\mathcal{D}\subseteq\mathcal{K}$ be a dense linear space and $\Omega\in\mathcal{D}$ a distinguished vector (henceforth called the vacuum). Let $\mathcal{S}=\mathcal{S}(\mathbb{R}^d,\mathbb{C}^N)$ be the space of Schwartz test functions with values in $\mathbb{C}^N$. A quantum field $\phi$ by definition is a linear mapping from $\mathcal{S}$ to the linear operators on $\mathcal{D}$. One usually assumes that $\mathcal{D}$ is generated as the linear span of vectors generated by repeated application of field operators to the vacuum. The following properties should hold for the quantum field $\phi$:

1. *Temperedness*: $f_n \to f$ in $\mathcal{S} \Rightarrow \langle \Psi, \phi(f_n)\Phi\rangle \to \langle \Psi, \phi(f)\Psi\rangle\ \forall \Psi,\Phi\in\mathcal{S}$.
2. *Covariance*: There exists a weakly continuous representation $U$ of the covering of the orthochronous, proper Poincaré group $\tilde{P}_+^{\uparrow}$ by linear operators on $\mathcal{D}$ which is $J$-unitary, that is, $U^{[*]} = U^{-1}$ with $U^{[*]} = JU^*J|_{\mathcal{D}}$ and leaves $\Omega$ invariant. $\phi$ is said to be covariant with respect to $U$ and a representation $\tau$ of the covering of the orthochronous, proper Lorentz group $\tilde{L}_+^{\uparrow}$ if $U(g)\phi(f)U(g)^{-1} = \phi(f_g)$, where $f_g(x) = \tau(\Lambda)f(\Lambda^{-1}(x-a))$, $g=\{\Lambda,a\}$, $\Lambda\in\tilde{L}_+^{\uparrow}$, $a\in\mathbb{R}^d$.
3. *Spectrality*: Let $U(a)$, $a\in\mathbb{R}^d$, be the representation of the translation group and let $\sigma = \cup_{\Psi,\Phi\in\mathcal{D}}\operatorname{supp}\mathcal{F}(\langle\Psi,U(.)\Phi\rangle)$ with $\mathcal{F}$ the Fourier transform (in the sense of tempered distributions). Formally, $\sigma$ is the joint spectrum of the generators of spacetime translations $U(a)$. The spectral condition then demands that $\sigma\subseteq\bar{V}_0^+$, the closed forward light cone in energy–momentum space.
4. *Locality*: There is a decomposition $\mathbb{C}^N=\oplus_\kappa V_\kappa$ such that for each $f,h\in\mathcal{S}$ taking values in a $V_\kappa$ and having spacelike separated supports one has either $[\phi(f),\phi(h)]=0$ or $\{\phi(f),\phi(h)\}=0$, where $[.,.]$ is the commutator and $\{.,.\}$ the anticommutator.
5. *Hermiticity*: There is an involution $*$ on $\mathcal{S}$ such that $\phi(f)^{[*]}=\phi(f^*)$.

The quantum-mechanical interpretation of the inner product of two vectors in $\mathcal{K}$ as a probability amplitude, however, gets lost. It has to be restored by the construction of a physical subspace of $\mathcal{K}$ where the restriction of the inner product is non-negative. This is called the Gupter–Bleuler gauge procedure. Typically, one first considers the problem of constructing quantum fields with indefinite metric, that is, the dynamical problem is addressed. This is often followed by the construction of the physical states, which involves implementation of quantum constraints.

The vacuum expectation values (VEVs), also called Wightman functions, of the quantum field theory with indefinite metric (IMQFT) are defined as

$$W_n(f_1 \otimes \cdots \otimes f_n) = \langle \Omega, \phi(f_1) \cdots \phi(f_n)\Omega \rangle \quad f_1, \ldots, f_n \in \mathcal{S} \qquad [1]$$

An axiomatic framework for (unconstrained) IMQFT has been suggested by G Morchio and F Strocchi in terms of the Wightman functions $W_n \in \mathcal{S}'$, $n \in \mathbb{N}_0$. Previous work on the topic had been done by J Yngvason. These generalized Wightman axioms of Morchio and Strocchi replace the positivity condition on the Wightman functions by a so-called Hilbert space structure condition (HSSC): for $n \in \mathbb{N}_0$ there exist $p_n$ a Hilbert seminorm on $\mathcal{S}^{\otimes n}$ such that

$$|W_{n+m}(f \otimes h)| \leq p_n(f) p_m(h) \quad \forall n, m \in \mathbb{N}_0 \quad f \in \mathcal{S}^{\otimes n},\ h \in \mathcal{S}^{\otimes m} \qquad [2]$$

This condition makes sure that a field algebra on a Krein space with VEVs equal to the given set of Wightman functions can be constructed. The remaining axioms of the Wightman framework – temperedness, covariance, spectral condition, locality, and Hermiticity – remain the same. Clustering of Wightman functions is assumed at least for massive theories:

$$\lim_{t\to\infty} W_{n+m}(f \otimes h_{ta}) = W_n(f) W_m(h) \quad \forall n, m \in \mathbb{N}_0 \quad f \in \mathcal{S}^{\otimes n},\ h \in \mathcal{S}^{\otimes m} \qquad [3]$$

for spacelike $a \in \mathbb{R}^d$. It fails to hold in certain physical contexts where multiple vacua (also called $\Theta$-vacua) accompanied with massless Goldstone bosons occur due to spontaneous symmetry breaking.

In the original Wightman axioms, there are essentially two nonlinear axioms: positivity and clustering. Here nonlinear means that checking that condition involves more than one VEV with a given number of field operators. The cluster condition can be linearized by an operation on the Wightman functions called “truncation.” The equations

$$W_n(f_1 \otimes \cdots \otimes f_n) = \sum_{I \in \mathcal{P}^{(n)}} \prod_{\substack{\{j_1,\ldots,j_l\} \in I \\ j_1 < j_2 < \cdots < j_l}} W_n^T(f_{j_1} \otimes \cdots \otimes f_{j_l}) \qquad [4]$$

recursively define the truncated Wightman functions $W_n^T$ for $n \in \mathbb{N}$. Here $\mathcal{P}^{(n)}$ stands for the set of all partitions of $\{1, \ldots, n\}$ into disjoint, nonempty sets. Unfortunately, the positivity condition (at least when combined with nontrivial scattering) becomes highly nonlinear for truncated Wightman functions. This can be seen as one explanation why it is so difficult to find nontrivial (i.e., corresponding to nontrivial interactions) solutions to the Wightman axioms.

But it turns out that, in contrast to positivity, the HSSC is essentially linear for truncated Wightman functions.

**Theorem 1** *If there exists a Schwartz norm $\|\cdot\|$ on $\mathcal{S}$ such that $W_n^T$ is continuous with respect to $\|\cdot\|^{\otimes n}$ for $n \in \mathbb{N}$ then the associated sequence of Wightman functions $\{W_n\}$ fulfills the HSSC [2].*

Note that $\|\cdot\|^{\otimes n}$ is well defined as $\mathcal{S}$ is a nuclear space. This theorem makes it much easier to construct IMQFTs. In particular, all known solutions of the linear program for truncated Wightman functions lead to an abundance of mathematical solutions to the axioms of IMQFT, as long as the singularities of truncated Wightman functions in position and energy–momentum space do not become increasingly stronger with growing $n$. For example, the perturbative solutions to Wightman functions of Ostendorf and Steinmann provide solutions when the perturbation series is truncated at a given order.

## Relativistic Fields from Euclidean Stochastic Equations

In the classical work on constructive quantum field theory, relativistic fields in spacetime dimensions $d = 2$ and 3 have been constructed by analytic continuation from Euclidean random fields. This, in particular, has led to firm connections between quantum field theory and equilibrium statistical mechanics. Let us discuss one specific class of solutions of the axioms of IMQFT for arbitrary $d$ which also stem from random fields related to an ensemble of statistical mechanics of classical, continuous particles. Mathematically, this is connected with using random fields with Poisson distribution. As in constructive QFT, the moments, also called Schwinger functions, of the random field can be analytically continued from Euclidean imaginary time to relativistic real time. That this is possible results from an explicit calculation. Axiomatic results cannot be used, as they depend on positivity or reflection positivity in the Euclidean spacetime, respectively.

By definition, a mixing Euclidean covariant random field $\varphi$ is an almost surely linear mapping from $\mathcal{S}_{\mathbb{R}} = \mathcal{S}(\mathbb{R}^d, \mathbb{R}^N)$ to the space of real-valued

measurable functions (random variables) on some probability space that fulfills the following properties:

1. *Temperedness*: $f_n \to f$ in $\mathcal{S}_{\mathbb{R}} \Rightarrow \varphi(f_n) \xrightarrow{\mathcal{L}} \varphi(f)$.
2. *Covariance*: $\varphi(f) \overset{\mathcal{L}}{=} \varphi(f_g)\ \forall f \in \mathcal{S}_{\mathbb{R}},\ g = \{\Lambda, a\}$, $\Lambda \in \mathrm{SO}(d),\ a \in \mathbb{R}^d,\ f_g(x) = \tau(\Lambda) f(\Lambda^{-1}(x-a))$ for some continuous representation $\tau : \mathrm{SO}(d) \to \mathrm{GL}(N)$.
3. *Mixing*: $\lim_{t\to\infty} \mathbb{E}[AB_{ta}] = \mathbb{E}[A]\mathbb{E}[B]$ for all square-integrable random variables $A = A(\varphi)$, $B = B(\varphi)$, and $B_{ta} = B(\varphi_{ta})$, $\varphi_{ta}(f) = \varphi(f_{ta})\ \forall f \in \mathcal{S}_{\mathbb{R}}$, $a \in \mathbb{R}^d \setminus \{0\}$.

The mixing condition in the Euclidean spacetime plays the same role as the cluster property in the generalized Wightman axioms.

In particular, we consider random fields $\varphi$ obtained as solutions of the SPDE $D\varphi = \eta$. In this equation, $\eta$ is a noise field, that is, $\eta$ is $\tau$-covariant for some representation of $\mathrm{SO}(d)$, $\eta(f)$ has infinitely divisible probability law and $\eta(f)$, $\eta(h)$ are independent $\forall f, h \in \mathcal{S}_{\mathbb{R}}$ with $\operatorname{supp} f \cap \operatorname{supp} h = \emptyset$. $D$ is a $\tau$-covariant (i.e., $\tau(\Lambda) D \tau(\Lambda)^{-1} = D \quad \forall \Lambda \in \mathrm{SO}(d)$) partial differential operator with constant coefficients (also pseudodifferential operators $D$ could be considered). From the classification of infinitely divisible probability laws, it is known that $\eta$ essentially consists of Gaussian white noise and Poisson fields and derivatives thereof. Such a Gauss–Poisson noise field by the Bochner–Minlos theorem is characterized by its Fourier transform. Direct relations with QFT arise if one chooses

$$\mathbb{E}[\mathrm{e}^{\mathrm{i}\eta(f)}] = \exp\left\{ \int_{\mathbb{R}^d} \psi(f) - f \cdot \bar{\sigma}^2 p(-\Delta) f \,\mathrm{d}x \right\}, \quad f \in \mathcal{S}_{\mathbb{R}} \qquad [5]$$

where $\psi : \mathbb{R}^N \to \mathbb{C}$ is a Lévy function,

$$\psi(t) = \mathrm{i}a \cdot t - \frac{t \cdot \sigma^2 t}{2} + z \int_{\mathbb{R}^N \setminus \{0\}} (\mathrm{e}^{\mathrm{i}t\cdot s} - 1)\,\mathrm{d}r(s), \quad t \in \mathbb{R}^N \qquad [6]$$

Here the centered dot represents a $\tau$-invariant scalar product on $\mathbb{R}^N$, $\sigma$ a positive-semidefinite $\tau$-invariant $N \times N$ matrix, $z \geq 0$ a real number and $r$ is a $\tau$-invariant probability measure on $\mathbb{R}^n \setminus \{0\}$ with all moments. Further, $\bar{\sigma}^2_{\alpha,\beta} = (\partial^2 \psi(t)/\partial t_\alpha \partial t_\beta)|_{t=0}$, and $p : [0,\infty) \to [0,\infty)$ is a polynomial depending on $D$. If $\hat{D}^{-1}$, the Fourier-transformed inverse of $D$, exists, it can be represented by

$$\hat{D}^{-1}(k) = \frac{Q_E(k)}{\prod_{l=1}^{P} (|k|^2 + m_l^2)^{\nu_l}} \qquad [7]$$

Here $Q_E(k)$ is a complex $N \times N$ matrix with polynomial entries being $\tau$-covariant, $\tau(\Lambda) Q_E (\Lambda^{-1}k) \tau(\Lambda)^{-1} = Q_E(k) \quad \forall \Lambda \in \mathrm{SO}(d),\ \ k \in \mathbb{R}^d$. $\nu_l \in \mathbb{N}$ and $m_1 \in \mathbb{C} \setminus (-\infty, 0)$ are parameters with the interpretation of the mass spectrum $(m_1, \ldots, m_P)$ and $(\nu_1, \ldots, \nu_P)$ the dipole degrees of the related masses. We restrict ourselves to the case of positive mass spectrum where $m_l > 0$, and in this case

$$p(t) = p(t, D) = \frac{\prod_{l=1}^{P} (t + m_l^2)^{\nu_l}}{\prod_{l=1}^{P} m_l^{2\nu_l}}, \quad t > 0 \qquad [8]$$

One can show that $\varphi$ obtained as the unique solution of the SPDE $D\varphi = \eta$ is a Euclidean covariant, mixing random field. The Schwinger functions (moments) of $\varphi$ are given by

$$S_n(f_1 \otimes \cdots \otimes f_n) = E[\varphi(f_1) \cdots \varphi(f_n)], \quad f_1, \ldots, f_n \in \mathcal{S}_{\mathbb{R}} \qquad [9]$$

Now the Schwinger functions can be calculated explicitly. They are determined by the truncated Schwinger functions, cf. [4], as follows: for $n = 2$,

$$S^{\mathrm{T}}_{2,\alpha_1,\alpha_2}(x_1, x_2) = \frac{Q^{\mathrm{E}}_{2,\alpha_1,\alpha_2}(-\mathrm{i}\,\underline{\nabla}_2)}{\prod_{l=1}^{N} m_l^{2\nu_l}} \left[ \prod_{l=1}^{N} (-\Delta + m_l^2)^{-\nu_l} \right] (x_1 - x_2) \qquad [10]$$

and for $n \geq 3$

$$S^{\mathrm{T}}_{n,\alpha_1\cdots\alpha_n}(x_1, \ldots, x_n) = Q^{\mathrm{E}}_{n,\alpha_1\cdots\alpha_n}(-\mathrm{i}\,\underline{\nabla}_n) \times \int_{\mathbb{R}^d} \prod_{j=1}^{n} \left[ \prod_{l=1}^{N} (-\Delta + m_l^2)^{-\nu_l} \right] (x_j - x)\,\mathrm{d}x \qquad [11]$$

where

$$Q^{\mathrm{E}}_{n,\alpha_1\cdots\alpha_n}(-\mathrm{i}\,\underline{\nabla}_n) = C^{\beta_1\cdots\beta_n} \prod_{l=1}^{n} Q_{E,\beta_l,\alpha_l}\left(-\mathrm{i}\frac{\partial}{\partial x_l}\right) \qquad [12]$$

with

$$C_{\beta_1\cdots\beta_n} = (-\mathrm{i})^n \frac{\partial^n \psi(t)}{\partial t_{\beta_1} \cdots \partial t_{\beta_n}}\bigg|_{t=0} \qquad [13]$$

and the Einstein convention of summation and raising/lowering of indices on $\mathbb{R}^N$ with respect to the invariant inner product $\cdot$ is applied. The Schwinger functions fulfill the requirements of $\tau$-covariance, symmetry, clustering, and Hermiticity from the Osterwalder–Schrader axioms of Euclidean QFT.

While there is no known general reason why a relativistic QFT should exist for a given set of Schwinger functions, one can take advantage of the explicit formulas [10]–[13] in order to calculate the analytic continuation from Euclidean to relativistic times explicitly.

It simplifies the considerations to exclude dipole fields, that is, one assumes that $\nu_l = 1$ for $l = 1, \ldots, n$. In physical terms, the no-dipole condition guarantees that the asymptotic fields in Minkowski spacetime fulfill the Klein–Gordon equation and thus generate particles in the usual sense if applied to the vacuum. If this condition is not imposed, asymptotic fields might only fulfill a dipole equation $(\Box + m^2)^2 \phi^{\text{in/out}} = 0$ or a related hyperbolic equation of even higher order, and the particle states generated by application of such fields to the vacuum require a gauge fixing (constraints) in order to obtain a physical interpretation. Given the no-dipole condition, one obtains by expansion into partial fractions

$$\frac{1}{\prod_{l=1}^{P}(|k|^2 + m_l^2)} = \sum_{l=1}^{N} \frac{b_l}{(|k|^2 + m_l^2)} \qquad [14]$$

with $b_l \in (0, \infty)$ uniquely determined and $b_l \neq 0$. For the truncated Schwinger functions, this implies $(n \geq 3)$ that

$$\begin{aligned} S^{\mathrm{T}}_{n,\alpha_1\cdots\alpha_n}&(x_1, \ldots, x_n) \\ &= Q^{\mathrm{E}}_{n,\alpha_1\cdots\alpha_n}(-\mathrm{i}\,\underline{\nabla}_n) \sum_{l_1,\ldots,l_n=1}^{P} \\ &\quad \times \prod_{r=1}^{n} b_{l_r} \int_{\mathbb{R}^d} \prod_{j=1}^{n} (-\Delta + m_{l_j}^2)^{-1}(x - x_j)\, \mathrm{d}x \end{aligned} \qquad [15]$$

At this point, a lengthy calculation yields a representation of the functions $\int_{\mathbb{R}^d} \prod_{j=1}^{n} (-\Delta + m_j^2)^{-1} (x - x_j)\, \mathrm{d}x$ as the Fourier–Laplace transform of a distribution $\hat{W}^{\mathrm{T}}_{n,m_1,\ldots,m_n}$ that fulfills the spectral condition. This is equivalent to the statement that the analytic continuation of such functions to relativistic times yields $W^{\mathrm{T}}_{n,m_1,\ldots,m_n}$, where the latter distribution is the inverse Fourier transform of $\hat{W}^{\mathrm{T}}_{n,m_1,\ldots,m_n}$. This distribution up to a constant that can be integrated into $Q^{\mathrm{E}}$ is given by

$$\left\{ \sum_{j=1}^{n} \prod_{l=1}^{j-1} \delta^{-}_{m_l}(k_l) \frac{(-1)}{k^2 - m_j^2} \prod_{l=j+1}^{n} \delta^{+}_{m_l}(k_l) \right\} \delta\left( \sum_{l=1}^{n} k_l \right) \qquad [16]$$

Here $\delta^{\pm}_m(k) = \theta(\pm k^0)\delta(k^2 - m^2)$, where $\theta$ is the Heaviside step function and $k^2 = k^{0^2} - |\boldsymbol{k}|^2$. On the other hand, the partial differential operator $Q^{\mathrm{E}}_n$ can be analytically continued in momentum space:

$$\begin{aligned} Q^{\mathrm{M}}_n&((k_1^0, \boldsymbol{k}_1), \ldots, (k_n^0, \boldsymbol{k}_n)) \\ &= Q^{\mathrm{E}}_n((\mathrm{i}k_1^0, \boldsymbol{k}_1), \ldots, (\mathrm{i}k_n^0, \boldsymbol{k}_n)) \end{aligned} \qquad [17]$$

$k_1, \ldots, k_n \in \mathbb{R}^d$. With the definition

$$\begin{aligned} \hat{W}^{\mathrm{T}}_{2,\alpha_1\alpha_2}(k_1, k_2) &= (2\pi)^{(d+1)} \frac{Q^{\mathrm{M}}_{2,\alpha_1\alpha_2}(k_1, k_2)}{\prod_{l=1}^{N} m_l^2} \\ &\quad \times \sum_{l=1}^{N} b_l\, \delta^{-}_{m_l}(k_1)\delta(k_1 + k_2) \end{aligned} \qquad [18]$$

and

$$\begin{aligned} \hat{W}^{\mathrm{T}}_{n,\alpha_1\cdots\alpha_n}&(k_1, \ldots, k_n) \\ &= Q^{\mathrm{M}}_{n,\alpha_1\cdots\alpha_n}(k_1, \ldots, k_n) \\ &\quad \times \sum_{l_1,\ldots,l_n=1}^{N} \prod_{j=1}^{n} b_{l_j}\, \hat{W}^{\mathrm{T}}_{n,m_{l_1},\ldots,m_{l_n}}(k_1, \ldots, k_n) \end{aligned} \qquad [19]$$

the analytic continuation of Schwinger functions can be summarized as follows:

**Theorem 2** *The truncated Schwinger functions $\mathcal{S}^{\mathrm{T}}_n$ have a Fourier–Laplace representation with $\hat{W}^{\mathrm{T}}_n$ defined in eqns [18] and [19]. Equivalently, $\mathcal{S}^{\mathrm{T}}_n$ is the analytic continuation of $W^{\mathrm{T}}_n$ from purely real relativistic time to purely imaginary Euclidean time. The truncated Wightman functions $W^{\mathrm{T}}_n$ fulfill the requirements of temperedness, relativistic covariance with respect to the representation of the orthochronous, proper Lorentz group $\tilde{\tau} : \mathrm{L}^{\uparrow}_{+}(d) \to$* Gl(L), *locality, spectral property, and cluster property. Here $\tilde{\tau}$ is obtained by analytic continuation of $\tau$ to a representation of the proper complex Lorentz group over $\mathbb{C}^d$ (which contains* SO($d$) *as a real submanifold) and restriction of this representation to the real orthochronous proper Lorentz group.*

Again making use of the explicit formula in Theorem 2, the condition of Theorem 1 can be verified. This proves the existence of IMQFT models associated with the class of random fields under discussion.

**Theorem 3** *The Wightman functions defined in Theorem 2 fulfill the HSSC [2]. In particular, there exists a QFT with indefinite metric such that the Wightman functions are given as the VEVs of that IMQFT.*

## Nontrivial Scattering

Theories as described in Theorem 2 obviously have trivial scattering behavior if the noise field $\eta$ is Gaussian, that is, if, in [7], $z = 0$. In the case where there is also a Poisson component in $\eta$, that is, $z > 0$, higher-order truncated Wightman functions do not vanish and such relativistic theories have nontrivial scattering.

Before the scattering of the models can be discussed, some comments about scattering in IMQFT in general are in order. The scattering

theory in axiomatic QFT, Haag–Ruelle theory, relies on positivity. In fact, one can show that in the class of models under discussion, the LSZ asymptotic condition is violated if dipole degrees of freedom are admitted. In that case more complicated asymptotic conditions have to be used. In any case, the Haag–Ruelle theory cannot be adapted to IMQFT.

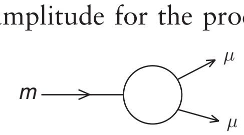
Nevertheless, asymptotic fields and states can be constructed in IMQFT if one imposes a no-dipole condition in a mathematically precise way. Then the LSZ asymptotic condition leads to the construction of mixed VEVs of asymptotic in- and out-fields with local fields. The collection of such VEVs is called the form-factor functional. After constructing this collection of mixed VEVs, one can try to check the HSSC for this functional and obtains a Krein space representation for the algebra generated by in- local and out-fields.

Following this line, asymptotic in- and out-particle states can be constructed for the given mass spectrum $(m_1, \ldots, m_P)$. If $a^{\mathrm{in/out}\dagger}_{\alpha, l}(k)$, $l = 1, \ldots, P$, denotes the creation operator for an incoming/outgoing particle with mass $m_l$, spin component $\alpha$, and energy–momentum $k$, the following scattering amplitude can be derived for $r$ incoming particles with masses $m_{l_1}, \ldots, m_{l_r}$ and $n - r$ outgoing particles with masses $m_{l_{r+1}}, \ldots, m_{l_n}$:

$$\left\langle a^{\mathrm{in}\dagger}_{\alpha_1, l_1}(k_1) \cdots a^{\mathrm{in}\dagger}_{\alpha_r, l_r}(k_r)\Omega, a^{\mathrm{out}\dagger}_{\alpha_{r+1}, l_{r+1}}(k_{r+1}) \cdots a^{\mathrm{out}\dagger}_{\alpha_n, l_n}(k_n)\Omega \right\rangle^{\mathrm{T}}$$
$$= -(2\pi)\mathrm{i}Q^{\mathrm{M}}_{\alpha_1,\ldots,\alpha_n}(-k_1, \ldots, -k_r, k_{r+1}, \ldots, k_n)$$
$$\times \prod_{j=1}^{n} \delta^{+}_{m_{l_j}}(k_j)\, \delta(K^{\mathrm{in}} - K^{\mathrm{out}}) \qquad [20]$$

$K^{\mathrm{in/out}}$ stand for the total energy–momentum of in- and out-particles, that is, $K^{\mathrm{in}} = \sum_{j=1}^{r} k_j$ and $K^{\mathrm{out}} = \sum_{j=r+1}^{n} k_j$.

Two immediate consequences can be drawn from [20]. First, choosing a model with nonvanishing Poisson part such that $C_{\beta_1\beta_2\beta_3} \neq 0$ and a differential operator $D$ containing in its mass spectrum the masses $m$ and $\mu$ with $m > 2\mu$, one gets a nonvanishing scattering amplitude for the process



[21]

even though in- and out-particle states consist of particles with well-defined sharp masses. Thus, for the incoming particle, the energy uncertainty, which for a particle at rest is proportional to the mass uncertainty, vanishes but still the particle undergoes a nontrivial decay and must have a finite decay time. This appears to be a contradiction to the energy–time uncertainty relation, which therefore seems to have an unclear status in IMQFT (i.e., in QFT including gauge fields). The origin of this inequality, which of course is experimentally very well tested, apparently has to be located in the constraints, that is, in the procedure of implementing a gauge, of the theory and not in the unconstrained IMQFT.

Second, one can replace somewhat artificially the polynomials $Q^{\mathrm{M}}_n$ in [17] by any other symmetric and relativistically covariant polynomial. If the sequence of the "new" $Q^{\mathrm{M}}_n$ is of uniformly bounded degree in any of the arguments $k_1, \ldots, k_n$, the redefined Wightman functions in [17] still fulfill the requirements of Theorem 1 and thus define a new relativistic, local IMQFT. The scattering amplitudes of such a theory are again well defined and given by [20]. For example, in the case of only one scalar particle with mass $m$, one can show that arbitrary Lorentz-invariant scattering behavior of bosonic particles can be reproduced by such theories for energies below an arbitrary maximal energy up to arbitrary precision. This kind of interpolation theorem shows that the outcome of an arbitrary scattering experiment can be reproduced within the formalism of (unconstrained) IMQFT as long as it is in agreement with the general requirements of Poincaré invariance and statistics.

## List of Symbols

## Introduction

The ordered patterns we observe in condensed matter and in high-energy physics are created by the quantum dynamics. Macroscopic systems exhibiting some kind of ordering, such as superconductors, ferromagnets, and crystals, are described by the underlying quantum dynamics. Even the large-scale structures in the universe, as well as the ordering in the biological systems appear to be the manifestation of the microscopic dynamics governing the elementary components of these systems. Thus, we talk of macroscopic quantum systems: these are quantum systems in the sense that, although they behave classically, some of their macroscopic features nevertheless cannot be understood without recourse to quantum theory.

The question then arises how the quantum dynamics generates the observed macroscopic properties. In other words, how it happens that the macroscopic scale characterizing those systems is dynamically generated out of the microscopic scale of the quantum elementary components (Umezawa 1993, Umezawa *et al.* 1982).

Moreover, we also observe a variety of phenomena where quantum particles coexist and interact with extended macroscopic objects which show a classical behavior, for example, vortices in superconductors and superfluids, magnetic domains in ferromagnets, dislocations and other topological defects (grain boundaries, point defects, etc.) in crystals, and so on.

We are thus also faced with the question of the quantum origin of topological defects and their interaction with quanta (Umezawa 1993, Umezawa *et al.* 1982): this is a crucial issue for the understanding of symmetry-breaking phase transitions and structure formation in a wide range of systems from condensed matter to cosmology (Kibble 1976, Zurek 1997, Volovik 2003).

Here, we will review how the generation of ordered structures and extended objects is explained in quantum field theory (QFT). We follow Umezawa (1993) and Umezawa *et al.* (1982) in our presentation. We will consider systems in which spontaneous symmetry breaking (SSB) occurs and show that topological defects originate by inhomogeneous (localized) condensation of quanta. The approach followed here is alternative to the usual one (Rajaraman 1982), in which one starts from the classical soliton solutions and then "quantizes" them, as well as to the QFT method based on dual (disorder) fields (Kleinert 1989).

In the next section we introduce some general features of QFT useful for our discussion and treat some aspects of SSB and the rearrangement of symmetry. Next we discuss the boson transformation theorem and the topological singularities of the boson condensate. We then present, as an example, a model with U(1) gauge invariance in which SSB, rearrangement of symmetry, and topological defects are present (Matsumoto *et al.* 1975a, b). There we show how macroscopic fields and currents are obtained from the microscopic quantum dynamics. The Nielsen–Olesen vortex solution is explicitly obtained as an example. The final section is devoted to conclusions.

## Symmetry and Order in QFT: A Dynamical Problem

QFT deals with systems with infinitely many degrees of freedom. The fields used for their description are operator fields whose mathematical significance is fully specified only when the state space where they operate is also assigned. This is the space of the states, or physical phase, of the system under given boundary conditions. A change in the boundary conditions may result in the transition of the system from one phase to another. For example, a change of temperature from above to below the critical temperature may induce the transition from the

normal to the superconducting phase in a metal. The identification of the state space where the field operators have to be realized is thus a physically nontrivial problem in QFT. In this respect, the QFT structure is drastically different from the one of quantum mechanics (QM). The reason is the following.

The von Neumann theorem (1955) in QM states that for systems with a finite number of degrees of freedom all the irreducible representations of the canonical commutation relations are unitarily equivalent. Therefore, in QM the physical system can only live in one single physical phase: unitary equivalence means indeed physical equivalence and thus there is no room (no representations) for physically different phases. Such a situation drastically changes in QFT where systems with infinitely many degrees of freedom are treated. In such a case, the von Neumann theorem does not hold and infinitely many unitarily inequivalent representations of the canonical commutation relations do in fact exist (Umezawa 1993, Umezawa *et al.* 1982). It is such richness of QFT that allows the description of different physical phases.

### QFT as a Two-Level Theory

In the perturbative approach, any quantum experiment or observation can be schematized as a scattering process where one prepares a set of free (noninteracting) particles (incoming particles or in-fields) which are then made to collide at some later time in some region of space (spacetime region of interaction). The products of the collision are expected to emerge out of the interaction region as free particles (outgoing particles or out-fields). Correspondingly, one has the in-field and the out-field state space. The interaction region is where the dynamics operates: given the in-fields and the in-states, the dynamics determines the out-fields and the out-states.

The incoming particles and the outgoing ones (also called quasiparticles in solid state physics) are well distinguishable and localizable particles only far away from the interaction region, at a time much before ($t=-\infty$) and much after ($t=+\infty$) the interaction time: in- and out-fields are thus said to be asymptotic fields, and for them the interaction forces are assumed not to operate (switched off).

The only regions accessible to observations are those far away (in space and in time) from the interaction region, that is, the asymptotic regions (the in- and out-regions). It is so since, at the quantum level, observations performed in the interaction region or vacuum fluctuations occurring there may drastically interfere with the interacting objects, thus changing their nature. Besides the asymptotic fields, one then also introduces dynamical or Heisenberg fields, that is, the fields in terms of which the dynamics is given. Since the interaction region is precluded from observation, we do not observe Heisenberg fields. Observables are thus solely described in terms of asymptotic fields.

Summing up, QFT is a "two-level" theory: one level is the interaction level where the dynamics is specified by assigning the equations for the Heisenberg fields. The other level is the physical level, the one of the asymptotic fields and of the physical state space directly accessible to observations. The equations for the physical fields are equations for free fields, describing the observed incoming/outgoing particles.

To be specific, let the Heisenberg operator fields be generically denoted by $\psi_{\mathrm{H}}(x)$ and the physical operator fields by $\varphi_{\mathrm{in}}(x)$. For definiteness, we choose to work with the in-fields, although the set of out-fields would work equally well. They are both assumed to satisfy equal-time canonical (anti)-commutation relations.

For brevity, we omit considerations on the renormalization procedure, which are not essential for the conclusions we will reach. The Heisenberg field equations and the free-field equations are written as

$$\Lambda(\partial)\psi_{\mathrm{H}}(x) = \mathcal{J}[\psi_{\mathrm{H}}](x) \qquad [1]$$

$$\Lambda(\partial)\varphi_{\mathrm{in}}(x) = 0 \qquad [2]$$

where $\Lambda(\partial)$ is a differential operator, $x \equiv (t, \boldsymbol{x})$ and $\mathcal{J}$ is some functional of the $\psi_{\mathrm{H}}$ fields, describing the interaction.

Equation [1] can be formally recast in the following integral form (Yang–Feldman equation):

$$\psi_{\mathrm{H}}(x) = \varphi_{\mathrm{in}}(x) + \Lambda^{-1}(\partial) * \mathcal{J}[\psi_{\mathrm{H}}](x) \qquad [3]$$

where $*$ denotes convolution. The symbol $\Lambda^{-1}(\partial)$ denotes formally the Green function for $\varphi_{\mathrm{in}}(x)$. The precise form of Green's function is specified by the boundary conditions. Equation [3] can be solved by iteration, thus giving an expression for the Heisenberg fields $\psi_{\mathrm{H}}(x)$ in terms of powers of the $\varphi_{\mathrm{in}}(x)$ fields; this is the Haag expansion in the LSZ formalism (or "dynamical map" in the language of Umezawa 1993 and Umezawa *et al.* 1982), which might be formally written as

$$\psi_{\mathrm{H}}(x) = F[x; \varphi_{\mathrm{in}}] \qquad [4]$$

(A (formal) closed form for the dynamical map is obtained in the closed time path (CTP) formalism (Blasone and Jizba 2002). Then the Haag expansion [4] is directly applicable to both equilibrium and nonequilibrium situations.)

We stress that the equality in the dynamical map [4] is a "weak" equality, which means that it must be understood as an equality among matrix elements computed in the Hilbert space of the physical particles.

We observe that mathematical consistency in the above procedure requires that the set of $\varphi_{\rm in}$ fields must be an irreducible set; however, it may happen that not all the elements of the set are known from the beginning. For example, there might be composite (bound states) fields or even elementary quanta whose existence is ignored in a first recognition. Then the computation of the matrix elements in physical states will lead to the detection of unexpected poles in the Green's functions, which signal the existence of the ignored quanta. One thus introduces the fields corresponding to these quanta and repeats the computation. This way of proceeding is called the self- consistent method (Umezawa 1993, Umezawa *et al.* 1982). Thus it is not necessary to have a one-to-one correspondence between the sets $\{\psi^j_{\rm H}\}$ and $\{\varphi^i_{\rm in}\}$, as it happens whenever the set $\{\varphi^i_{\rm in}\}$ includes composite particles.

### The Dynamical Rearrangement of Symmetry

As already mentioned, in QFT the Fock space for the physical states is not unique since one may have several physical phases, for example, for a metal the normal phase and the superconducting phase, and so on. Fock spaces describing different phases are unitarily inequivalent spaces and correspondingly we have different expectation values for certain observables and even different irreducible sets of physical quanta. Thus, finding the dynamical map involves singling out the Fock space where the dynamics has to be realized.

Let us now suppose that the Heisenberg field equations are invariant under some group $G$ of transformations of $\psi_{\rm H}$:

$$\psi_{\rm H}(x) \rightarrow \psi'_{\rm H}(x) = g[\psi_{\rm H}(x)] \qquad [5]$$

with $g \in G$. The symmetry is spontaneously broken when the vacuum state in the Fock space $\mathcal{H}$ is not invariant under the group $G$ but only under one of its subgroups (Umezawa 1993, Umezawa *et al.* 1982).

On the other hand, eqn [4] implies that when $\psi_{\rm H}$ is transformed as in [5], then

$$\varphi_{\rm in}(x) \rightarrow \varphi'_{\rm in}(x) = g'[\varphi_{\rm in}(x)] \qquad [6]$$

with $g'$ belonging to some group of transformations $G'$ and such that

$$g[\psi_{\rm H}(x)] = F[g'[\varphi_{\rm in}(x)]] \qquad [7]$$

When symmetry is spontaneously broken it is $G' \neq G$, with $G'$ the group contraction of $G$; when symmetry is not broken then $G' = G$.

Since $G$ is the invariance group of the dynamics, eqn [4] requires that $G'$ is the group under which free fields equations are invariant, that is, also $\varphi'_{\rm in}$ is a solution of [2]. Since eqn [4] is a weak equality, $G'$ depends on the choice of the Fock space $\mathcal{H}$ among the physically realizable unitarily inequivalent state spaces. Thus, we see that the (same) original invariance of the dynamics may manifest itself in different symmetry groups for the $\varphi_{\rm in}$ fields according to different choices of the physical state space. Since this process is constrained by the dynamical equations [1], it is called the dynamical rearrangement of symmetry (Umezawa 1993, Umezawa *et al.* 1982).

In conclusion, different ordering patterns appear to be different manifestations of the same basic dynamical invariance. The discovery of the process of the dynamical rearrangement of symmetry leads to a unified understanding of the dynamical generation of many observable ordered patterns. This is the phenomenon of the dynamical generation of order. The contraction of the symmetry group is the mathematical structure controlling the dynamical rearrangement of the symmetry. For a qualitative presentation see Vitiello (2001).

One can now ask which ones are the carriers of the ordering information among the system elementary constituents and how the long-range correlations and the coherence observed in ordered patterns are generated and sustained. The answer is in the fact that SSB implies the appearance of bosons (Goldstone 1961, Goldstone *et al.* 1962, Nambu and Jona-Lasinio 1961), the so-called Nambu–Goldstone (NG) modes or quanta. They manifest as long-range correlations and thus they are responsible of the above-mentioned change of scale, from microscopic to macroscopic. The coherent boson condensation of NG modes turns out to be the mechanism by which order is generated, as we will see in an explicit example in a later section.

## The "Boson Transformation" Method

We now discuss the quantum origin of extended objects (defects) and show how they naturally emerge as macroscopic objects (inhomogeneous condensates) from the quantum dynamics. At zero temperature, the classical soliton solutions are then recovered in the Born approximation. This approach is known as the "boson transformation" method (Umezawa 1993, Umezawa *et al.* 1982).

### The Boson Transformation Theorem

Let us consider, for simplicity, the case of a dynamical model involving one scalar field $\psi_{\rm H}$ and one asymptotic field $\varphi_{\rm in}$ satisfying eqns [1] and [2], respectively.

As already remarked, the dynamical map is valid only in a weak sense, that is, as a relation among matrix elements. This implies that eqn [4] is not unique, since different sets of asymptotic fields and the corresponding Hilbert spaces can be used in its construction. Let us indeed consider a c–number function $f(x)$, satisfying the $\varphi_{\rm in}$ equations of motion [2]:

$$\Lambda(\partial)f(x) = 0 \qquad [8]$$

The boson transformation theorem (Umezawa 1993, Umezawa *et al.* 1982) states that the field

$$\psi^f_{\rm H}(x) = F[x; \varphi_{\rm in} + f] \qquad [9]$$

is also a solution of the Heisenberg equation [1]. The corresponding Yang–Feldman equation takes the form

$$\psi^f_{\rm H}(x) = \varphi_{\rm in}(x) + f(x) + \Lambda^{-1}(\partial) * \mathcal{J}[\psi^f_{\rm H}](x) \qquad [10]$$

The difference between the two solutions $\psi_{\rm H}$ and $\psi^f_{\rm H}$ is only in the boundary conditions. An important point is that the expansion in [9] is obtained from that in [4] by the spacetime-dependent translation

$$\varphi_{\rm in}(x) \to \varphi_{\rm in}(x) + f(x) \qquad [11]$$

The essence of the boson transformation theorem is that the dynamics embodied in eqn [1] contains an internal freedom, represented by the possible choices of the function $f(x)$, satisfying the free-field equation [8].

We also observe that the transformation [11] is a canonical transformation since it leaves invariant the canonical form of commutation relations.

Let $|0\rangle$ denote the vacuum for the free field $\varphi_{\rm in}$. The vacuum expectation value of eqn [10] gives

$$\begin{aligned}\phi^f(x) &\equiv \langle 0|\psi^f_{\rm H}(x)|0\rangle \\ &= f(x) + \left\langle 0\middle|\left[\Lambda^{-1}(\partial) * \mathcal{J}[\psi^f_{\rm H}](x)\right]\middle|0\right\rangle \end{aligned} \qquad [12]$$

The c–number field $\phi^f(x)$ is the order parameter. We remark that it is fully determined by the quantum dynamics. In the classical or Born approximation, which consists in taking $\langle 0|\mathcal{J}[\psi^f_{\rm H}]|0\rangle = \mathcal{J}[\phi^f]$, that is, neglecting all the contractions of the physical fields, we define $\phi^f_{\rm cl}(x) \equiv \lim_{\hbar\to 0}\phi^f(x)$. In this limit, we have

$$\Lambda(\partial)\phi^f_{\rm cl}(x) = \mathcal{J}[\phi^f_{\rm cl}](x) \qquad [13]$$

that is, $\phi^f_{\rm cl}(x)$ provides the solution of the classical Euler–Lagrange equation.

Beyond the classical level, in general, the form of this equation changes. The Yang–Feldman equation [10] gives not only the equation for the order parameter, eqn [13], but also, at higher orders in $\hbar$, the dynamics of the physical quanta in the potential generated by the "macroscopic object" $\phi^f(x)$ (Umezawa 1993, Umezawa *et al.* 1982).

One can show (Umezawa 1993, Umezawa *et al.* 1982) that the class of solutions of eqn [8] which lead to topologically nontrivial (i.e., carrying a nonzero topological charge) solutions of eqn [13], are those which have some sort of singularity with respect to Fourier transform. These can be either divergent singularities or topological singularities. The first are associated to a divergence of $f(x)$ for $|\boldsymbol{x}| = \infty$, at least in some direction. Topological singularities are instead present when $f(x)$ is not single-valued, that is, it is path dependent. In both cases, the macroscopic object described by the order parameter, carries a nonzero topological charge.

### Topological Singularities and Massless Bosons

An important result is that the boson transformation functions carrying topological singularities are only allowed for massless bosons (Umezawa 1993, Umezawa *et al.* 1982).

Consider a generic boson field $\chi_{\rm in}$ satisfying the equation

$$(\partial^2 + m^2)\chi_{\rm in}(x) = 0 \qquad [14]$$

and suppose that the function $f(x)$ for the boson transformation $\chi_{\rm in}(x) \to \chi_{\rm in}(x) + f(x)$ carries a topological singularity. It is then not single-valued and thus path dependent:

$$G^+_{\mu\nu}(x) \equiv [\partial_\mu, \partial_\nu]f(x) \neq 0, \quad \text{for certain}\, \mu, \nu, x \qquad [15]$$

On the other hand, $\partial_\mu f(x)$, which is related with observables, is single-valued, that is, $[\partial_\rho, \partial_\nu]\partial_\mu f(x) = 0$. Recall that $f(x)$ is solution of the $\chi_{\rm in}$ equation:

$$(\partial^2 + m^2)f(x) = 0 \qquad [16]$$

From the definition of $G^+_{\mu\nu}(x)$ and the regularity of $\partial_\mu f(x)$, it follows, by computing $\partial^\mu G^+_{\mu\nu}(x)$, that

$$\partial_\mu f(x) = \frac{1}{\partial^2 + m^2}\partial^\lambda G^+_{\lambda\mu}(x) \qquad [17]$$

This equation and the antisymmetric nature of $G^+_{\mu\nu}(x)$ then lead to $\partial^2 f(x) = 0$, which in turn implies $m = 0$. Thus, we conclude that [15] is only compatible with massless equation for $\chi_{\rm in}$.

The topological charge is defined as

$$N_{\mathrm{T}} = \int_C \mathrm{d}l^\mu \partial_\mu f = \int_S \mathrm{d}S_\mu \epsilon^{\mu\nu\sigma}\partial_\nu\partial_\sigma f = \frac{1}{2}\int_S \mathrm{d}S^{\mu\nu} G^+_{\mu\nu} \qquad [18]$$

Here $C$ is a contour enclosing the singularity and $S$ a surface with $C$ as boundary. $N_{\mathrm{T}}$ does not depend on the path $C$ provided this does not cross the singularity. The dual tensor $G^{\mu\nu}(x)$ is

$$G^{\mu\nu}(x) \equiv -\tfrac{1}{2}\epsilon^{\mu\nu\lambda\rho}G^+_{\lambda\rho}(x) \qquad [19]$$

and satisfies the continuity equation

$$\partial_\mu G^{\mu\nu}(x) = 0 \Leftrightarrow \partial_\mu G^+_{\lambda\rho}(x) + \partial_\rho G^+_{\mu\lambda}(x) + \partial_\lambda G^+_{\rho\mu}(x) = 0 \qquad [20]$$

Equation [20] completely characterizes the topological singularity (Umezawa 1993, Umezawa *et al.* 1982).

## An Example: The Anderson–Higgs–Kibble Mechanism and the Vortex Solution

We consider a model of a complex scalar field $\phi(x)$ interacting with a gauge field $A_\mu(x)$ (Anderson 1958, Higgs 1960, Kibble 1967). The lagrangian density $\mathcal{L}[\phi(x), \phi^*(x), A_\mu(x)]$ is invariant under the global and the local U(1) gauge transformations (we do not assume a particular form for the Lagrangian density, so the following results are quite general):

$$\phi(x) \to \mathrm{e}^{\mathrm{i}\theta}\phi(x), \quad A_\mu(x) \to A_\mu(x) \qquad [21]$$

$$\phi(x) \to \mathrm{e}^{\mathrm{i}e_0\lambda(x)}\phi(x), \quad A_\mu(x) \to A_\mu(x) + \partial_\mu\lambda(x) \qquad [22]$$

respectively, where $\lambda(x) \to 0$ for $|x_0| \to \infty$ and/or $|\boldsymbol{x}| \to \infty$ and $e_0$ is the coupling constant. We work in the Lorentz gauge $\partial_\mu A^\mu(x) = 0$. The generating functional, including the gauge constraint, is (Matsumoto *et al.* 1975a, b)

$$\mathcal{Z}[J, K] = \frac{1}{\mathcal{N}}\int [\mathrm{d}A_\mu][\mathrm{d}\phi][\mathrm{d}\phi^*][\mathrm{d}B] \times \exp\left[\mathrm{i}\,\mathcal{S}[A_\mu, B, \phi]\right] \qquad [23]$$

$$\mathcal{S} = \int \mathrm{d}^4x\Big[\mathcal{L}(x) + B(x)\partial^\mu A_\mu(x) + K^*(x)\phi(x) + K(x)\phi^*(x) + J^\mu(x)A_\mu(x) + \mathrm{i}\epsilon|\phi(x) - v|^2\Big]$$

$$\mathcal{N} = \int [\mathrm{d}A_\mu][\mathrm{d}\phi][\mathrm{d}\phi^*][\mathrm{d}B] \times \exp\left[\mathrm{i}\int \mathrm{d}^4x\Big(\mathcal{L}(x) + \mathrm{i}\epsilon|\phi(x) - v|^2\Big)\right]$$

$B(x)$ is an auxiliary field which implements the gauge-fixing condition (Matsumoto *et al.* 1975a, b). Notice the $\epsilon$-term where $v$ is a complex number; its rôle is to specify the condition of symmetry breaking under which we want to compute the functional integral and it may be given the physical meaning of a small external field triggering the symmetry breaking (Matsumoto *et al.* 1975a, b). The limit $\epsilon \to 0$ must be made at the end of the computations. We will use the notation

$$\langle F[\phi]\rangle_{\epsilon,J,K} \equiv \frac{1}{\mathcal{N}}\int [\mathrm{d}A_\mu][\mathrm{d}\phi][\mathrm{d}\phi^*][\mathrm{d}B]F[\phi] \times \exp\left[\mathrm{i}\mathcal{S}[A_\mu, B, \phi]\right] \qquad [24]$$

with $\langle F[\phi]\rangle_\epsilon \equiv \langle F[\phi]\rangle_{\epsilon,J=K=0}$ and $\langle F[\phi]\rangle \equiv \lim_{\epsilon\to 0}\langle F[\phi]\rangle_\epsilon$.

The fields $\phi, A_\mu$, and $B$ appearing in the generating functional are c-number fields. In the following, the Heisenberg operator fields corresponding to them will be denoted by $\phi_{\mathrm{H}}, A_{\mathrm{H}\mu}$, and $B_{\mathrm{H}}$, respectively. Thus, the spontaneous symmetry breaking condition is expressed by $\langle 0|\phi_{\mathrm{H}}(x)|0\rangle \equiv \tilde{v} \neq 0$, with $\tilde{v}$ constant.

Since in the functional integral formalism the functional average of a given c-number field gives the vacuum expectation value of the corresponding operator field, for example, $\langle F[\phi]\rangle \equiv \langle 0|F[\phi_{\mathrm{H}}]|0\rangle$, we have $\lim_{\epsilon\to 0}\langle\phi(x)\rangle_\epsilon \equiv \langle 0|\phi_{\mathrm{H}}(x)|0\rangle = \tilde{v}$.

Let us introduce the following decompositions:

$$\phi(x) = \frac{1}{\sqrt{2}}[\psi(x) + \mathrm{i}\chi(x)]$$

$$K(x) = \frac{1}{\sqrt{2}}[K_1(x) + \mathrm{i}K_2(x)]$$

$$\rho(x) \equiv \psi(x) - \langle\psi(x)\rangle_\epsilon$$

Note that $\langle\chi(x)\rangle_\epsilon = 0$ because of the invariance under $\chi \to -\chi$.

### The Goldstone Theorem

Since the functional integral [23] is invariant under the global transformation [21], we have that $\partial\mathcal{Z}[J,K]/\partial\theta = 0$ and subsequent derivatives with respect to $K_1$ and $K_2$ lead to

$$\langle\psi(x)\rangle_\epsilon = \sqrt{2}\epsilon v\int \mathrm{d}^4y\langle\chi(x)\chi(y)\rangle_\epsilon = \sqrt{2}\epsilon v\Delta_\chi(\epsilon, 0) \qquad [25]$$

In momentum space the propagator for the field $\chi$ has the general form

$$\Delta_\chi(0, p) = \lim_{\epsilon\to 0}\left[\frac{Z_\chi}{p^2 - m_\chi^2 + \mathrm{i}\epsilon a_\chi} + (\text{continuum contributions})\right] \qquad [26]$$

Here $Z_\chi$ and $a_\chi$ are renormalization constants. The integration in eqn [25] picks up the pole contribution at $p^2 = 0$, and leads to

$$\tilde{v} = \sqrt{2}\frac{Z_\chi}{a_\chi} v \Leftrightarrow m_\chi = 0, \quad \tilde{v} = 0 \Leftrightarrow m_\chi \neq 0 \quad [27]$$

The Goldstone theorem (Goldstone 1961, Goldstone *et al.* 1962) is thus proved: if the symmetry is spontaneously broken ($\tilde{v} \neq 0$), a massless mode must exist, whose field is $\chi(x)$, that is, the NG boson mode. Since it is massless, it manifests as a long-range correlation mode. (Notice that in the present case of a complex scalar field model, the NG mode is an elementary field. In other models, it may appear as a bound state, for example, the magnon in (anti)ferromagnets.) Note that

$$\frac{\partial}{\partial v}\langle\psi(x)\rangle_\epsilon = \sqrt{2}\epsilon \int \mathrm{d}^4 y \langle\rho(x)\rho(y)\rangle_\epsilon \quad [28]$$

and because $m_\rho \neq 0$, the right-hand side of this equation vanishes in the limit $\epsilon \to 0$; therefore, $\tilde{v}$ is independent of $|v|$, although the phase of $|v|$ determines the one of $\tilde{v}$ (from eqn [25]): as in ferromagnets, once an external magnetic field is switched on, the system is magnetized independently of the strength of the external field.

### The Dynamical Map and the Field Equations

Observing that the change of variables [21] (and/or [22]) does not affect the generating functional, we may obtain the Ward–Takahashi identities. Also, using $B(x) \to B(x) + \lambda(x)$ in [23] gives $\langle\partial^\mu A_\mu(x)\rangle_{\epsilon,J,K} = 0$. One then finds the following two-point function pole structures (Matsumoto *et al.* 1975a, b):

$$\langle B(x)\chi(y)\rangle = \lim_{\epsilon\to 0}\left\{\frac{-\mathrm{i}}{(2\pi)^4}\int \mathrm{d}^4 p\, \mathrm{e}^{-\mathrm{i}p(x-y)}\frac{e_0\tilde{v}}{p^2 + \mathrm{i}\epsilon a_\chi}\right\} \quad [29]$$

$$\langle B(x)A^\mu(y)\rangle = \partial_x^\mu \frac{\mathrm{i}}{(2\pi)^4}\int \mathrm{d}^4 p\, \mathrm{e}^{-\mathrm{i}p(x-y)}\frac{1}{p^2} \quad [30]$$

$$\langle B(x)B(y)\rangle = \lim_{\epsilon\to 0}\left\{\frac{-\mathrm{i}}{(2\pi)^4}\int \mathrm{d}^4 p\, \mathrm{e}^{-\mathrm{i}p(x-y)}\frac{(e_0\tilde{v})^2}{Z_\chi} \times \left[\frac{1}{p^2 + \mathrm{i}\epsilon a_\chi} - \frac{1}{p^2}\right]\right\} \quad [31]$$

The absence of branch-cut singularities in propagators [29]–[31] suggests that $B(x)$ obeys a free-field equation. In addition, eqn [31] indicates that the model contains a massless negative-norm state (ghost) besides the NG massless mode $\chi$. Moreover, it can be shown (Matsumoto *et al.* 1975a, b) that a massive vector field $U_{\mathrm{in}}^\mu$ also exists in the theory. Note that because of the invariance $(\chi, A_\mu, B) \to (-\chi, -A_\mu, -B)$, all the other two-point functions must vanish.

The dynamical maps expressing the Heisenberg operator fields in terms of the asymptotic operator fields are found to be (Matsumoto *et al.* 1975a, b)

$$\phi_{\mathrm{H}}(x) = :\exp\left\{\mathrm{i}\frac{Z_\chi^{1/2}}{\tilde{v}}\chi_{\mathrm{in}}(x)\right\}\left[\tilde{v} + Z_\rho^{1/2}\rho_{\mathrm{in}}(x) + \mathcal{F}[\rho_{\mathrm{in}}, U_{\mathrm{in}}^\mu, \partial(\chi_{\mathrm{in}} - b_{\mathrm{in}})]\right]: \quad [32]$$

$$A_{\mathrm{H}}^\mu(x) = Z_3^{1/2}U_{\mathrm{in}}^\mu(x) + \frac{Z_\chi^{1/2}}{e_0\tilde{v}}\partial^\mu b_{\mathrm{in}}(x) + :\mathcal{F}^\mu[\rho_{\mathrm{in}}, U_{\mathrm{in}}^\mu, \partial(\chi_{\mathrm{in}} - b_{\mathrm{in}})]: \quad [33]$$

$$B_{\mathrm{H}}(x) = \frac{e_0\tilde{v}}{Z_\chi^{1/2}}[b_{\mathrm{in}}(x) - \chi_{\mathrm{in}}(x)] + c \quad [34]$$

where $:\ldots:$ denotes the normal ordering and the functionals $\mathcal{F}$ and $\mathcal{F}^\mu$ are to be determined within a particular model. In eqns [32]–[34], $\chi_{\mathrm{in}}$ denotes the NG mode, $b_{\mathrm{in}}$ the ghost mode, $U_{\mathrm{in}}^\mu$ the massive vector field, and $\rho_{\mathrm{in}}$ the massive matter field. In eqn [34] $c$ is a c-number constant, whose value is irrelevant since only derivatives of $B$ appear in the field equations (see below). $Z_3$ represents the wave function renormalization for $U_{\mathrm{in}}^\mu$. The corresponding field equations are

$$\partial^2\chi_{\mathrm{in}}(x) = 0, \qquad \partial^2 b_{\mathrm{in}}(x) = 0$$
$$(\partial^2 + m_\rho^2)\rho_{\mathrm{in}}(x) = 0 \quad [35]$$

$$(\partial^2 + m_V^2)U_{\mathrm{in}}^\mu(x) = 0, \quad \partial_\mu U_{\mathrm{in}}^\mu(x) = 0 \quad [36]$$

with $m_V{}^2 = (Z_3/Z_\chi)(e_0\tilde{v})^2$. The field equations for $B_{\mathrm{H}}$ and $A_{\mathrm{H}\mu}$ read (Matsumoto *et al.* 1975a, b)

$$\partial^2 B_{\mathrm{H}}(x) = 0, \quad -\partial^2 A_{\mathrm{H}\mu}(x) = j_{\mathrm{H}\mu}(x) - \partial_\mu B_{\mathrm{H}}(x) \quad [37]$$

with $j_{\mathrm{H}\mu}(x) = \delta\mathcal{L}(x)/\delta A_{\mathrm{H}}^\mu(x)$. One may then require that the current $j_{\mathrm{H}\mu}$ is the only source of the gauge field $A_{\mathrm{H}\mu}$ in any observable process. This amounts to impose the condition: ${}_p\langle b|\partial_\mu B_{\mathrm{H}}(x)|a\rangle_p = 0$, that is,

$$(-\partial^2)_p\langle b|A_{\mathrm{H}\mu}^0(x)|a\rangle_p = {}_p\langle b|\, j_{\mathrm{H}\mu}(x)|a\rangle_p \quad [38]$$

where $|a\rangle_p$ and $|b\rangle_p$ denote two generic physical states and $A_{\mathrm{H}}^{0\mu}(x) \equiv A_{\mathrm{H}}^\mu(x) - e_0\tilde{v} :\partial^\mu b_{\mathrm{in}}(x):$. Equations [38] are the classical Maxwell equations. The condition ${}_p\langle b|\partial_\mu B_{\mathrm{H}}(x)|a\rangle_p = 0$ leads to the Gupta–Bleuler–like condition

$$[\chi_{\mathrm{in}}^{(-)}(x) - b_{\mathrm{in}}^{(-)}(x)]|a\rangle_p = 0 \quad [39]$$

where $\chi_{\mathrm{in}}^{(-)}$ and $b_{\mathrm{in}}^{(-)}$ are the positive-frequency parts of the corresponding fields. Thus, we see that $\chi_{\mathrm{in}}$ and $b_{\mathrm{in}}$ cannot participate in any observable reaction.

This is confirmed by the fact that they are present in the $S$-matrix in the combination $(\chi_{\rm in} - b_{\rm in})$ (Matsumoto *et al.* 1975a, b). It is to be remarked, however, that the NG boson does not disappear from the theory: we shall see below that there are situations in which the NG fields do have observable effects.

### The Dynamical Rearrangement of Symmetry and the Classical Fields and Currents

From eqns [32]–[33] we see that the local gauge transformations of the Heisenberg fields

$$\begin{aligned}&\phi_{\rm H}(x) \rightarrow e^{ie_0\lambda(x)}\phi_{\rm H}(x)\\ &A^\mu_{\rm H}(x) \rightarrow A^\mu_{\rm H}(x) + \partial^\mu\lambda(x), \quad B_{\rm H}(x) \rightarrow B_{\rm H}(x)\end{aligned} \qquad [40]$$

with $\partial^2\lambda(x) = 0$, are induced by the in-field transformations

$$\begin{aligned}\chi_{\rm in}(x) &\rightarrow \chi_{\rm in}(x) + \frac{e_0\tilde{v}}{Z_\chi^{1/2}}\lambda(x)\\ b_{\rm in}(x) &\rightarrow b_{\rm in}(x) + \frac{e_0\tilde{v}}{Z_\chi^{1/2}}\lambda(x)\\ \rho_{\rm in}(x) &\rightarrow \rho_{\rm in}(x), \quad U^\mu_{\rm in}(x) \rightarrow U^\mu_{\rm in}(x)\end{aligned} \qquad [41]$$

On the other hand, the global phase transformation $\phi_{\rm H}(x) \rightarrow e^{i\theta}\phi_{\rm H}(x)$ is induced by

$$\begin{aligned}&\chi_{\rm in}(x) \rightarrow \chi_{\rm in}(x) + \frac{\tilde{v}}{Z_\chi^{1/2}}\theta f(x), \quad b_{\rm in}(x) \rightarrow b_{\rm in}(x)\\ &\rho_{\rm in}(x) \rightarrow \rho_{\rm in}(x), \quad U^\mu_{\rm in}(x) \rightarrow U^\mu_{\rm in}(x)\end{aligned} \qquad [42]$$

with $\partial^2 f(x) = 0$ and the limit $f(x) \rightarrow 1$ to be performed at the end of computations. Note that under the above transformations, the in-field equations and the $S$-matrix are invariant and that $B_{\rm H}$ is changed by an irrelevant c-number (in the limit $f \rightarrow 1$).

Consider now the boson transformation $\chi_{\rm in}(x) \rightarrow \chi_{\rm in}(x) + \alpha(x)$: in local gauge theories the boson transformation must be compatible with the Heisenberg field equations but also with the physical state condition [39]. Under the boson transformation with $\alpha(x) = \tilde{v}Z_\chi^{-1/2}\theta f(x)$ and $\partial^2 f(x) = 0$, $B_{\rm H}$ changes as

$$B_{\rm H}(x) \rightarrow B_{\rm H}(x) - \frac{e_0\tilde{v}^2}{Z_\chi}f(x) \qquad [43]$$

eqn [38] is thus violated when the Gupta–Bleuler-like condition is imposed. In order to restore it, the shift in $B_{\rm H}$ must be compensated by means of the following transformation on $U^\mu_{\rm in}$:

$$U^\mu_{\rm in}(x) \rightarrow U^\mu_{\rm in}(x) + Z_3^{-1/2}a^\mu(x), \quad \partial_\mu a^\mu(x) = 0 \qquad [44]$$

with a convenient c-number function $a^\mu(x)$. The dynamical maps of the various Heisenberg operators are not affected by [44] since they contain $U^\mu_{\rm in}$ and $B_{\rm H}$ in a combination such that the changes of $B_{\rm H}$ and of $U^\mu_{\rm in}$ compensate each other provided

$$(\partial^2 + m_V^2)a_\mu(x) = \frac{m_V^2}{e_0}\partial_\mu f(x) \qquad [45]$$

Equation [45] thus obtained is the Maxwell equation for the massive potential vector $a_\mu$ (Matsumoto *et al.* 1975a, b). The classical ground state current $j^\mu$ turns out to be

$$j^\mu(x) \equiv \langle 0|j^\mu_{\rm H}(x)|0\rangle = m_V^2\left[a^\mu(x) - \frac{1}{e_0}\partial^\mu f(x)\right] \qquad [46]$$

The term $m_V^2 a^\mu(x)$ is the Meissner current, while $(m_V^2/e_0)\partial^\mu f(x)$ is the boson current. The key point here is that both the macroscopic field and current are given in terms of the boson condensation function $f(x)$.

Two remarks are in order: first, note that the terms proportional to $\partial^\mu f(x)$ are related to observable effects, for example, the boson current which acts as the source of the classical field. Second, note that the macroscopic ground state effects do not occur for regular $f(x)(G^+_{\mu\nu}(x) = 0)$. In fact, from [45] we obtain $a_\mu(x) = (1/e_0)\partial_\mu f(x)$ for regular $f(x)$ which implies zero classical current $(j_\mu = 0)$ and zero classical field $(F_{\mu\nu} = \partial_\mu a_\nu - \partial_\nu a_\mu)$, since the Meissner and the boson current cancel each other.

In conclusion, the vacuum current appears only when $f(x)$ has topological singularities and these can be created only by condensation of massless bosons, that is, when SSB occurs. This explains why topological defects appear in the process of phase transitions, where NG modes are present and gradients in their condensate densities are nonzero (Kibble 1976, Zurek 1997).

On the other hand, the appearance of spacetime order parameter is no guarantee that persistent ground state currents (and fields) will exist: if $f(x)$ is a regular function, the spacetime dependence of $\tilde{v}$ can be gauged away by an appropriate gauge transformation.

Since, as already mentioned, the boson transformation with regular $f(x)$ does not affect observable quantities, the $S$-matrix is actually given by

$$S = :S\left[\rho_{\rm in}, U^\mu_{\rm in} - \frac{1}{m_V}\partial(\chi_{\rm in} - b_{\rm in})\right]: \qquad [47]$$

This is indeed independent of the boson transformation with regular $f(x)$:

$$\begin{aligned}S \rightarrow S' = :S\bigg[\rho_{\rm in}, U^\mu_{\rm in} &- \frac{1}{m_V}\partial(\chi_{\rm in} - b_{\rm in})\\ &+ Z_3^{-1/2}(a^\mu - \frac{1}{e_0}\partial^\mu f)\bigg]:\end{aligned} \qquad [48]$$

since $a_\mu(x) = (1/e_0)\partial_\mu f(x)$ for regular $f(x)$. However, $S' \neq S$ for singular $f(x)$: $S'$ includes the interaction of the quanta $U^\mu_{\rm in}$ and $\phi_{\rm in}$ with the classically behaving macroscopic defects (Umezawa 1993, Umezawa *et al.* 1982).

### The Vortex Solution

Below we consider the example of the Nielsen–Olesen vortex string solution. We show which one is the boson function $f(x)$ controlling the nonhomogeneous NG boson condensation in terms of which the string solution is described. For brevity, we only report the results of the computations. The detailed derivation as well as the discussion of further examples can be found in (Umezawa 1993, Umezawa *et al.* 1982).

In the present U(1) problem, the electromagnetic tensor and the vacuum current are (Umezawa 1993, Umezawa *et al.* 1982, Matsumoto *et al.* 1975a, b)

$$F_{\mu\nu}(x) = \partial_\mu a_\nu(x) - \partial_\nu a_\mu(x) = 2\pi \frac{m_V^2}{e_0} \int d^4x' \Delta_c(x-x') G^+_{\mu\nu}(x') \quad [49]$$

$$j_\mu(x) = -2\pi \frac{m_V^2}{e_0} \int d^4x' \Delta_c(x-x') \partial^\nu_{x'} G^+_{\nu\mu}(x') \quad [50]$$

respectively, and satisfy $\partial^\mu F_{\mu\nu}(x) = -j_\nu(x)$. In these equations,

$$\Delta_c(x-x') = \frac{1}{(2\pi)^4} \int d^4p\, e^{-ip(x-x')} \frac{1}{p^2 - m_V^2 + i\epsilon} \quad [51]$$

The line singularity for the vortex (or string) solution can be parametrized by a single line parameter $\sigma$ and by the time parameter $\tau$. A static vortex solution is obtained by setting $y_0(\tau,\sigma)=\tau$ and $\boldsymbol{y}(\tau,\sigma)=\boldsymbol{y}(\sigma)$, with $y$ denoting the line coordinate. $G^+_{\mu\nu}(x)$ is nonzero only on the line at $y$ (we can consider more lines but let us limit to only one line, for simplicity). Thus, we have

$$\begin{aligned} G_{0i}(x) &= \int d\sigma \frac{dy_i(\sigma)}{d\sigma} \delta^3[\boldsymbol{x} - \boldsymbol{y}(\sigma)] \quad G_{ij}(x) = 0 \\ G^+_{ij}(x) &= -\epsilon_{ijk} G_{0k}(x), \quad G^+_{0i}(x) = 0 \end{aligned} \quad [52]$$

Equation [49] shows that these vortices are purely magnetic. We obtain

$$\begin{aligned} \partial_0 f(x) &= 0 \\ \partial_i f(x) &= \frac{1}{(2\pi)^2} \int d\sigma \epsilon_{ijk} \frac{dy_k(\sigma)}{d\sigma} \partial^x_j \\ &\quad \times \int d^3p \frac{e^{i\boldsymbol{p}\cdot(\boldsymbol{x}-\boldsymbol{y}(\sigma))}}{\boldsymbol{p}^2} \end{aligned} \quad [53]$$

that is, by using the identity $(2\pi)^{-2}\int d^3p(e^{i\boldsymbol{p}\cdot\boldsymbol{x}}/\boldsymbol{p}^2) = 1/2|\boldsymbol{x}|$,

$$\nabla f(x) = -\frac{1}{2} \int d\sigma \frac{d\boldsymbol{y}_k(\sigma)}{d\sigma} \wedge \nabla_x \frac{1}{|\boldsymbol{x} - \boldsymbol{y}(\sigma)|} \quad [54]$$

Note that $\nabla^2 f(x) = 0$ is satisfied.

A straight infinitely long vortex is specified by $y_i(\sigma) = \sigma\delta_{i3}$ with $-\infty < \sigma < \infty$. The only nonvanishing component of $G^{\mu\nu}(x)$ are $G^{03}(x) = G^+_{12}(x) = \delta(x_1)\delta(x_2)$. Equation [54] gives (Umezawa 1993, Umezawa *et al.* 1982, Matsumoto 1975a, b)

$$\begin{aligned} \frac{\partial}{\partial x_1} f(x) &= \frac{1}{2} \int d\sigma \frac{\partial}{\partial x_2} [x_1^2 + x_2^2 + (x_3 - \sigma)^2]^{-1/2} \\ &= -\frac{x_2}{x_1^2 + x_2^2} \\ \frac{\partial}{\partial x_2} f(x) &= \frac{x_1}{x_1^2 + x_2^2}, \quad \frac{\partial}{\partial x_3} f(x) = 0 \end{aligned} \quad [55]$$

and then

$$f(x) = \tan^{-1}\left(\frac{x_2}{x_1}\right) = \theta(x) \quad [56]$$

We have thus determined the boson transformation function corresponding to a particular vortex solution. The vector potential is

$$\begin{aligned} a_1(x) &= -\frac{m_V^2}{2e_0} \int d^4x' \Delta_c(x-x') \frac{x_2'}{x_1'^2 + x_2'^2} \\ a_2(x) &= \frac{m_V^2}{2e_0} \int d^4x' \Delta_c(x-x') \frac{x_1'}{x_1'^2 + x_2'^2} \\ a_3(x) &= a_0(x) = 0 \end{aligned} \quad [57]$$

and the only nonvanishing component of $F_{\mu\nu}$:

$$\begin{aligned} F_{12}(x) &= -2\pi \frac{m_V^2}{e_0} \int d^4x' \Delta_c(x-x') \delta(x_1')\delta(x_2') \\ &= \frac{m_V^2}{e_0} K_0\left(m_V \sqrt{x_1^2 + x_2^2}\right) \end{aligned} \quad [58]$$

Finally, the vacuum current eqn [50] is given by

$$\begin{aligned} j_1(x) &= -\frac{m_V^3}{e_0} \frac{x_2}{\sqrt{x_1^2 + x_2^2}} K_1\left(m_V \sqrt{x_1^2 + x_2^2}\right) \\ j_2(x) &= \frac{m_V^3}{e_0} \frac{x_1}{\sqrt{x_1^2 + x_2^2}} K_1\left(m_V \sqrt{x_1^2 + x_2^2}\right) \\ j_3(x) &= j_0(x) = 0 \end{aligned} \quad [59]$$

We observe that these results are the same of the Nielsen–Olesen vortex solution. Notice that we did not specify the potential in our model but only the invariance properties. Thus, the invariance properties of the dynamics determine the characteristics of the topological solutions. The vortex solution

manifests the original U(1) symmetry through the cylindrical angle $\theta$ which is the parameter of the U(1) representation in the coordinate space.

## Conclusions

We have discussed how topological defects arise as inhomogeneous condensates in QFT. Topological defects are shown to have a genuine quantum nature. The approach reviewed here goes under the name of "boson transformation method" and relies on the existence of unitarily inequivalent representations of the field algebra in QFT.

Describing quantum fields with topological defects amounts then to properly choose the physical Fock space for representing the Heisenberg field operators. Once the boundary conditions corresponding to a particular soliton sector are found, the Heisenberg field operators embodied with such conditions contain the full information about the defects, the quanta and their mutual interaction. One can thus calculate Green's functions for particles in the presence of defects. The extension to finite temperature is discussed in Blasone and Jizba (2002) and Manka and Vitiello (1990).

As an example we have discussed a model with U(1) gauge invariance and SSB and we have obtained the Nielsen–Olesen vortex solution in terms of localized condensation of Goldstone bosons. These thus appear to play a physical role, although, in the presence of gauge fields, they do not show up in the physical spectrum as excitation quanta. The function $f(x)$ controlling the condensation of the NG bosons must be singular in order to produce observable effects. Boson transformations with regular $f(x)$ only amount to gauge transformations. For the treatment of topological defects in nonabelian gauge theories, see Manka and Vitiello (1990).

Finally, when there are no NG modes, as in the case of the kink solution or the sine-Gordon solution, the boson transformation function has to carry divergence singularity at spatial infinity (Umezawa 1993, Umezawa *et al.* 1982, Blasone and Jizba 2002). The boson transformation has also been discussed in connection with the Bäklund transformation at a classical level and the confinement of the constituent quanta in the coherent condensation domain.

For further reading on quantum fields with topological defects, see Blasone *et al.* (2006).

## Introduction

In general relativity, the gravitational field is encoded in the Riemannian geometry of spacetime. Much of the conceptual compactness and mathematical elegance of the theory can be traced back to this central idea. The encoding is also directly responsible for the most dramatic ramifications of the theory: the big bang, black holes, and gravitational waves. However, it also leads one to the conclusion that spacetime itself must end and physics must come to a halt at the big bang and inside black holes, where the gravitational field becomes singular. But this reasoning ignores quantum physics entirely. When the curvature becomes large, of the order of $1/\ell_{\mathrm{Pl}}^2 = c^3/G\hbar$, quantum effects dominate and predictions of general relativity can no longer be trusted. In this "Planck regime," one must use an appropriate synthesis of general relativity and quantum physics, that is, a quantum gravity theory. The predictions of this theory are likely to be quite different from those of general relativity. In the real, quantum world, evolution may be completely nonsingular. Physics may not come to a halt and quantum theory could extend classical spacetime.

There are a number of different approaches to quantum gravity. One natural avenue is to retain the interplay between gravity and geometry but now use "quantum" Riemannian geometry in place of the standard, classical one. This is the key idea underlying loop quantum gravity. There are several calculations which indicate that the well-known failure of the standard perturbative approach to quantum gravity may be primarily due to its basic assumption that spacetime can be modeled as a smooth continuum at all scales. In loop quantum gravity, one adopts a nonperturbative approach. There is no smooth metric in the background. Geometry is not only dynamical but quantum mechanical from "birth." Its fundamental excitations turn out to be one dimensional and polymer-like. The smooth continuum is only a coarse-grained approximation. While a fully satisfactory quantum gravity theory still awaits us (in any approach), detailed investigations have been carried out to completion in simplified models – called mini- and midi-superspaces. They show that quantum spacetime does not end at singularities. Rather, quantum geometry serves as a "bridge" to another large classical spacetime.

This article will focus on structural issues from the perspective of mathematical physics. For complementary perspectives and further details, *see* Loop Quantum Gravity, Canonical General Relativity, Quantum Cosmology, Black Hole Mechanics, and Spin Foams in this Encyclopedia.

## Basic Framework

The starting point is a Hamiltonian formulation of general relativity based on spin connections (Ashtekar 1987). Here, the phase space $\mathbf{\Gamma}$ consists of canonically conjugate pairs $(A, \mathbb{P})$, where $A$ is a connection on a 3-manifold $M$ and $\mathbb{P}$ a 2-form, both of which take values in the Lie algebra su(2). Since $\mathbf{\Gamma}$ can also be thought of as the phase space of the SU(2) Yang–Mills theory, in this approach there is a unified kinematic framework for general relativity that describes gravity and the gauge theories which describe the other three basic forces of nature. The connection $A$ enables one to parallel transport chiral spinors (such as the left-handed fermions of the standard electroweak model) along curves in $M$. Its curvature is directly related to the electric and magnetic parts of the spacetime "Riemann tensor." The dual $P$ of $\mathbb{P}$ plays a double role (the dual is defined via $\int_M \mathbb{P} \wedge \omega = \int_M P \lrcorner \omega$ for any 1-form $\omega$ on $M$). Being the momentum canonically conjugate to $A$, it is analogous to the Yang–Mills electric field. But (apart from a constant), it is also an orthonormal triad (with density weight 1) on $M$ and therefore determines the positive-definite ("spatial") 3-metric, and hence the Riemannian geometry of $M$. This dual role of $P$ is a reflection of the fact that now SU(2) is the (double cover of the) group of rotations of the orthonormal spatial triads on $M$ itself rather than of rotations in an "internal" space associated with $M$.

To pass to quantum theory, one first constructs an algebra of "elementary" functions on $\mathbf{\Gamma}$ (analogous to the phase-space functions $x$ and $p$ in the case of a particle) which are to have unambiguous operator analogs. The holonomies

$$h_e(A) := \mathcal{P} \exp - \int_e A \qquad [1]$$

associated with a curve/edge $e$ on $M$ are (SU(2)-valued) configuration functions on $\mathbf{\Gamma}$. Similarly,

given a 2-surface $S$ on $M$, and an su(2)-valued (test) function $f$ on $M$,

$$P_{S,f} := \int_S \mathrm{tr}(f\,\mathbb{P}) \qquad [2]$$

is a momentum function on $\Gamma$, where tr is over the su(2) indices. (For simplicity of presentation, all fields are assumed to be smooth and curves/edges $e$ and surfaces $S$, finite and piecewise analytic in a specific sense. The extension to smooth curves and surfaces was carried out by Bacz and Sawin, Lewandowski and Thiemann, and Fleischhack. It is technically more involved but the final results are qualitatively the same.) The symplectic structure on $\Gamma$ enables one to calculate the Poisson brackets $\{h_e, P_{S,f}\}$. The result is a linear combination of holonomies and can be written as a Lie derivative,

$$\{h_e, P_{S,f}\} = \mathcal{L}_{X_{S,f}} h_e \qquad [3]$$

where $X_{S,f}$ is a derivation on the ring generated by holonomy functions, and can therefore be regarded as a vector field on the configuration space $\mathcal{A}$ of connections. This is a familiar situation in classical mechanics of systems whose configuration space is a finite-dimensional manifold. Functions $h_e$ and vector fields $X_{S,f}$ generate a Lie algebra. As in quantum mechanics on manifolds, the first step is to promote this algebra to a quantum algebra by demanding that the commutator be given by $\mathrm{i}\hbar$ times the Lie bracket. The result is a $\star$-algebra $\mathfrak{a}$, analogous to the algebra generated by operators $\exp \mathrm{i}\lambda\hat{x}$ and $\hat{p}$ in quantum mechanics. By exponentiating the momentum operators $\hat{P}_{S,f}$ one obtains $\mathfrak{W}$, the analog of the quantum-mechanical Weyl algebra generated by $\exp \mathrm{i}\lambda\hat{x}$ and $\exp \mathrm{i}\mu\hat{p}$.

The main task is to obtain the appropriate representation of these algebras. In that representation, quantum Riemannian geometry can be probed through the momentum operators $\hat{P}_{S,f}$, which stem from classical orthonormal triads. As in quantum mechanics on manifolds or simple field theories in flat space, it is convenient to divide the task into two parts. In the first, one focuses on the algebra $\mathfrak{C}$ generated by the configuration operators $\hat{h}_c$ and finds all its representations, and in the second one considers the momentum operators $\hat{P}_{S,f}$ to restrict the freedom.

$\mathfrak{C}$ is called the holonomy algebra. It is naturally endowed with the structure of an abelian $C^\star$ algebra (with identity), whence one can apply the powerful machinery made available by the Gel'fand theory. This theory tells us that $\mathfrak{C}$ determines a unique compact, Hausdorff space $\bar{\mathcal{A}}$ such that the $C^\star$ algebra of all continuous functions on $\bar{\mathcal{A}}$ is naturally isomorphic to $\mathfrak{C}$. $\bar{\mathcal{A}}$ is called the Gel'fand spectrum of $\mathfrak{C}$. It has been shown to consist of "generalized connections" $\bar{A}$ defined as follows: $\bar{A}$ assigns to any oriented edge $e$ in $M$ an element $\bar{A}(e)$ of SU(2) (a "holonomy") such that $\bar{A}(e^{-1}) = [\bar{A}(e)]^{-1}$; and, if the endpoint of $e_1$ is the starting point of $e_2$, then $\bar{A}(e_1 \circ e_2) = \bar{A}(e_1)\cdot \bar{A}(e_2)$. Clearly, every smooth connection $A$ is a generalized connection. In fact, the space $\mathcal{A}$ of smooth connections has been shown to be dense in $\bar{\mathcal{A}}$ (with respect to the natural Gel'fand topology thereon). But $\bar{\mathcal{A}}$ has many more "distributional elements." The Gel'fand theory guarantees that every representation of the $C^\star$ algebra $\mathfrak{C}$ is a direct sum of representations of the following type: the underlying Hilbert space is $\mathcal{H} = L^2(\bar{\mathcal{A}}, \mathrm{d}\mu)$ for some measure $\mu$ on $\bar{\mathcal{A}}$ and (regarded as functions on $\bar{\mathcal{A}}$) elements of $\mathfrak{C}$ act by multiplication. Since there are many inequivalent measures on $\bar{\mathcal{A}}$, there is a multitude of representations of $\mathfrak{C}$. A key question is how many of them can be extended to representations of the full algebra $\mathfrak{a}$ (or $\mathfrak{W}$) without having to introduce any "background fields" which would compromise diffeomorphism covariance. Quite surprisingly, the requirement that the representation be cyclic with respect to a state which is invariant under the action of the (appropriately defined) group Diff $M$ of piecewise-analytic diffeomorphisms on $M$ singles out a unique irreducible representation. This result was established for $\mathfrak{a}$ by Lewandowski, Okołów, Sahlmann and Thiemann, and for $\mathfrak{W}$ by Fleischhack. It is the quantum geometry analog to the seminal results by Segal and others that characterized the Fock vacuum in Minkowskian field theories. However, while that result assumes not only Poincaré invariance but also specific (namely free) dynamics, it is striking that the present uniqueness theorems make no such restriction on dynamics. The requirement of diffeomorphism invariance is surprisingly strong and makes the "background-independent" quantum geometry framework surprisingly tight.

This representation had been constructed by Ashtekar, Baez, and Lewandowski some ten years before its uniqueness was established. The underlying Hilbert space is given by $\mathcal{H} = L^2(\bar{\mathcal{A}}, \mathrm{d}\mu_o)$ where $\mu_o$ is a diffeomorphism-invariant, faithful, regular Borel measure on $\bar{\mathcal{A}}$, constructed from the normalized Haar measure on SU(2). Typical quantum states can be visualized as follows. Fix: (1) a graph $\alpha$ on $M$ (by a graph on $M$ we mean a set of a finite number of embedded, oriented intervals called edges; if two edges intersect, they do so only at one or both ends, called vertices), and (2) a smooth function $\psi$ on $[\mathrm{SU}(2)]^n$. Then, the function

$$\Psi_\gamma(\bar{A}) := \psi(\bar{A}(e_1), \ldots, \bar{A}(e_n)) \qquad [4]$$

on $\bar{\mathcal{A}}$ is an element of $\mathcal{H}$. Such states are said to be "cylindrical" with respect to the graph $\alpha$ and their space is denoted by $\mathrm{Cyl}_\alpha$. These are "typical states" in the sense that $\mathrm{Cyl} := \cup_\alpha \mathrm{Cyl}_\alpha$ is dense in $\mathcal{H}$. Finally, as ensured by the Gel'fand theory, the holonomy (or configuration) operators $\hat{h}_e$ act just by multiplication. The momentum operators $\hat{P}_{S,f}$ act as Lie derivatives: $\hat{P}_{S,f}\Psi = -\mathrm{i}\hbar\mathcal{L}_{X_{S,f}}\Psi$.

**Remark** Given any graph $\alpha$ in $M$, and a labeling of each of its edges by a nontrivial irreducible representation of SU(2) (i.e., by a nonzero half integer $j$), one can construct a finite-dimensional Hilbert space $\mathcal{H}_{\alpha,j}$, which can be thought of as the state space of a spin system "living on" the graph $\alpha$. The full Hilbert space admits a simple decomposition: $\mathcal{H} = \oplus_{\alpha,j}\mathcal{H}_{\alpha,j}$. This is called the spin-network decomposition. The geometric operators discussed in the next section leave each $\mathcal{H}_{\alpha,j}$ invariant. Therefore, the availability of this decomposition greatly simplifies the task of analyzing their properties.

## Geometric Operators

In the classical theory, $E := 8\pi G\gamma P$ has the interpretation of an orthonormal triad field (or a "moving frame") on $M$ (with density weight 1). Here, $\gamma$ is a dimensionless, strictly positive number, called the Barbero–Immirzi parameter, which arises as follows. Because of emphasis on connections, in the classical theory the first-order Palatini action is a more natural starting point than the second-order Einstein–Hilbert action. Now, there is a freedom to add a term to the Palatini action which vanishes when Bianchi identities are satisfied and therefore does not change the equations of motion. $\gamma$ arises as the coefficient of this term. In some respects $\gamma$ is analogous to the $\theta$ parameter of Yang–Mills theory. Indeed, while theories corresponding to any permissible values of $\gamma$ are related by a canonical transformation classically, quantum mechanically this transformation is not unitarily implementable. Therefore, although there is a unique representation of the algebra $\mathfrak{a}$ (or $\mathfrak{W}$), there is a one-parameter family of inequivalent representations of the algebra of geometric operators generated by suitable functions of orthonormal triads $E$, each labeled by the value of $\gamma$. This is a genuine quantization ambiguity. As with the $\theta$ ambiguity in QCD, the actual value of $\gamma$ in nature has to be determined experimentally. The current strategy in quantum geometry is to fix its value through a thought experiment involving black hole thermodynamics (see below).

The basic object in quantum Riemannian geometry is the triad flux operator $\hat{E}_{S,f} := 8\pi G\gamma\hat{P}_{S,f}$. It is self-adjoint and all its eigenvalues are discrete. To define other geometric operators such as the area operator $\hat{A}_S$ associated with a surface $S$ or a volume operator $\hat{V}_R$ associated with a region $R$, one first expresses the corresponding phase-space functions in terms of the "elementary" functions $E_{S_i,f_i}$ using suitable surfaces $S_i$ and test functions $f_i$ and then promotes $E_{S_i,f_i}$ to operators. Even though the classical expressions are typically nonpolynomial functions of $E_{S_i,f_i}$, the final operators are all well defined, self-adjoint and with purely discrete eigenvalues. Therefore, in the sense of the word used in elementary quantum mechanics (e.g., of the hydrogen atom), one says that geometry is quantized. Because the theory has no background metric or indeed any other background field, all geometric operators transform covariantly under the action of the Diff $M$. This diffeomorphism covariance makes the final expressions of operators rather simple. In the case of the area operator, for example, the action of $\hat{A}_S$ on a state $\Psi_\alpha$ [4] depends entirely on the points of intersection of the surface $S$ and the graph $\alpha$ and involves only right- and left-invariant vector fields on copies of SU(2) associated with edges of $\alpha$ which intersect $S$. In the case of the volume operator $\hat{V}_R$, the action depends on the vertices of $\alpha$ contained in $R$ and, at each vertex, involves the right- and left-invariant vector fields on copies of SU(2) associated with edges that meet at each vertex.

To display the explicit expressions of these operators, let us first define on $\mathrm{Cyl}_\alpha$ three basic operators $\hat{J}_j^{(v,e)}$, with $j \in \{1,2,3\}$, associated with the pair consisting of an edge $e$ of $\alpha$ and a vertex $v$ of $e$:

$$\hat{J}_j^{(v,e)}\Psi_\alpha(\bar{A}) = \begin{cases} \mathrm{i}\dfrac{\mathrm{d}}{\mathrm{d}t}|_{t=0}\psi_\alpha(\ldots, U_e(\bar{A})\exp(t\tau_j),\ldots) \\ \quad \text{if } e \text{ begins at } v \\ \mathrm{i}\dfrac{\mathrm{d}}{\mathrm{d}t}|_{t=0}\psi_\alpha(\ldots,\exp(-t\tau_j)U_e(\bar{A}),\ldots) \\ \quad \text{if } e \text{ ends at } v \end{cases} \qquad [5]$$

where $\tau_j$ denotes a basis in su(2) and "..." stands for the rest of the arguments of $\Psi_\alpha$ which remain unaffected. The quantum area operator $A_s$ is assigned to a finite two-dimensional submanifold $S$ in $M$. Given a cylindrical state we can always represent it in the form [4] using a graph $\alpha$ adapted to $S$, such that every edge $e$ either intersects $S$ at exactly one endpoint, or is contained in the closure $\bar{S}$, or does not intersect $\bar{S}$. For each vertex $v$ in $S$ of the graph $\alpha$, the family of edges intersecting $v$ can be divided into three classes: edges $\{e_1,\ldots,e_u\}$ lying on one side (say "above") $S$, edges $\{e_{u+1},\ldots,e_{u+d}\}$ lying

on the other side (say "below"), and edges contained in $S$. To each $v$ we assign a generalized Laplace operator

$$\Delta_{S,v} = -\eta^{ij}\left(\sum_{I=1}^{u}\hat{J}_i^{(v,e_I)} - \sum_{I=u+1}^{u+d}\hat{J}_i^{(v,e_I)}\right) \times \left(\sum_{K=1}^{u}\hat{J}_j^{(v,e_K)} - \sum_{K=u+1}^{u+d}\hat{J}_j^{(v,e_K)}\right) \quad [6]$$

where $\eta_{ij}$ stands for –1/2 the Killing form on su(2). Now, the action of the quantum area operator $\hat{A}_S$ on $\Psi_\alpha$ is defined as follows:

$$\hat{A}_S\Psi_\alpha = 4\pi\gamma\ell_{\mathrm{Pl}}^2\sum_{v\in S}\sqrt{-\Delta_{S,v}}\Psi_\alpha \quad [7]$$

The quantum area operator has played the most important role in applications. Its complete spectrum is known in a closed form. Consider arbitrary sets $j_I^{(u)}, j_I^{(d)}$, and $j_I^{(u+d)}$ of half-integers, subject to the condition

$$j_I^{(u+d)} \in \{|j_I^{(u)} - j_I^{(d)}|, |j_I^{(u)} - j_I^{(d)}| + 1, \ldots, j_I^{(u)} + j_I^{(d)}\} \quad [8]$$

where $I$ runs over any finite number of integers. The general eigenvalues of the area operator are given by:

$$a_S = 4\pi\gamma\ell_{\mathrm{Pl}}^2\sum_I\Big(2j_I^{(u)}(j_I^{(u)}+1) + 2j_I^{(d)}(j_I^{(d)}+1) - j_I^{(u+d)}(j_I^{(u+d)}+1)\Big)^{1/2} \quad [9]$$

On the physically interesting sector of SU(2)-gauge-invariant subspace $\mathcal{H}_{\mathrm{inv}}$ of $\mathcal{H}$, the lowest eigenvalue of $\hat{A}_S$ – "the area gap" – depends on some global properties of $S$. Specifically, it "knows" whether the surface is open, or a 2-sphere, or, if $M$ is a 3-torus, a (nontrivial) 2-torus in $M$. Finally, on $\mathcal{H}_{\mathrm{inv}}$, one is often interested only in the subspace of states $\Psi_\alpha$, where $\alpha$ has no edges which lie within a given surface $S$. Then, the expression of eigenvalues simplifies considerably:

$$a_S = 8\pi\gamma\ell_{\mathrm{Pl}}^2\sum_I\sqrt{j_I(j_I+1)} \quad [10]$$

To display the action of the quantum volume operator $\hat{V}_R$, for each vertex $v$ of a given graph $\alpha$, let us first define an operator $\hat{q}_v$ on $\mathrm{Cyl}_\alpha$.

$$\hat{q}_v = (8\pi\gamma\ell_{\mathrm{Pl}}^2)^3\frac{1}{48} \times \sum_{e,e',e''}\epsilon(e,e',e'')c^{ijk}\hat{J}_i^{(v,e)}\hat{J}_j^{(v,e')}\hat{J}_k^{(v,e'')} \quad [11]$$

where $e$, $e'$, and $e''$ run over the set of edges intersecting $v$, $\epsilon(e,e',e'')$ takes values $\pm1$ or 0 depending on the orientation of the half-lines tangent to the edges at $v$, $[\tau_i,\tau_j] = c^k{}_{ij}\tau_k$ and the indices are raised by the tensor $\eta_{ij}$. The action of the quantum volume operator on a cylindrical state [4] is then given by

$$\hat{V}_R\Psi_\alpha = \kappa_o\sum_{v\in R}\sqrt{|\hat{q}_v|}.\Psi_\alpha \quad [12]$$

Here, $\kappa_o$ is an overall, independent of a graph, constant resulting from an averaging.

The volume operator plays an unexpectedly important role in the definition of both the gravitational and matter contributions to the scalar constraint operator which dictates dynamics. Finally, a notable property of the volume operator is the following. Let $R(p,\epsilon)$ be a family of neighborhoods of a point $p \in M$. Then, as indicated above, $\hat{V}_{R(p,\epsilon)}\Psi_\alpha = 0$ if $\alpha$ has no vertex in the neighborhood. However, if $\alpha$ has a vertex at $p$

$$\lim_{\epsilon\to0}\hat{V}_{R(x,\epsilon)}\Psi_\alpha$$

exists but is not necessarily zero. This is a reflection of the "distributional" nature of quantum geometry.

**Remark** States $\Psi_\alpha \in \mathrm{Cyl}$ have support only on the graph $\alpha$. In particular, they are simply annihilated by geometric operators such as $\hat{A}_S$ and $\hat{V}_R$ if the support of the surface $S$ and the region $R$ does not intersect the support of $\alpha$. In this sense the fundamental excitations of geometry are one dimensional and geometry is polymer-like. States $\Psi_\alpha$, where $\alpha$ is just a "small graph," are highly quantum mechanical – like states in QED representing just a few photons. Just as coherent states in QED require an infinite superposition of such highly quantum states, to obtain a semiclassical state approximating a given classical geometry, one has to superpose a very large number of such elementary states. More precisely, in the Gel'fand triplet $\mathrm{Cyl} \subset \mathcal{H} \subset \mathrm{Cyl}^\star$, semiclassical states belong to the dual $\mathrm{Cyl}^\star$ of Cyl.

## Applications

Since quantum Riemannian geometry underlies loop quantum gravity and spin-foam models, all results obtained in these frameworks can be regarded as its applications. Among these, there are two which have led to resolutions of long-standing issues. The first concerns black hole entropy, and the second, quantum nature of the big bang.

### Black Holes

Seminal advances in fundamentals of black hole physics in the mid-1970s suggested that the entropy of large black holes is given by $S_{\mathrm{BH}} = (a_{\mathrm{hor}}/4\ell_{\mathrm{Pl}}^2)$,

where $a_{\rm hor}$ is the horizon area. This immediately raised a challenge to potential quantum gravity theories: give a statistical mechanical derivation of this relation. For familiar thermodynamic systems, a statistical mechanical derivation begins with an identification the microscopic degrees of freedom. For a classical gas, these are carried by molecules; for the black body radiation, by photons; and for a ferromagnet, by Heisenberg spins. What about black holes? The microscopic building blocks cannot be gravitons because the discussion involves stationary black holes. Furthermore, the number of microscopic states is absolutely huge: some $\exp 10^{77}$ for a solar mass black hole, a number that completely dwarfs the number of states of systems one normally encounters in statistical mechanics. Where does this huge number come from? In loop quantum gravity, this is the number of states of the "quantum horizon geometry."

The idea behind the calculation can be heuristically explained using the "It from Bit" argument, put forward by Wheeler in the 1990s. Divide the black hole horizon into elementary cells, each with one Planck unit of area, $\ell_{\rm Pl}^2$, and assign to each cell two microstates. Then the total number of states $\mathcal{N}$ is given by $\mathcal{N} = 2^n$, where $n = (a_{\rm hor}/\ell_{\rm Pl}^2)$ is the number of elementary cells, whence entropy is given by $S = \ln \mathcal{N} \sim a_{\rm hor}$. Thus, apart from a numerical coefficient, the entropy (It) is accounted for by assigning two states (Bit) to each elementary cell. This qualitative picture is simple and attractive. However, the detailed derivation in quantum geometry has several new features.

First, Wheeler's argument would apply to any 2-surface, while in quantum geometry the surface must represent a horizon in equilibrium. This requirement is encoded in a certain boundary condition that the canonically conjugate pair $(A, \mathbb{P})$ must satisfy at the surface and plays a crucial role in the quantum theory. Second, the area of each elementary cell is not a fixed multiple of $\ell_{\rm Pl}^2$ but is given by [10], where $I$ labels the elementary cells and $j_I$ can be any half-integer (such that the sum is within a small neighborhood of the classical area of the black hole under consideration). Finally, the number of quantum states associated with an elementary cell labeled by $j_I$ is not 2 but $(2j_I + 1)$.

The detailed theory of the quantum horizon geometry and the standard statistical mechanical reasoning is then used to calculate the entropy and the temperature. For large black holes, the leading contribution to entropy is proportional to the horizon area, in agreement with quantum field theory in curved spacetimes. (The subleading term $-(1/2)\ln(a_{\rm hor}/\ell_{\rm Pl}^2)$ is a quantum gravity correction to Hawking's semiclassical result. This correction, with the –1/2 factor, is robust in the sense that it also arises in other approaches.) However, as one would expect, the proportionality factor depends on the Barbero–Immirzi parameter $\gamma$ and so far loop quantum gravity does not have an independent way to determine its value. The current strategy is to determine $\gamma$ by requiring that, for the Schwarzschild black hole, the leading term agrees exactly with Hawking's semiclassical answer. This requirement implies that $\gamma$ is the root of algebraic equation and its value is given by $\gamma \approx 0.2735$. Now, quantum geometry theory is completely fixed. One can calculate entropy of other black holes, with angular momentum and distortion. A nontrivial check on the strategy is that for all these cases, the coefficient in the leading-order term again agrees with Hawking's semiclassical result.

The detailed analysis involves a number of structures of interest to mathematical physics. First, the intrinsic horizon geometry is described by a U(1) Chern–Simons theory on a punctured 2-sphere (the horizon), the level $k$ of the theory being given by $k = a_{\rm hor}/4\pi\gamma\ell_{\rm Pl}^2$. The punctures are simply the intersections of the excitations of the polymer geometry in the bulk with the horizon 2-surface. Second, because of the horizon boundary conditions, in the classical theory the gauge group SU(2) is reduced to U(1) at the horizon. At each puncture, it is further reduced to the discrete subgroup $\mathbb{Z}_k$ of U(1), sometimes referred to as a "quantum U(1) group." Third, the "surface phase space" associated with the horizon is represented by a noncommutative torus. Finally, the surface Chern–Simons theory is entirely unrelated to the bulk quantum geometry theory but the quantum horizon boundary condition requires that the spectrum of a certain operator in the Chern–Simons theory must be identical to that of another operator in the bulk theory. The surprising fact is that there is an exact agreement. Without this seamless matching, a coherent description of the quantum horizon geometry would not have been possible.

The main weakness of this approach to black hole entropy stems from the Barbero–Immirzi ambiguity. The argument would be much more compelling if the value of $\gamma$ were determined by independent considerations, without reference to black hole entropy. (By contrast, for extremal black holes, string theory provides the correct coefficient without any adjustable parameter. The AdS/CFT duality hypothesis (as well as other semiquantitative) arguments have been used to encompass certain black holes which are away from extremality. But in these cases, it is not known if the numerical coefficient is

1/4 as in Hawking's analysis.) It's primary strengths are twofold. First, the calculation encompasses all realistic black holes – not just extremal or near-extremal – including the astrophysical ones, which may be highly distorted. Hairy black holes of mathematical physics and cosmological horizons are also encompassed. Second, in contrast to other approaches, one works directly with the physical, curved geometry around black holes rather than with a flat-space system which has the same number of states as the black hole of interest.

### The Big Bang

Most of the work in physical cosmology is carried out using spatially homogeneous and isotropic models and perturbations thereon. Therefore, to explore the quantum nature of the big bang, it is natural to begin by assuming these symmetries. Then the spacetime metric is determined simply by the scale factor $a(t)$ and matter fields $\phi(t)$ which depend only on time. Thus, because of symmetries, one is left with only a finite number of degrees of freedom. Therefore, field-theoretic difficulties are bypassed and passage to quantum theory is simplified. This strategy was introduced already in the late 1960s and early 1970s by DeWitt and Misner. Quantum Einstein's equations now reduce to a single differential equation of the type

$$\frac{\partial^2}{\partial a^2}(f(a)\Psi(a,\phi)) = \text{const.}\, \hat{H}_\phi\, \Psi(a,\phi) \qquad [13]$$

on the wave function $\Psi(a,\phi)$, where $\hat{H}_\phi$ is the matter Hamiltonian and $f(a)$ reflects the freedom in factor ordering. Since the scale factor $a$ vanishes at the big bang, one has to analyze the equation and its solutions near $a = 0$. Unfortunately, because of the standard form of the matter Hamiltonian, coefficients in the equation diverge at $a = 0$ and the evolution cannot be continued across the singularity unless one introduces unphysical matter or a new principle. A well-known example of new input is the Hartle–Hawking boundary condition which posits that the universe starts out without any boundary and a metric with positive-definite signature and later makes a transition to a Lorentzian metric.

Bojowald and others have shown that the situation is quite different in loop quantum cosmology because quantum geometry effects make a qualitative difference near the big bang. As in older quantum cosmologies, one carries out a symmetry reduction at the classical level. The final result differs from older theories only in minor ways. In the homogeneous, isotropic case, the freedom in the choice of the connection is encoded in a single function $c(t)$ and, in that of the momentum/triad, in another function $p(t)$. The scale factor is given by $a^2 = |p|$. (The variable $p$ itself can assume both signs; positive if the triad is left handed and negative if it is right handed. $p$ vanishes at degenerate triads which are permissible in this approach.) The system again has only a finite number of degrees of freedom. However, quantum theory turns out to be inequivalent to that used in older quantum cosmologies.

This surprising result comes about as follows. Recall that in quantum geometry, one has well-defined holonomy operators $\hat{h}$ but there is no operator corresponding to the connection itself. In quantum mechanics, the analog would be for operators $\hat{U}(\lambda)$ corresponding to the classical functions $\exp i\lambda x$ to exist but not be weakly continuous in $\lambda$; the operator $\hat{x}$ would then not exist. Once the requirement of weak continuity is dropped, von Neumann's uniqueness theorem no longer holds and the Weyl algebra can have inequivalent irreducible representations. The one used in loop quantum cosmology is the direct analog of full quantum geometry. While the space $\mathcal{A}$ of smooth connections reduces just to the real line $\mathbb{R}$, the space $\bar{\mathcal{A}}$ of generalized connections reduces to the Bohr compactification $\bar{\mathbb{R}}_{\text{Bohr}}$ of the real line. (This space was introduced by the mathematician Harold Bohr (Nils' brother) in his theory of almost-periodic functions. It arises in the present application because holonomies turn out to be almost periodic functions of $c$.) The Hilbert space of states is thus $\mathcal{H} = L^2(\bar{\mathbb{R}}_{\text{Bohr}}, \mathrm{d}\mu_o)$ where $\mu_o$ is the Haar measure on (the abelian group) $\bar{\mathbb{R}}_{\text{Bohr}}$. As in full quantum geometry, the holonomies act by multiplication and the triad/momentum operator $\hat{p}$ via Lie derivatives.

To facilitate comparison with older quantum cosmologies, it is convenient to use a representation in which $\hat{p}$ is diagonal. Then, quantum states are functions $\Psi(p,\phi)$. But the Wheeler–DeWitt equation is now replaced by a difference equation:

$$C^+(p)\,\Psi(p+4p_o,\phi) + C^o(p)\,\Psi(p,\phi) + C^-(p)\,\Psi(p-4p_o)(\phi) = \text{const.}\, \hat{H}_\phi\Psi(p,\phi) \qquad [14]$$

where $p_o$ is determined by the lowest eigenvalue of the area operator ("area gap") and the coefficients $C^\pm(p)$ and $C^o(p)$ are functions of $p$. In a backward "evolution," given $\Psi$ at $p+4$ and $p$, such a "recursion relation" determines $\Psi$ at $p-4$, provided $C^-$ does not vanish at $p-4$. The coefficients are well behaved and nowhere vanishing, whence the evolution does not stop at any finite $p$, either in the past or in the future. Thus, near $p = 0$ this equation is drastically different from the Wheeler–DeWitt equation [13]. However, for large $p$ – that is, when the universe is large – it is well

approximated by [13] and smooth solutions of [13] are approximate solutions of the fundamental discrete equation [14] in a precise sense.

To complete quantization, one has to introduce a suitable Hilbert space structure on the space of solutions to [14], identify physically interesting operators and analyze their properties. For simple matter fields, this program has been completed. With this machinery at hand, one begins with semiclassical states which are peaked at configurations approximating the classical universe at late times (e.g., now) and evolves backwards. Numerical simulations show that the state remains peaked at the classical solution till very early times when the matter density becomes of the order of Planck density. This provides, in particular, a justification, from first principles, for the assumption that spacetime can be taken to be classical even at the onset of the inflationary era, just a few Planck times after the (classical) big bang. While one would expect a result along these lines to hold on physical grounds, technically it is nontrivial to obtain semiclassicality over such huge domains. However, in the Planck regime near the big bang, there are major deviations from the classical behavior. Effectively, gravity becomes repulsive, the collapse is halted and then the universe re-expands. Thus, rather than modifying spacetime structure just in a tiny region near the singularity, quantum geometry effects open a bridge to another large classical universe. These are dramatic modifications of the classical theory.

For over three decades, hopes have been expressed that quantum gravity would provide new insights into the true nature of the big bang. Thanks to quantum geometry effects, these hopes have been realized and many of the long-standing questions have been answered. While the final picture has some similarities with other approaches, (e.g., "cyclic universes," or pre-big-bang cosmology), only in loop quantum cosmology is there a fully deterministic evolution across what was the classical big-bang. However, so far, detailed results have been obtained only in simple models. The major open issue is the inclusion of perturbations and subsequent comparison with observations.

# Quantum Group Differentials, Bundles and Gauge Theory

**T Brzeziński**, University of Wales Swansea, Swansea, UK

## Introduction

Mathematics of classical gauge theories is contained in the theory of principal and associated vector bundles. Principal bundles describe pure gauge fields and their transformations, while the associated bundles contain matter fields. A structure group of a bundle has a meaning of a gauge group, while the base manifold is a spacetime for the theory. In this article, we review the theory of bundles in which a structure group is a quantum group and base space or spacetime might be noncommutative. To fully deal with geometric aspects, we first review differential geometry of quantum groups. Then we describe the theory of quantum principal bundles, connections on such bundles, gauge transformations, associated vector bundles and their sections. We indicate that, for a certain class of quantum principal bundles, sections of an associated bundle become vector bundles of noncommutative geometry *à la* Connes, that is,

finite projective modules. The theory is illustrated by two explicit examples that can be viewed as deformations of the classical magnetic monopole and the instanton.

## Differential Structures on Algebras

### Algebraic Conventions

Throughout this article, $A$ ($P$ etc.,) will be an associative unital complex algebra. To gain some geometric intuition the reader can think of $A$ as an algebra of continuous complex functions on a compact (Hausdorff) space $X$, $C(X)$, with product given by pointwise multiplication $fg(x) = f(x)g(x)$, and with the unit provided by a constant function $x \mapsto 1$. The algebra $C(X)$ is commutative, but, in what follows, we do not assume that $A$ is a commutative algebra. By an $A$-bimodule we mean a vector space with mutually commuting left and right actions of $A$. All modules are unital (i.e., the unit element of $A$ acts trivially). On elements, the multiplication in an algebra or an action of $A$ on a module is denoted by juxtaposition.

### Differential Calculus on an Algebra

A first-order differential calculus on $A$ is a pair $(\Omega^1(A), \mathrm{d})$, where $\Omega^1(A)$ is an $A$-bimodule and $\mathrm{d}: A \to \Omega^1(A)$ is a linear map such that:

1. for all $a, b \in A$, $\mathrm{d}(ab) = (\mathrm{d}a)b + a\mathrm{d}b$ (the Leibniz rule); and
2. every $\omega \in \Omega^1(A)$ can be written as $\omega = \sum_i a_i \mathrm{d}b_i$ for some $a_i, b_i \in A$.

Elements of $\Omega^1(A)$ are called differential 1-forms and the map d is called an exterior derivative. As a motivating example, take $A = C(X)$ and $\Omega^1(A)$ the space of 1-forms on $X$ (sections of the cotangent bundle $T^*X$), and d the usual exterior differential.
Higher-differential forms corresponding to $(\Omega^1(A), \mathrm{d})$ are defined as elements of a differential graded algebra $\Omega(A)$. This is an algebra which can be decomposed into the direct sum of $A$-bimodules $\Omega^n(A)$, that is, $\Omega(A) = A \oplus \Omega^1(A) \oplus \Omega^2(A) \oplus \cdots$. In addition to $\mathrm{d}: A \to \Omega^1(A)$, there are maps $\mathrm{d}_n: \Omega^n(A) \to \Omega^{n+1}(A)$ such that, for all $\omega_n \in \Omega^n(A)$, $\omega_k \in \Omega^k(A)$,

1. $\mathrm{d}_1 \circ \mathrm{d} = 0$ and $\mathrm{d}_{n+1} \circ \mathrm{d}_n = 0, n = 1, 2, \ldots$;
2. $\omega_n \omega_k \in \Omega^{n+k}(A)$; and
3. $\mathrm{d}_{n+k}(\omega_n \omega_k) = (\mathrm{d}_n \omega_n)\omega_k + (-1)^n \omega_n(\mathrm{d}_k \omega_k)$.

Elements of $\Omega^n(A)$ are known as "differential $n$-forms." $\Omega^n(A)$ contains all linear combinations of expressions $a_0\, \mathrm{d}a_1\, \mathrm{d}a_2 \cdots \mathrm{d}a_n$ with $a_0, \ldots, a_n \in A$. One says that $\Omega(A)$ satisfies the "density condition" if any element of $\Omega^n(A)$ is of the above form, for any $n$. To simplify notation, one writes d for $\mathrm{d}_n$.

As an example of $\Omega(A)$, take $A = C(X)$ and then the exterior algebra $\Omega(X)$ for $\Omega(A)$. The exterior algebra satisfies density condition as any $n$-form can be written as $f(x) \wedge \mathrm{d}g(x) \wedge \mathrm{d}h(x) \wedge \cdots$. The wedge product is anticommutative, but for a noncommutative algebra $A$, the anticommutativity of the product in $\Omega(A)$ cannot be generally required.

### The Universal Differential Calculus

Any algebra $A$ comes equipped with a universal differential calculus denoted by $(\Omega^1 A, \mathrm{d})$. $\Omega^1 A$ is defined as the kernel of the multiplication map, that is, $\Omega^1 A := \{\sum_i a_i \otimes b_i \in A \otimes A \mid \sum_i a_i b_i = 0\} \subseteq A \otimes A$. The derivative is defined by $\mathrm{d}(a) = 1 \otimes a - a \otimes 1$. The $n$-forms are defined as $\Omega^n A = \Omega^1 A \otimes_A \Omega^1 A \otimes_A \cdots \otimes_A \Omega^1 A$ ($n$-copies of $\Omega^1 A$). $\Omega^n A$ can be identified with a subspace of $A \otimes A \otimes \cdots \otimes A$ ($n+1$-copies of $A$) consisting of all such elements that vanish upon multiplication of any two consecutive factors. With this identification, higher derivatives read

$$\mathrm{d}\Big(\sum_i a_0^i \otimes a_1^i \otimes \cdots \otimes a_n^i\Big) = \sum_{k=0}^{n+1} \sum_i (-1)^k a_0^i \otimes a_1^i \otimes \cdots \otimes a_{k-1}^i \otimes 1 \otimes a_k^i \cdots \otimes a_n^i$$

The universal differential calculus satisfies the density condition.

This calculus captures very little (if any) of the geometry of the underlying algebra $A$, but it has the universality property, that is, any differential calculus on $A$ can be obtained as a quotient of $\Omega A$. In other words, any differential calculus $\Omega(A)$ is fully determined by a system of $A$-sub-bimodules $N_n \in A^{\otimes n+1}$ (or homogeneous ideals in the algebra $\Omega A$), so that $\Omega^n(A) = \Omega^n A / N_n$. The differentials d in $\Omega(A)$ are derived from universal differentials via the canonical projections $\pi_n: \Omega^n A \to \Omega^n(A)$.

Typical examples of algebras in quantum geometry are given by generators and relations, that is, $A = \mathbb{C}\langle x_1, \ldots, x_n\rangle / \langle R_i(x_1, \ldots, x_n)\rangle$, where $\mathbb{C}\langle x_1, \ldots, x_n\rangle$ is a free algebra on generators $x_k$ and $R_i(x_1, \ldots, x_n)$ are polynomials, so that $R_i(x_1, \ldots, x_n) = 0$ in $A$. Correspondingly, the modules $\Omega^n(A)$ are given by generators and relations. If $\Omega(A)$ satisfies the density condition, that the whole of $\Omega(A)$ must be generated by some 1-forms. The sub-bimodules $N_n$ contain relations satisfied by these generators.

### $*$-Calculi

If $A$ is a $*$-algebra, then a calculus is called a "$*$-calculus" provided $\Omega(A)$ is a graded $*$-algebra, and $\mathrm{d}(\rho^*) = (\mathrm{d}\rho)^*$, for all $\rho \in \Omega(A)$.

## Differential Structures on Quantum Groups (Hopf Algebras)

### Hopf Algebra Preliminaries

From now on, $A$ is a Hopf algebra (quantum group), with a coproduct $\Delta : A \to A \otimes A$, counit $\varepsilon : A \to \mathbb{C}$ and antipode $S$. We use Sweedler's notation $\Delta(a) = \sum a_{(1)} \otimes a_{(2)}$. We also write $A^+ = \ker \varepsilon$ (the augmentation ideal).

For any algebra $P$, the convolution product of linear maps $f, g : A \to P$ is a linear map $f * g : A \to P$, defined by $f * g(a) = \sum f(a_{(1)}) * g(a_{(2)})$. A map $f : A \to P$ is said to be convolution invertible, provided there exists $f^{-1} : A \to P$ such that $f * f^{-1} = f * f^{-1} = 1\varepsilon$.

An $A$-coaction on a comodule $V$, $\varrho : V \to V \otimes A$, is denoted by $\varrho(v) = \sum v_{(0)} \otimes v_{(1)}$. The right adjoint coaction in $A$ is a map

$$\mathrm{Ad} : A \to A \otimes A,$$
$$\mathrm{Ad}(a) = \sum a_{(2)} \otimes (Sa_{(1)})a_{(3)}$$

A subspace $B$ of $A$ is said to be "Ad-invariant" provided $\mathrm{Ad}(B) \subseteq B \otimes A$. For example, $A^+$ is such a space.

### Covariant Differential Calculi

For Hopf algebras one can study calculi that are covariant with respect to $\Delta$. For $A = \mathbb{C}[G]$ (an algebra of functions on a Lie group), this corresponds to the covariance of a differential structure on $G$ with respect to regular representations.

A first-order differential calculus $\Omega^1(A)$ on a quantum group $A$ is said to be left-covariant, if there exists a linear map $\Delta_{\mathrm{L}} : \Omega^1(A) \to A \otimes \Omega^1(A)$ (called a left coaction) such that, for all $a, b \in A$,

$$\Delta_{\mathrm{L}}(a\mathrm{d}b) = \sum a_{(1)}b_{(1)} \otimes a_{(2)}\mathrm{d}b_{(2)}$$

$\Omega^1(A)$ is called a right-covariant differential calculus if there exists a linear map $\Delta_{\mathrm{R}} : \Omega^1(A) \to \Omega^1(A) \otimes A$ (called a right coaction) such that, for all $a, b \in A$,

$$\Delta_{\mathrm{R}}(a\mathrm{d}b) = \sum a_{(1)}\mathrm{d}b_{(1)} \otimes a_{(2)}b_{(2)}$$

If $\Omega^1(A)$ is both left- and right-covariant, it is called a "bicovariant differential calculus." A bicovariant $\Omega^1(A)$ has a structure of a Hopf $A$-bimodule, that is, it is an $A$-bimodule and an $A$-bicomodule such that the coactions are compatible with actions.

The universal calculus on $A$ is bicovariant with coactions

$$\Delta_{\mathrm{R}}^{U}\Big(\sum_i a^i \otimes b^i\Big) = \sum_i a^i_{(1)} \otimes b^i_{(1)} \otimes a^i_{(2)}b^i_{(2)},$$
$$\Delta_{\mathrm{L}}^{U}\Big(\sum_i a^i \otimes b^i\Big) = \sum_i a^i_{(1)}b^i_{(1)} \otimes a^i_{(2)} \otimes b^i_{(2)}$$

Since $\Omega^1(A) = \Omega^1 A/N$ for an $A$-sub-bimodule $N \in \Omega^1 A$, the calculus $\Omega^1(A)$ is left (resp. right) covariant if and only if $\Delta_{\mathrm{L}}^{U}(N) \subseteq A \otimes N$ (resp. $\Delta_{\mathrm{R}}^{U}(N) \subseteq N \otimes A$).

### The Woronowicz Theorems

A form $\omega$ in a left-covariant differential calculus $\Omega^1(A)$ is said to be left-invariant provided $\Delta_{\mathrm{L}}(\omega) = 1 \otimes \omega$. $\Omega^1(A)$ is a free $A$-module with basis given by left-invariant forms, that is, one can choose a set of left-invariant forms $\omega^i$ such that any 1-form $\rho$ can be uniquely written as a finite sum $\rho = \sum_i a_i\omega^i$, $a_i \in A$.

The first Woronowicz theorem states that there is a one-to-one correspondence between left-covariant calculi on $A$ and right $A$-ideals $Q \subseteq A^+$. The correspondence is provided by the map

$$\kappa : A \otimes Q \to N, \qquad a \otimes q \mapsto \sum aSq_{(1)} \otimes q_{(2)}$$

where $N$ is such that $\Omega^1(A) = (\Omega^1 A)/N$. The inverse of $\kappa$ reads $\kappa^{-1}(\sum_i a^i \otimes b^i) = \sum_i a^i b^i_{(1)} \otimes b^i_{(2)}$. The map $\kappa$ induces the map $\bar{\kappa} : A^+/Q \to \Omega^1(A)$, via $\omega([a]) = [\kappa(1 \otimes a)]$ where $[-]$ denotes cosets in $A^+/Q$ and in $\Omega^1(A) = (\Omega^1 A)/N$. This establishes a one-to-one correspondence between the space $\Lambda^1 = A^+/Q$ and the space of left-invariant 1-forms in $\Omega^1(A)$. The dual space to $\Lambda^1$, that is, the space of linear functionals $\Lambda^1 \to \mathbb{C}$, is often termed a "quantum Lie algebra" or a "quantum tangent space" corresponding to a left-covariant calculus $\Omega^1(A)$. The dimension of $\Lambda^1$ is known as a dimension of $\Omega^1(A)$.

The definitions and analysis of right-covariant differential calculi are done in a symmetric manner. For a bicovariant calculus, a form $\omega$ that is both left- and right-invariant, is termed a "bi-invariant" form.

The second Woronowicz theorem states a one-to-one correspondence between bicovariant differential calculi and Ad-invariant $A$-ideals $Q \subseteq A^+$ (cf. the subsection "Hopf algebra preliminaries"). The correspondence is provided by the map $\kappa$ above. For the universal calculus, $Q$ is trivial, and hence $\Lambda^1 = A^+ = \ker(\varepsilon)$.

### Higher-order Bicovariant Calculi

Given a first-order bicovariant calculus $\Omega^1(A)$, one constructs a braiding operator, known as the

"Woronowicz braiding" $\tau : \Omega^1(A) \otimes_A \Omega^1(A) \to \Omega^1(A) \otimes_A \Omega^1(A)$ by setting $\tau(a\omega \otimes_A \eta) = a\eta \otimes_A \omega$ for all $a \in A$, and any left-invariant $\omega$ and right-invariant $\eta$, and then extending it $A$-linearly to the whole of $\Omega^1(A) \otimes_A \Omega^1(A)$. This operator satisfies the braid relation $(\mathrm{id} \otimes_A \tau) \circ (\tau \otimes_A \mathrm{id}) \circ (\mathrm{id} \otimes_A \tau) = (\tau \otimes_A \mathrm{id}) \circ (\mathrm{id} \otimes_A \tau) \circ (\tau \otimes_A \mathrm{id})$, and is invertible provided the antipode $S$ is invertible. The Woronowicz braiding is used to define symmetric forms as those invariant under $\tau$. One then defines exterior 2-forms as elements of $\Omega^1(A) \otimes_A \Omega^1(A)/\ker(\mathrm{id} - \tau)$, and introduces the wedge product. The wedge product is not in general anticommutative, but one does have $\omega \wedge \eta = -\eta \wedge \omega$ for bi-invariant $\omega, \eta$. This construction is extended to higher forms and leads to the definition of the exterior algebra $\Omega(A)$. To define exterior $n$-forms, one maps any permutation on $n$-elements to the corresponding element of the braid group generated by $\tau$ and then takes the quotient of the $n$th tensor power of $\Omega^1(A)$ by all elements corresponding to even permutations. The differential $\mathrm{d} : A \to \Omega^1(A)$ is extended to an exterior differential in the whole of $\Omega(A)$ in the following way. First, $\Omega^1(A)$ is extended by a one-dimensional $A$-bimodule generated by a form $\theta$ that is required to be bi-invariant. The resulting extended bimodule (which, in general, is not a first-order differential calculus, as $\theta$ is not necessarily of the form $\sum_i a_i \,\mathrm{d}b_i$, for some $a_i, b_i \in A$) is then determined from the relation $\mathrm{d}a = \theta a - a\theta$ for all $a \in A$. Higher exterior derivative is then defined by $\mathrm{d}\rho = \theta \wedge \rho - (-1)^n \rho \wedge \theta$, for any $\rho \in \Omega^n(A)$.

The algebra $\Omega(A)$ is a $\mathbb{Z}_2$-graded differential Hopf algebra, that is, it has a coproduct such that

$$\Delta(\omega \wedge \eta) = \sum (-1)^{|\omega_{(2)}||\eta_{(1)}|} \omega_{(1)} \wedge \eta_{(1)} \otimes \omega_{(2)} \wedge \eta_{(2)}$$

where $|\omega_{(2)}|$ etc., denotes the degree of a homogeneous component in the decomposition of $\Delta(\omega)$. Furthermore,

$$\Delta(\mathrm{d}\omega) = \sum \left( \mathrm{d}\omega_{(1)} \otimes \omega_{(2)} + (-1)^{|\omega_{(1)}|} \omega_{(1)} \otimes \mathrm{d}\omega_{(2)} \right)$$

On the 1-forms this coproduct is simply the sum $\Delta_{\mathrm{L}} + \Delta_{\mathrm{R}}$.

### Classification

There is no unique covariant differential calculus on $A$, so classification of covariant differential calculi is an important problem. For example, it is known that the quantum group $\mathrm{SU}_q(2)$ admits a left-covariant three-dimensional calculus, but there is no three-dimensional bicovariant calculus. On the other hand, there are two four-dimensional bicovariant calculi on $\mathrm{SU}_q(2)$. Differential calculi are classified for standard quantum groups such as $\mathrm{SL}_q(N)$ or $\mathrm{Sp}_q(N)$.

General classification results are based on the equivalence between the category of Hopf bimodules of a finite-dimensional Hopf algebra $A$ and that of Yetter–Drinfeld or crossed modules of $A$. These are the modules of the Drinfeld double of $A$. As a result, in the case of a finite-dimensional factorizable coquasitriangular Hopf algebra $A$ with a dual Hopf algebra $H$, the bicovariant $\Omega^1(A)$ are in one-to-one correspondence with two-sided ideals in $H^+$. If, in addition, $A$ is semisimple, then (coirreducible) calculi are in one-to-one correspondence with nontrivial irreducible representations of $H$. This can be extended to infinite-dimensional algebras, provided one works over a field of formal power series in the deformation parameter.

## Quantum Group Principal Bundles

### Quantum Principal Bundles

In classical geometry, a (topological) principal bundle is a locally compact Hausdorff space with a (continuous) free and proper action of a locally compact group (e.g., a Lie group). In terms of algebras of functions this gives rise to the following structure. $A$ is a Hopf algebra (the model is functions on a group $G$), $P$ is a right $A$-comodule algebra with a coaction $\Delta_P : P \to P \otimes A$ (the model is functions on a total space $X$). Let $B = \{b \in P \mid \Delta_P(b) = b \otimes 1\}$ be the coinvariant subalgebra (the model is functions on a base manifold $M = X/G$). Fix a bicovariant calculus $\Omega^1(A)$, with the corresponding $Q$ and $\Lambda^1 = A^+/Q$ as in the subsection "The Woronowicz theorems." Take a differential calculus $\Omega^1(P) = \Omega^1 P/N_P$ such that:

1. $\Delta_{\Omega^1 P}(N_P) \subseteq N_P \otimes A$, where for all $\sum_i p^i \otimes q^i \in \Omega^1 P$,
$$\Delta_{\Omega^1 P}\left( \sum_i p^i \otimes q^i \right) = \sum_i p^i_{(0)} \otimes q^i_{(0)} \otimes p^i_{(1)} q^i_{(1)} \in \Omega^1 P \otimes A$$
2. $\tilde{\chi}(N_P) \subseteq N_P \otimes Q$, where
$$\tilde{\chi} : \Omega^1 P \to P \otimes A^+, \quad \sum_i p^i \otimes q^i \mapsto \sum_i p^i \Delta_P(q^i) = \sum_i p^i q^i_{(0)} \otimes q^i_{(1)}$$
3. $N_B = N_P \cap \Omega^1 B$ gives rise to a differential structure $\Omega^1(B) = \Omega^1 B/N_B$ on $B$. Condition (1) ensures that $\Delta_{\Omega^1 P}$ descends to a coaction $\Delta_{\Omega^1(P)} : \Omega^1(P) \to \Omega^1(P) \otimes A$, while (2) allows for defining a map
$$\mathrm{ver} : \Omega^1(P) \to P \otimes \Lambda^1, \qquad \mathrm{ver}([\omega]) = [\tilde{\chi}(\omega)]$$

Since $B$ is a subalgebra of $P$, the $P$-bimodule

$$P\Omega^1(B)P := \left\{ \sum_i p^i(\mathrm{d}b^i)q^i | p^i, q^i \in P, b^i \in B \right\}$$

is a sub-bimodule of $\Omega^1 P$, known as horizontal forms. $P$ is called a "quantum principal bundle" over $B$ with quantum structure group $A$ and calculi $\Omega^1(A)$ and $\Omega^1(P)$ provided the following sequence;

$$0 \longrightarrow P\Omega^1(B)P \longrightarrow \Omega^1(P) \xrightarrow{\mathrm{ver}} P \otimes \Lambda^1 \longrightarrow 0$$

is exact. This definition reflects the geometric content of principal bundles, but is not restricted to any specific differential calculus. The surjectivity of ver corresponds to the freeness of the (co)action, while the condition $\ker(\mathrm{ver}) = P\Omega^1(B)P$ corresponds to identification of vertical vector fields as those that are annihilated by horizontal forms.

### The Universal Calculus Case

In the universal calculus case, both $N_P$ and $Q$ in the previous subsection are trivial, and $\mathrm{ver} = \tilde{\chi}$. Universal horizontal forms $P(\Omega^1 B)P$ coincide with the kernel of the canonical projection $P \otimes_B P \to P \otimes P$. The exactness of the sequence in the last subsection is equivalent to the requirement that the map

$$\begin{aligned} \mathrm{can} : P \otimes_B P &\to P \otimes A \\ p \otimes_B q &\mapsto p\Delta_P(q) = \sum pq_{(0)} \otimes q_{(1)} \end{aligned}$$

be bijective. In algebra, such an inclusion of algebras $B \subseteq P$ is known as a Hopf–Galois extension. Thus, a geometric notion of a quantum principal bundle with the universal calculus is the same as the algebraic notion of a Hopf–Galois extension.

If (2) in the previous subsection is replaced by stronger conditions $\tilde{\chi}(N_P) = N_P \otimes Q$ and $(N_P \cap \ker \tilde{\chi}) \subseteq P(\Omega^1 B)P$, then exactness of the sequence in the previous subsection is equivalent to the bijectivity of "can." Thus, although defined in a purely algebraic way, the notion of a Hopf–Galois extension carries deep geometric meaning. It therefore makes sense to consider primarily Hopf–Galois extensions and then specify differential structure in such a way that this stronger version of (2) is satisfied. Henceforth, unless specified otherwise, a quantum principal bundle is taken with the universal differential calculus.

### Quantum Homogeneous Bundles

Suppose that $P$ is a Hopf algebra, and that there is a Hopf algebra surjection $\pi : P \to A$. This induces a coaction of $P$ on $A$ via $\Delta_P = (\mathrm{id} \otimes \pi) \circ \Delta$, where now $\Delta$ is a coproduct in $P$. $P$ is a quantum principal $A$-bundle over the coinvariants $B$, provided $\ker \pi \subseteq B^+P$, where $B^+ = B \cap P^+$. $B$ is a left quantum homogeneous space in the sense that $\Delta(B) \subseteq P \otimes B$, and $P$ is known as a quantum homogeneous bundle. An example of this is the standard quantum 2-sphere – a quantum homogeneous space of $SU_q(2)$ (see the subsection "The Dirac $q$-monopole"). This construction reflects the classical construction of a principal bundle over a homogeneous space, since every homogeneous space of a group $G$ can be identified with a quotient $G/H$, where $H \subseteq G$ is a subgroup. Not every quantum homogeneous space can be obtained in this way (e.g., nonstandard quantum 2-spheres), as quantum groups $P$ do not have sufficiently many quantum subgroups $A$ (in a sense of Hopf algebra projections $\pi : P \to A$). To study gauge theory on general quantum homogeneous spaces, more general notion of a bundle needs to be developed (see the subsection "Generalizations of quantum principal bundles").

A general differential calculus on a quantum homogeneous bundle is specified by choosing a left-covariant calculus on $P$ with an ideal $Q_P \in P^+$ such that $(\mathrm{id} \otimes \pi) \circ \mathrm{Ad}(Q_P) \subseteq Q_P \otimes A$. A bicovariant calculus on $A$ is then given by $Q_A = \pi(Q_P)$.

### Quantum Trivial Bundles

A quantum principal bundle (with the universal differential calculus) is said to be "trivial" or "cleft" provided there exists a linear map $\Phi : A \to P$ such that

1. $\Phi(1) = 1$ (unitality);
2. $\Delta_P \circ \Phi = (\Phi \otimes \mathrm{id}) \circ \Delta$ (*colinearity* or *covariance*); and
3. $\Phi$ is convolution invertible (cf. the subsection "Hopf algebra preliminaries").

$\Phi$ is called a trivialization. In this case, $P$ is isomorphic to $B \otimes A$ as a left $B$-module and right $A$-comodule via the map $B \otimes A \to P, b \otimes a \mapsto b\Phi(a)$. In particular, an $A$-covariant (i.e., colinear) algebra map $j : A \to P$ is a trivialization (the convolution inverse of $j$ is $j \circ S$).

Based on trivial bundles, locally trivial bundles can be constructed by choosing a compatible covering of $B$ (in terms of ideals).

At this point, the reader should be warned that the notion of a trivial quantum principal bundle includes bundles which are not trivial classically (i.e., do not correspond to functions on the Cartesian product of spaces). As an example, consider the Möbius strip viewed as a $\mathbb{Z}_2$-principal bundle over the circle $S^1$. Obviously, this is not a trivial bundle (the Möbius strip is not isomorphic to

$S^1 \times \mathbb{Z}_2$). It can be shown, however, that the quantum principal bundle corresponding to the Möbius strip has a trivialization $\Phi$ in the above sense.

### Generalizations of Quantum Principal Bundles

In the case of majority of quantum homogeneous spaces, the map $\pi$ in the subsection "Quantum homogeneous bundles" is a coalgebra and right $P$-module map, but not an algebra map. Thus, the induced coaction is not an algebra map either. To cover examples like these, one needs to introduce a generalization of quantum principal bundles. Consider an algebra $P$ that is also a right comodule of a coalgebra $C$ with coaction $\Delta_P$. Define

$$B := \Big\{ b \in P | \forall p \in P, \Delta_P(bp) = b\Delta_P(p) = \sum bp_{(0)} \otimes p_{(1)} \Big\}$$

$B$ is a subalgebra of $P$. $P$ is a principal coalgebra-bundle over $B$ or $B \subseteq P$ is a coalgebra-Galois extension provided the map

$$\mathrm{can} : P \otimes_B P \to P \otimes C$$
$$p \otimes_B q \mapsto p\Delta_P(q) = \sum pq_{(0)} \otimes q_{(1)}$$

is bijective. This purely algebraic requirement induces a rich symmetry structure on $P$, given in terms of entwining, which allows one for developing various differential geometric notions such as those discussed in the next section. The lack of space does not permit us to describe this theory here.

## Connections, Gauge Transformations, Matter Fields

### Connections and Connection Forms

A "connection" in a quantum principal bundle with calculi $\Omega^1(P), \Omega^1(A)$ is a left $P$-linear map $\Pi : \Omega^1(P) \to \Omega^1(P)$ such that:

1. $\Pi \circ \Pi = \Pi$ ($\Pi$ is a projection);
2. $\ker \Pi = P\Omega^1(B)P$; and
3. $\Delta_{\Omega^1(P)} \circ \Pi = (\Pi \otimes \mathrm{id}) \circ \Delta_{\Omega^1(P)}$ (colinearity or covariance).

The exact sequence in the subsection "Quantum principal bundles" implies that $\Pi$ is a left $P$-linear projection if and only if there exists a left $P$-linear map $\sigma : P \otimes \Lambda^1 \to \Omega^1(P)$ such that $\mathrm{ver} \circ \sigma = \mathrm{id}$. Since $\sigma$ is left $P$-linear, it is fully specified by its action on $\Lambda^1$. This leads to the equivalent definition of a connection as a connection form or a gauge field, that is, a map $\omega : \Lambda^1 \to \Omega^1(P)$ such that:

1. for all $\lambda \in \Lambda^1, \mathrm{ver}(\omega(\lambda)) = 1 \otimes \lambda$; and
2. $\Delta_{\Omega^1(P)} \circ \omega = (\omega \otimes \mathrm{id}) \circ \mathrm{Ad}^1_\Lambda$ (Ad-covariance), where $\mathrm{Ad}_{\Lambda^1}$ is a projection of the adjoint coaction to $\Lambda^1$, that is, $\mathrm{Ad}_{\Lambda^1}([a]) = [\mathrm{Ad}(a)]$ (well defined, because $Q$ is Ad-invariant for a bicovariant calculus, see the subsection "The Woronowicz theorems").

The correspondence between connections and connection 1-forms is given by the formula

$$\prod(p\mathrm{d}q) = \sum pq_{(0)}\omega([q_{(1)}])$$

In the universal differential calculus case, $\Lambda^1 = A^+$, hence $\omega$ can be viewed as a map $\omega : A \to \Omega^1 P$, such that $\omega(1) = 0$. The map $\mathcal{F}_\omega : A \to \Omega^2 P$, given by $\mathcal{F}_\omega = \mathrm{d}\omega + \omega * \omega$ is called a "curvature" of $\omega$. The curvature satisfies the Bianchi identity, $\mathrm{d}\mathcal{F}_\omega = \mathcal{F}_\omega * \omega - \omega * \mathcal{F}_\omega$.

In the case of a trivial bundle with trivialization $\Phi$ and universal calculus, any linear map $\beta : A \to \Omega^1 B$ such that $\beta(1) = 0$ defines a connection 1-form

$$\omega = \Phi^{-1} * \mathrm{d}\Phi + \Phi^{-1} * \beta * \Phi$$

The corresponding curvature is $\mathcal{F}_\omega = \Phi^{-1} * \mathcal{F}_\beta * \Phi$, where $\mathcal{F}_\beta = \mathrm{d}\beta + \beta * \beta$.

In the case of a quantum homogeneous bundle with calculus determined by $Q_P \in P^+$ and $Q_A = \pi(Q_P)$ (cf. the subsection "Quantum homogeneous bundles"), a canonical connection form can be assigned to any algebra map $i : A \to P$ such that

1. $\pi \circ i = \mathrm{id}$ ($i$-splits $\pi$);
2. $\varepsilon_P \circ i = \varepsilon_A$ (co-unitality);
3. $(\mathrm{id} \otimes \pi) \circ \mathrm{Ad}_P \circ i = (i \otimes \mathrm{id}) \circ \mathrm{Ad}_A$ (Ad-covariance); and
4. $i(Q_A) \subseteq Q_P$ (differentiability).

Explicitly, $\omega([a]) = \sum (Si(a)_{(1)})\mathrm{d}i(a)_{(2)}$.

### Covariant Derivative: Strong Connections

A covariant derivative associated to a connection $\Pi$ is a map $\mathrm{D} : P \to P\Omega^1(B)P, p \mapsto \mathrm{d}p - \Pi(\mathrm{d}p)$. A covariant derivative maps elements of $P$ into horizontal forms, since $\ker \Pi = P\Omega^1(B)P$, and satisfies the Leibniz rule $\mathrm{D}(bp) = (\mathrm{d}b)p + b\mathrm{D}p$, for all $b \in B$, $p \in P$.

A connection is "strong" provided $\mathrm{D}(p) \in \Omega^1(B)P$. A covariant derivative of a strong connection is a connection on module $P$ in the sense of Connes. Furthermore, in the universal calculus case, and when $A$ has invertible antipode, the existence of strong connections leads to rich gauge theory of associated bundles (cf. the subsection "Associated bundles: matter fields"). A connection in a trivial bundle

described in the subsection "Connections and connection forms" is strong (and every strong connection in a trivial bundle is of this form). Assuming invertibility of the antipode in $A$, a canonical connection in a quantum homogeneous bundle described in that subsection is strong provided Ad-covariance (3) is replaced by conditions $(\mathrm{id}\otimes\pi)\circ\Delta\circ i=(i\otimes\mathrm{id})\circ\Delta_A$ (right covariance) and $(\pi\otimes\mathrm{id})\circ\Delta\circ i=(\mathrm{id}\otimes i)\circ\Delta_A$ (left covariance), where $\Delta$ is a coproduct in $P$, and $\Delta_A$ is a coproduct in $A$.

In the universal calculus case, the map D can be extended to a map $\mathrm{D}:\Omega^1P\to\Omega^2P$ via the formula $\mathrm{D}(\rho)=\mathrm{d}\rho+\sum\rho_{(0)}\omega(\rho_{(1)})$. Then $\mathrm{D}\circ\mathrm{D}(p)=\sum p_{(0)}\mathcal{F}_\omega(p_{(1)})$, where $\mathcal{F}_\omega$ is the curvature of $\omega$ (cf. the subsection "Connections and connection forms"). This explains the relationship between a curvature understood as the square of a covariant derivative and $\mathcal{F}_\omega$.

## Bundle Automorphisms and Gauge Transformations

A quantum bundle automorphism is a left $B$-linear right $A$-covariant (i.e., colinear) automorphism $F:P\to P$ such that $F(1)=1$. Bundle automorphisms form a group with operation $FG=G\circ F$. This group is isomorphic to the group $\mathcal{G}(P)$ of gauge transformations, that is, maps $f:A\to P$ that satisfy the following conditions:

1. $f(1_A)=1_P$ (unitality);
2. $\Delta_P\circ f=(f\otimes\mathrm{id})\circ\mathrm{Ad}$ (Ad-covariance); and
3. $f$ is convolution invertible (cf. the subsection "Hopf algebra preliminaries").

The product in $\mathcal{G}(P)$ is the convolution product (cf. the subsection "Hopf algebra preliminaries"). The group of gauge transformations acts on the space of (strong) connection forms $\omega$ via the formula

$$f\triangleright\omega=f*\omega*f^{-1}+f*\mathrm{d}f^{-1},\quad\forall f\in\mathcal{G}(P)$$

This resembles the gauge transformation law of a gauge field in the standard gauge theory. The curvature transforms covariantly as $\mathcal{F}_{f\triangleright\omega}=f*\mathcal{F}_\omega*f^{-1}$.

In the case of a trivial principal bundle, gauge transformations correspond to a change of the trivialization and can be identified with convolution-invertible maps $\gamma:A\to B$ such that $\gamma(1)=1$. A map $\beta:A\to\Omega^1B$ that induces a connection as in the subsection "Connections and connection forms" is transformed to $\gamma*\beta*\gamma^{-1}+\gamma*\mathrm{d}\gamma^{-1}$, and the curvature $\mathcal{F}_\beta\mapsto\gamma*\mathcal{F}_\beta*\gamma^{-1}$.

## Associated Bundles: Matter Fields

Given a right $A$-comodule (corepresentation) $\varrho:V\to V\otimes A$ one defines a quantum vector bundle associated to $P$ as

$$E=\left\{\sum_i v^i\otimes p^i\in V\otimes P\,\middle|\,\sum_i v^i_{(0)}\otimes p^i_{(0)}\otimes v^i_{(1)}p^i_{(1)}=\sum_i v^i\otimes p^i\otimes 1\right\}\subseteq V\otimes P$$

$E$ is a right $B$-module with product $(\sum_i v^i\otimes p^i)b=\sum_i v^i\otimes p^ib$. A right $B$-linear map $s:E\to B$ is called a section of $E$. The space of sections $\Gamma(E)$ is a left $B$-module via $(bs)(p)=bs(p)$.

The theory of associated bundles is particularly rich when $A$ has a bijective antipode and $P$ has a strong connection form $\omega$. In this case, $\Gamma(E)$ is isomorphic to the left $B$-module $\Gamma_\varrho$ of maps $\phi:V\to P$ such that $\Delta_P\circ\phi=(\phi\otimes\mathrm{id})\circ\varrho$. If $V$ is finite dimensional, then $\Gamma_\varrho$ is a finite projective $B$-module, that is, it is a module of sections of a noncommutative vector bundle in the sense of Connes. The strong connection induces a map $\nabla:\Gamma_\varrho\to\Omega^1B\otimes_B\Gamma_\varrho$, given by $\nabla(\phi)(v)=\mathrm{d}\phi(v)+\sum\phi(v_{(0)})\omega(v_{(1)})$. $\nabla$ is a connection in the sense of Connes (in a projective left $B$-module), that is, for all $b\in B,\phi\in\Gamma_\varrho$, $\nabla(b\phi)=\mathrm{d}b\otimes_B\phi+b\nabla(\phi)$.

In the case of a trivial bundle, $\Gamma_\varrho$ can be identified with the space of linear maps $V\to B$. Thus, sections of an associated bundle correspond to pullbacks of matter fields, as in the classical local gauge theory matter fields are defined as functions on a spacetime with values in a representation (vector) space of the gauge group.

## The Dirac $q$-Monopole

This is an example of a strong connection in a quantum homogeneous bundle (cf. the subsection "Quantum homogeneous bundles"). $P=\mathrm{SU}_q(2)$ is a matrix Hopf $*$-algebra with matrix of generators

$$\begin{pmatrix} a & -qc^* \\ c & a^* \end{pmatrix}$$

and relations

$$ac=qca,\qquad ac^*=qc^*a,\qquad cc^*=c^*c$$
$$a^*a+c^*c=1,\qquad aa^*+q^2cc^*=1$$

where $q$ is a real parameter. $A=\mathbb{C}[U(1)]$ is a Hopf $*$-algebra generated by unitary and group-like $u$ (i.e., $uu^*=u^*u=1,\Delta(u)=u\otimes u$). The $*$-projection $\pi:P\to A$ is defined by $\pi(a)=u$. The coinvariant subalgebra $B$ is generated by $x=cc^*$, $z=ac^*$, $z^*=ca^*$. The elements $x$ and $z$ satisfy relations

$$x^*=x,\qquad zx=q^2xz,$$
$$zz^*=q^2x(1-q^2x),\qquad z^*z=x(1-x)$$

Thus, $B$ is the algebra of functions on the standard quantum 2-sphere. A strong connection is obtained from a bicovariant $*$-map $i: A \to P$ given by $i(u^n) = a^n$ (cf. the subsections "Quantum homogeneous bundles," "Connections and connection forms," and "Covariant derivative: strong connections"). Explicitly, the connection form reads

$$\omega(u^n) = \sum_{k=0}^{n} \binom{n}{k}_{q^{-2}} c^{*k} a^{*n-k} \mathrm{d}(a^{n-k} c^k)$$
$$\omega(u^{*n}) = \sum_{k=0}^{n} q^{2k} \binom{n}{k}_{q^{-2}} a^{n-k} c^k \mathrm{d}(c^{*k} a^{*n-k})$$

where the deformed binomial coefficients are defined for any number $x$ by

$$\binom{n}{k}_x = \frac{(x^n - 1)(x^{n-1} - 1) \cdots (x^{k+1} - 1)}{(x^{n-k} - 1)(x^{n-k-1} - 1) \cdots (x - 1)}$$

There is a family $V_n, n \in \mathbb{Z}$ of one-dimensional corepresentations of $\mathbb{C}[\mathrm{U}(1)]$ with $V_n = \mathbb{C}$ and $\varrho^n(1) = 1 \otimes u^n, n \geq 0$ and $\varrho^n(1) = 1 \otimes u^{*n}, n < 0$. This leads to the family of finite projective modules $\Gamma_n = \Gamma_{\varrho^n}$ as described in the subsection "Associated bundles: matter fields." The Hermitian projectors $\boldsymbol{e}(n)$ of these modules come out as, for $n > 0$,

$$e(n)_{ij} = \sqrt{\binom{n}{i}_{q^{-2}} \binom{n}{j}_{q^{-2}}} a^{n-i} c^i c^{*j} a^{*n-j}, \quad i, j = 0, 1, \ldots, n$$
$$e(-n)_{ij} = q^{i+j} \sqrt{\binom{n}{i}_{q^{-2}} \binom{n}{j}_{q^{-2}}} c^{*i} a^{*n-i} a^{n-j} c^j, \quad i, j = 0, 1, \ldots, n$$

The $\boldsymbol{e}(n)$ describe $q$-monopoles of magnetic charge $-n$. For example, the charge-1 projector explicitly reads

$$\begin{pmatrix} 1 - x & z^* \\ z & q^2 x \end{pmatrix}$$

and reduces to the usual charge-1 Dirac monopole projector when $q = 1$. The covariant derivatives $\nabla$ are Levi-Civita or Grassmann connections in modules $\Gamma_n$ corresponding to projectors $\boldsymbol{e}(n)$.

### The $q$-Instanton

This is an example of a coalgebra bundle and the associated vector bundle, which is a deformation of an instanton (with instanton number 1). $P = \mathbb{C}[S_q^7]$ is the $*$-algebra of polynomial functions on the quantum 7-sphere. As a $*$-algebra it is defined by generators $z_1, z_2, z_3, z_4$ and relations

$$z_i z_j = q z_j z_i \quad (\text{for } i < j)$$
$$z_j^* z_i = q z_i z_j^* \quad (\text{for } i \neq j)$$
$$z_k^* z_k = z_k z_k^* + (1 - q^2) \sum_{j<k} z_j z_j^*,$$
$$\sum_{k=1} z_k z_k^* = 1$$

where $q \in \mathbb{R}$. The coaction of the $*$-Hopf algebra $A = \mathrm{SU}_q(2)$ (cf. the previous subsection) on $P$ is constructed as follows. Start with the quantum group $\mathrm{U}_q(4)$, generated by a matrix $\boldsymbol{t} = (t_{ij})_{i,j=1}^4$ and view $\mathbb{C}[S_q^7]$ as a right quantum homogeneous space of $\mathrm{U}_q(4)$ generated by the bottom row in $\boldsymbol{t}$. Thus, there is a right coaction of $\mathrm{U}_q(4)$ on $\mathbb{C}[S_q^7]$ obtained by the restriction of the coproduct in $\mathrm{U}_q(4)$. Next, project $\mathrm{U}_q(4)$ to $\mathrm{SU}_q(2)$ by a suitable coideal and a right ideal in $\mathrm{U}_q(4)$. The corresponding canonical surjection $r: \mathrm{U}_q(4) \to \mathrm{SU}_q(2)$ is a coalgebra map, characterized as a right $\mathrm{U}_q(4)$-module map by $r(t_{11} t_{22} - q t_{12} t_{21}) = 1$ and

$$r(\boldsymbol{t}) = \begin{pmatrix} \boldsymbol{u} & 0 \\ 0 & \boldsymbol{u} \end{pmatrix}, \qquad \bar{\boldsymbol{u}} = \begin{pmatrix} u_{22} & -u_{21} \\ -u_{12} & u_{11} \end{pmatrix}$$

where $\boldsymbol{u} = (u_{ij})_{i,j=1}^2$ is the matrix of generators of $\mathrm{SU}_q(2)$ (cf. the previous subsection). When applied to the coaction of $\mathrm{U}_q(4)$ on $\mathbb{C}[S_q^7]$, $r$ induces the required coaction $\Delta_P: \mathbb{C}[S_q^7] \to \mathbb{C}[S_q^7] \otimes \mathrm{SU}_q(2)$. Explicitly, the coaction comes out on generators as $\Delta_P(z_j) = \sum_i z_i \otimes r(t_{ij})$. The coaction $\Delta_P$ is not an algebra map. The coinvariant subalgebra $B$ is a $*$-algebra generated by

$$a = z_1 z_4^* - z_2 z_3^*$$
$$b = z_1 z_3 + q^{-1} z_2 z_4$$
$$R = z_1 z_1^* + z_2 z_2^*$$

The elements $a, a^*, b, b^*, R$ satisfy the following relations:

$$Ra = q^{-2} aR, \qquad Rb = q^2 bR$$
$$ab = q^3 ba, \qquad ab^* = q^{-1} b^* a$$
$$aa^* + q^2 bb^* = R(1 - q^2 R)$$
$$aa^* = q^2 a^* a + (1 - q^2) R^2$$
$$b^* b = q^4 bb^* + (1 - q^2) R$$

Hence $B$ can be understood as a deformation of the algebra of functions on the 4-sphere and is denoted by $\mathbb{C}[\Sigma_q^4]$. One can show that the map "can" in the subsection "Generalizations of quantum principal bundles" is bijective, hence there is an $\mathrm{SU}_q(2)$-coalgebra principal bundle with the total space the quantum 7-sphere $\mathbb{C}[S_q^7]$ and the base space the

quantum 4-sphere $\mathbb{C}[\Sigma_q^4]$. By abstract arguments that involve cosemisimplicity of $SU_q(2)$, one can prove that there exists a strong connection in this bundle; this is the $q$-deformed instanton field. At the time of writing this article, however, the explicit form of this connection is not known.

On the other hand, following the classical construction of an instanton, one can take the fundamental two-dimensional corepresentation $V = \mathbb{C}^2$ of $SU_q(2)$ and explicitly construct $q$-instanton projection with instanton number 1. Writing $e_1, e_2$ for the basis of $V$, the coaction $\varrho: V \to V \otimes SU_q(2)$ is given by

$$(e_j) = \sum_i e_i \otimes u_{ij}$$

The associated bundle (cf. the subsection "Associated bundles: matter fields") is a finite projective left module over $\mathbb{C}[\Sigma_q^4]$. The corresponding $q$-instanton projector comes out as

$$\begin{pmatrix} q^2 R & 0 & qa & q^2 b \\ 0 & q^2 R & qb^* & -q^3 a^* \\ qa^* & qb & 1-R & 0 \\ q^2 b^* & -q^3 a & 0 & 1-q^4 R \end{pmatrix}$$

# Quantum Hall Effect

**K Hannabuss**, University of Oxford, Oxford, UK

## Introduction

When a current flows in a thin sample with a transverse magnetic field $B$, the Lorentz force deflects the trajectories of the charge carriers, producing an excess charge on one side and a charge deficiency on the other, and creating a potential difference across the conductor perpendicular to both the direct current and the magnetic field. This is known as the Hall effect, in honour of E H Hall, who, inspired by a remark of Maxwell, first demonstrated it in thin samples of gold foil in October 1879 (Hall's subsequent measurements of the potential difference showed that the carriers could be positively or negatively charged for different materials). A schematic diagram of Hall's experiment and the lateral separation of charges is shown in Figure 1.

Equilibrium is reached when the magnetic force balances that from the potential difference $E$ due to the displaced charge. When the charge carriers are electrons, with the electron density $n$, and the electron current $J$, this gives $neE = JB$. Comparison with Ohm's law, $J = \sigma E$, gives conductance (the reciprocal of resistance) to be $\sigma = ne/B$. More generally, considering the currents and fields as

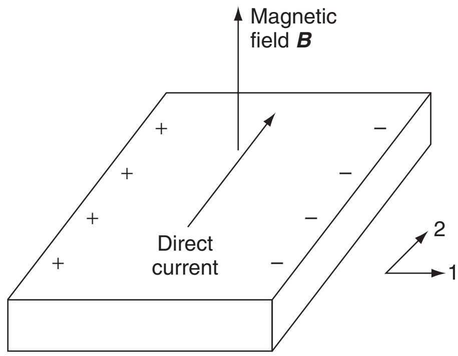

**Figure 1** Schematic diagram of charge separation in Hall's experiment.

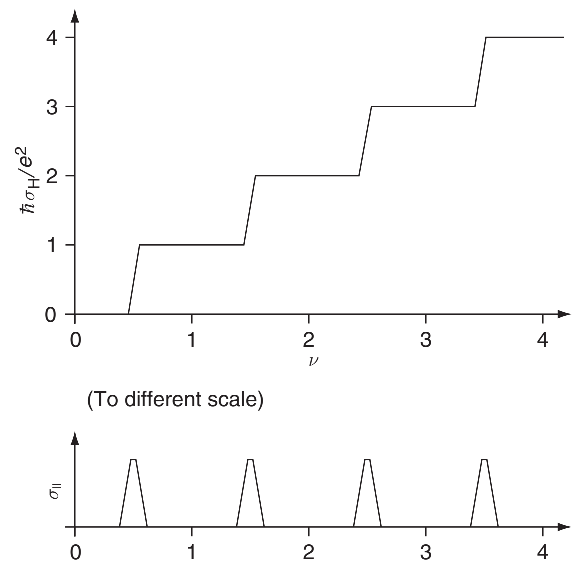

**Figure 2** Schematic diagram of the Hall and direct conductivities plotted against the filling factor $\nu$.

vectors, $\sigma$ is represented by a matrix. Rescaling by the sample thickness $\delta$, the diagonal components of $\delta\sigma$ give the direct conductivity $\sigma_{\|}$ and its off-diagonal elements give the Hall conductivity: $\sigma_H = \delta\sigma_{21}$. (For systems symmetric under 90° rotations, $\sigma_{11} = \sigma_{22}$ and $\sigma_{12} = -\sigma_{21}$.) In quantum theory, one usually works in terms of the filling fraction $\nu = n\delta h/eB$ and then $\sigma_H = \nu e^2/h$.

In 1980 von Klitzing, Dorda, and Pepper discovered that at very low temperatures in very high magnetic fields, the Hall conductivity $\sigma_H$ is quantized as integral multiples of $e^2/\hbar$, a fact known as the integer quantum hall effect (IQHE). The integer multiples were accurate to 1 part in $10^8$, and the effect was exceptionally robust against changes in the geometry of the samples and in the experimental parameters. Indeed, the unprecedented accuracy of the effect led to its adoption as the international standard for resistance in 1990.

More precisely, the Hall conductivity was no longer proportional to the filling fraction $\nu$, but the graph of $\sigma_H$ against $\nu$ displayed a sequence of jumps, as shown in Figure 2. In this figure, the conductivity has plateau at the integer multiples of $e^2/\hbar$, and jumps between them within fairly small ranges of the filling fraction. Moreover, the direct conductivity vanishes where the Hall conductivity takes its constant integral values.

These results raise numerous questions.

1. Why does the conductivity take such precise integer values, and why are they so stable under changes of the geometry and physical parameters?
2. Why does the direct conductivity vanish, except in regions where the Hall conductivity jumps between integer values, and how are such jumps possible?

Moreover, any theory must also explain why these features are not present under the more normal conditions of the classical Hall effect. The following features seem to play a role, and in the case of the first three, even in the classical effect.

1. As Hall discovered, the samples must be very thin to exhibit even the classical effect. (Nowadays they are often a surface layer between two semiconductors.)
2. The samples are macroscopic and much larger than the quantum wavelengths appearing in the problem.
3. The electric field is small enough that nonlinear effects are negligible.
4. The quantum effect appears only at a very low temperature.

The first of these suggests that we should idealize to the case where the motion of the charge carriers is restricted to a two-dimensional region, and the second that we may work in the thermodynamic limit where the conducting surface is the whole of $\boldsymbol{R}^2$. The third and fourth ensure both that the linear Ohm's law should be adequate, and also that it should be enough to consider the limiting cases of very weak electric fields and zero temperature. Multiple limits of this sort raise delicate mathematical issues. Indeed, many plausible models of the effect turn out, on careful analysis, to predict vanishing Hall conductivity.

A theoretical explanation of the quantization of the conductivity was soon suggested by Laughlin. Exploiting the apparent independence of sample geometry, he considered a cylindrical conductor where quantization followed on consideration of

the flux tubes threading it. Laughlin's choice of a particular configuration precluded investigation of the influence of changing geometry. This was soon provided by Thouless, Kohmoto, Nightingale, and de Nijs, who argued (from a lattice version of the problem) that the conductivity could be identified with the Chern character of a line bundle over a Brillouin zone (a quotient of momentum space by the action of the reciprocal crystal lattice), so that it had to be integral and the stability of the effect was a consequence of the topological nature of $\sigma$. Unfortunately, whilst suggestive, this explanation worked only under the physically implausible constraint that the magnetic flux through a crystal cell was rational, offered no explanation of the link between the Hall and direct conductivities, and, working with a periodic Hamiltonian, made no allowance for the impurities and disorder usually important in solid-state problems of this sort.

Notwithstanding these deficiencies, this model contained important insights, which inspired Bellissard to model the effect using Connes' newly developed noncommutative geometry (Bellissard 1986, Connes 1986). (Kunz produced a Hilbert space theory at about the same time, but that has been rather less influential.) Connes' work turned out to contain all the relevant concepts and tools needed to provide a good understanding of the effect, based on interpreting the conductivity as a noncommutative Chern character for a noncommutative version of the Brillouin zone. In fact, the techniques of noncommutative geometry seemed to fit the quantum Hall effect so well that this has become one of the standard examples of the theory.

Even whilst the theorists were struggling to explain the experiments, observations by Tsui, Störmer, and Gossard showed that, with suitable care, fractional Hall conductivities could also be observed, although these were far less stable than those given by integers. One, therefore, distinguishes between IQHE and the fractional quantum Hall effect (FQHE), and this survey concentrates largely on the former. One simplifying feature of the IQHE is that it seems to be comprehensible at the level of individual noninteracting electrons, whereas the FQHE certainly involves some kind of interaction and many-body theory.

This article presents an outline of the connection between noncommutative differential geometry and the IQHE, and concludes by discussing some of the approaches to the FQHE, and some other applications of noncommutative geometry and mathematical directions suggested by the theory. The sections alternate between the physical model and the mathematical abstraction from it.

There are good surveys of the area (Bellissard *et al.* 1994, McCann 1998) explaining how the mathematical model arises out of the physics, the mathematical models themselves. As well as being the standard reference for noncommutative geometry, Connes (1994) discusses the Hall effect. These resources contain good bibliographies, which may be consulted for further references.

## Electron Motion in a Magnetic Field

The following discussion restricts attention to motion in two dimensions, with electrons as the charge carriers, and no interactions between them. (The first condition is essential; the second could be relaxed a little to allow sufficiently long-lived quasi-particles.) A single free electron with mass $m$ and charge $e$ moving in the $x_1$–$x_2$ plane with a constant transverse magnetic field $\boldsymbol{B}$ in the positive $x_3$-direction, can be described by the Landau Hamiltonian

$$H_{\mathrm{L}} = |\boldsymbol{P} - e\boldsymbol{A}|^2/2m \qquad [1]$$

where $\boldsymbol{A} = \frac{1}{2}\boldsymbol{B} \times \boldsymbol{X}$ is a magnetic vector potential that gives rise to $\boldsymbol{B}$. This problem is exactly solvable by, for example, introducing $\boldsymbol{K}_{\pm} = (K_{\pm}^1, K_{\pm}^2) = \boldsymbol{P} \mp e\boldsymbol{A}$. The components of $\boldsymbol{K}_+$ and $\boldsymbol{K}_-$ commute with each other, but $[K_{\pm}^1, K_{\pm}^2] = \pm i\hbar eB$. Comparison with the harmonic oscillator shows that the energy spectrum of $H_{\mathrm{L}} = [(K_+^1)^2 + (K_+^2)^2]/2m$ is $\{(n + \frac{1}{2})\hbar eB/m \colon n \in \boldsymbol{Z}\}$. Since $H_{\mathrm{L}}$ commutes with the components of $\boldsymbol{K}_-$, each of these Landau energy levels is infinitely degenerate, and the filling fraction $\nu$ measures what proportion of states in the Landau levels are filled. The frequency $\omega_c = eB/m$ is the cyclotron frequency for classical circular orbits in the magnetic field.

The degeneracy of the Landau Hamiltonian can also be understood in terms of the magnetic translations obtained by exponentiating the connection defined by the magnetic potential $\boldsymbol{A}$: $\nabla_j = \partial_j + ieA_j/\hbar = iK_-^j/\hbar$. More precisely, we set

$$U(\boldsymbol{a}) = \exp(-i\boldsymbol{a} \cdot \nabla) = \exp(-i\boldsymbol{a} \cdot \boldsymbol{K}_-/\hbar) \qquad [2]$$

which clearly commutes with $H_{\mathrm{L}}$, expressing the translational symmetry of this model. The curvature $[\nabla_1, \nabla_2] = B$ of the connection manifests itself in the identities

$$U(\boldsymbol{a})U(\boldsymbol{b}) = e^{(1/2)i\phi}U(\boldsymbol{a} + \boldsymbol{b}) = e^{i\phi}U(\boldsymbol{b})U(\boldsymbol{a}) \qquad [3]$$

where $\phi = e\boldsymbol{B} \cdot (\boldsymbol{a} \times \boldsymbol{b})/\hbar$ measures the magnetic flux through the parallelogram spanned by $\boldsymbol{a}$ and $\boldsymbol{b}$. These show that $U$ is a projective representation of $\boldsymbol{R}^2$ with projective multiplier $\lambda(\boldsymbol{a}, \boldsymbol{b}) = \exp(\frac{1}{2}i\phi)$.

The significance of this is that, unless $\phi$ is an integer multiple of $2\pi$, $U(\boldsymbol{a})$ and $U(\boldsymbol{b})$ generate a noncommutative algebra. This replaces the commutative algebra of functions on two-dimensional momentum space and leads naturally to a noncommutative geometry.

The unembellished Landau Hamiltonian cannot describe the Hall effect without adding an electric potential $e\boldsymbol{E}\cdot\boldsymbol{X}$ to drive the current in the sample. (Alternatively, and useful for the later discussion, one could use the radiation gauge in which, instead of introducing a scalar potential, a time-dependent term is added to $\boldsymbol{A}$ so that $\boldsymbol{E}=-\partial\boldsymbol{A}/\partial t$.)

The quantum Hall effect also depends crucially on the effects of impurities in the conducting material. These can be modeled by adding a random potential $V_\omega$ with $\omega$ in a compact probability space $\Omega$ to obtain $H_\omega = H_\mathrm{L} + e\boldsymbol{E}\cdot\boldsymbol{X} + V_\omega(X)$. A continuous function $f$ on $\Omega$ can be interpreted as a random variable, and its expectation $\tau_\Omega(f)$ gives a trace on the $C^*$-algebra $C(\Omega)$ (i.e., a positive linear functional such that $\tau_\Omega(AB)=\tau_\Omega(BA)$).

Although the magnetic translations commute with $H_\mathrm{L}$, they do not generally commute with the potentials so they act on $\Omega$, but, on the other hand, the physics of a disordered system and its translates should be the same, so we assume that the probability measure and hence also $\tau_\Omega$ are invariant under magnetic translations. (As noted earlier, we work in the thermodynamic limit, where the Hall sample expands to fill $\boldsymbol{R}^2$, so we do not need to worry about translations moving the sample itself.) Then $\Omega$ with the magnetic translation action can be interpreted as the noncommutative Brillouin zone. (A space $\Omega$ can be reconstructed from the magnetic translations of the resolvents of the Hamiltonians (Bellisard *et al.* 1994).)

The current $\boldsymbol{J}$ may be defined as the functional derivative of the Hamiltonian with respect to the vector potential $\boldsymbol{A}$ or, in components, $J_k = \delta_k H = \delta H/\delta A_k$. For the Landau Hamiltonian, this gives

$$\mathrm{i}\hbar\delta_k H_\mathrm{L} = \mathrm{i}e\hbar(P_k - eA_k)/m = e[X_k, H_\mathrm{L}] \qquad [4]$$

a relation which persists for $H = H_\mathrm{L} + V(X)$ whenever the potential $V$ is independent of $\boldsymbol{A}$, so that $\delta_k H = -\mathrm{i}e[X_k, H]/\hbar = e\,\mathrm{d}X_k/\mathrm{d}t$, the charge times velocity, as one might expect. The operator functional calculus delivers a similar formula for derivations of the spectral projections of $H$. We have $\delta_k = e\partial_k/\hbar$, where, in view of the commutation relations, $\partial_k = -\mathrm{i}[X_k, \cdot\,]$ can be regarded as a momentum-space derivative, confirming that we are dealing with the differential geometry of momentum space.

We now wish to calculate the expected current $\langle J_k\rangle$, in a thermal state with chemical potential $\mu$ at inverse temperature $\beta = 1/kT$ (where $k$ is Boltzmann's constant and the temperature is $T$(kelvin). Using the Fermi–Dirac distribution, the grand canonical expectation value is

$$\langle J_k\rangle = \mathrm{tr}\left[\left(1+\mathrm{e}^{-\beta(H-\mu)}\right)^{-1} J_k\right] \qquad [5]$$

Since the quantum Hall effect occurs at low temperatures (large $\beta$) and for weak fields, we formally proceed to those limits. Then $(1+\mathrm{e}^{-\beta(H-\mu)})^{-1}$ tends to the projection $P_\mathrm{F}$ onto the states with energy less than the Fermi energy $E_\mathrm{F}$ in the absence of the electric field. The limiting expected current is, therefore, $\mathrm{tr}(P_\mathrm{F}J_k) = \mathrm{tr}(P_\mathrm{F}\delta_k H)$, where $H$ is now the Hamiltonian including the electric field (without which there would be no current).

A detailed calculation of the Hall conductivity using the Kubo–Greenwood formula shows that the conductivity matrix is actually

$$\sigma_{kj} = \mathrm{i}(e^2/\hbar)\mathrm{tr}(P_\mathrm{F}[\partial_j P_\mathrm{F}, \partial_k P_\mathrm{F}]) \qquad [6]$$

In particular, this immediately implies that the direct conductivity terms $\sigma_{jj}$ vanish, as observation suggested. The derivation of [6] requires great care, and references may be found in the surveys, but a formal argument in the next section may lend this expression some plausibility.

## The Noncommutative Geometry

The principal ingredient for noncommutative geometry is an algebra, and thus we shall now consider a class of algebras broad enough to include the physical example.

The action of the magnetic translations on $\Omega$ defines automorphisms of the $C^*$-algebra $C(\Omega)$, which permit the construction of a twisted crossed-product algebra, in which these automorphisms are represented by conjugation. Because much of the theory has been formulated with lattice approximations using $\boldsymbol{Z}^2$ rather than $\boldsymbol{R}^2$, it is useful to work more generally with a separable locally compact abelian group $G$ with continuous multiplier $\lambda$, and a homomorphism $\alpha$ to automorphisms of a $C^*$-algebra $\mathcal{A}_1$ with trace $\tau_1$, which will in practice be the commutative algebra $C(\Omega)$ with $\tau_\Omega$. The twisted crossed product $\mathcal{A} = C(\mathcal{A}_1, G, \lambda)$ can be constructed as the norm completion of the continuous compactly

supported functions from $G$ to $\mathcal{A}_1$ with the product, adjoint and norm

$$(f^*g)(x) = \int_G \lambda(y, x-y) f(y)(\alpha_y g)(x-y)\,\mathrm{d}y \quad [7]$$

$$f^*(x) = \lambda(x, -x)^{-1} f(-x)^* \quad [8]$$

$$\|f\| = \max\left\{\int_G \|f(x)\|_{\mathcal{A}_1}\,\mathrm{d}x, \int_G \|f^*(x)\|_{\mathcal{A}_1}\,\mathrm{d}x\right\} \quad [9]$$

integration being with respect to the Haar measure. The crossed-product algebra is noncommutative, both because of the action of $G$ and due to the multiplier $\lambda$. It has a trace $\tau[f] = \tau_1[f(0)]$ and, when $G = \boldsymbol{R}^2$, has derivations given by $\partial_k f = -\mathrm{i}x_k f(\boldsymbol{x})$.

As an example, consider the case of periodic potentials invariant under translation by vectors $\boldsymbol{a}$ and $\boldsymbol{b}$. Then the group $G \cong \boldsymbol{Z}^2$ generated by $\boldsymbol{a}$ and $\boldsymbol{b}$ acts trivially on $\Omega$ and the crossed-product algebra is just a product of $\mathcal{A}_1$ and the twisted group algebra of complex-valued functions $C(\boldsymbol{C}, G, \lambda)$, generated by $U(\boldsymbol{a})$ and $U(\boldsymbol{b})$. We already noted that the algebra is commutative only when the flux $\phi \in 2\pi\boldsymbol{Z}$, in which case it is just the convolution algebra of $\boldsymbol{Z}^2$, which by Fourier transforming (effectively setting $U(\boldsymbol{a}) = \mathrm{e}^{\mathrm{i}\alpha}$ and $U(\boldsymbol{b}) = \mathrm{e}^{\mathrm{i}\beta}$) is the algebra $C(\boldsymbol{T}^2)$, with torus coordinates $\alpha$ and $\beta$. For fluxes which are rational multiples of $2\pi$ we obtain a matrix algebra, whilst irrational fluxes give an infinite-dimensional irrational rotation algebra or noncommutative torus, a standard example in noncommutative geometry.

Any $*$-representation $\rho$ of $\mathcal{A}_1$ on a Hilbert space $\mathcal{H}_\rho$ can be induced to a $*$-representation $\pi_\rho$ of the twisted crossed product on $\mathcal{H} = L^2(G, \mathcal{H}_\rho)$ by setting

$$(\pi_\rho(f)\psi)(x) = \int_G \lambda(x, y-x)^{-1} \rho(\alpha_{-x} f)(y-x)\psi(y)\,\mathrm{d}y \quad [10]$$

for $f \in \mathcal{A}$ and $\psi \in \mathcal{H}$. When $\mathcal{A}_1 = \mathrm{C}(\Omega)$, we may take $\rho$ to be a one-dimensional irreducible $*$-representations given by evaluating the function at a point $\omega \in \Omega$.

When $G = \boldsymbol{R}^2$, it is easy to construct a Fredholm module from $\pi_\rho$. The space $\mathcal{H}_2 = \mathcal{H} \otimes \boldsymbol{C}^2$ has actions $\pi_\rho$ of $\mathcal{A}$ on the first factor and of the Pauli spin matrices $\sigma_1, \sigma_2, \sigma_3$, on the second. It may be regarded as a graded module with grading operator $\sigma_3$, and

$$F = (x_1^2 + x_2^2)^{-1/2}(x_1\sigma_1 + x_2\sigma_2) \quad [11]$$

provides a Connes–Fredholm involution which anticommutes with $\sigma_3$. Detailed technical results of Connes show how to use the supertrace on $\mathcal{H}_2$ and the Dixmier trace to interpret the physically important quantities in this setting.

We now turn to the formal derivation of the key alternative expression for the conductivity. In the abstract algebraic setting, when $p \in \mathcal{A}$ is a projection in the domain of a derivation $\delta$ the derivative of $(1-p)p = 0$ gives

$$0 = \delta((1-p)p) = (1-p)\delta(p) - \delta(p)p \quad [12]$$

and then an easy calculation leads to

$$[p, [\delta p, p]] = 2p(\delta p)p - (\delta p)p^2 - p^2(\delta p) = -\delta p \quad [13]$$

In the identity for elements $a$, $b$, $c$, and $h \in \mathcal{A}$

$$\begin{aligned} &\tau([a, [b, c]]h) - \tau(c[[h, a], b]) \\ &\quad = \tau([a, [b, c]h]) + \tau([b, c[h, a]]) = 0 \end{aligned} \quad [14]$$

we set $a = c = p$ and $b = \delta p$ to obtain

$$\tau([p, [\delta p, p]]h) = \tau(p[[h, p], \delta p]) \quad [15]$$

Combining this with [12] when $\tau \circ \delta = 0$, one obtains

$$\begin{aligned} \tau(p\delta h) &= \tau(\delta(ph)) - \tau(\delta(p)h) \\ &= \tau([p, [\delta p, p]]h) = \tau(p[[h, p], \delta p]) \end{aligned} \quad [16]$$

## The Hall Conductivity and Anderson Localisation

Substituting $p = P_\mathrm{F}$ and $h = H$ in formula [16] would give the current $\mathrm{tr}(P_\mathrm{F}[[H, P_\mathrm{F}], \delta P_\mathrm{F}])$. Since $\delta_k$ is proportional to the commutator with $X_k$, it is true that $\mathrm{tr} \circ \delta_k = 0$, but, unfortunately, $P_\mathrm{F}$ need not lie in the domain of $\delta_k$, and $H$ is unbounded, further compounding the difficulties. These are serious problems, although the situation is not quite as bad as it seems. Without the electrostatic term $e\boldsymbol{E} \cdot \boldsymbol{X}$ in $H, P_\mathrm{F}$ would have been a spectral projection with which $H$ would commute, so that

$$[H, P_\mathrm{F}] = e[\boldsymbol{E} \cdot \boldsymbol{X}, P_\mathrm{F}] = eE_j[X_j, P_\mathrm{F}] = \mathrm{i}eE_j\partial_j P_\mathrm{F} \quad [17]$$

and $H$ disappears from the formula, to be replaced by $\partial_j P_\mathrm{F}$. This would give the expected current $\mathrm{i}(e^2/\hbar)\mathrm{tr}(P_\mathrm{F}[\partial_j P_\mathrm{F}, \partial_k P_\mathrm{F}])E_j$, and the conductivity matrix

$$\sigma_{kj} = \mathrm{i}(e^2/\hbar)\mathrm{tr}(P_\mathrm{F}[\partial_j P_\mathrm{F}, \partial_k P_\mathrm{F}]) \quad [18]$$

given earlier (there is no need to scale by the thickness in two dimensions).

However it is derived, this expression for the conductivity only makes sense under suitable conditions, otherwise $\mathrm{tr}(P_F[\partial_j P_F, \partial_k P_F])$ might either be undefined (because $P_F$ is not differentiable) or might not be trace class. There is a simple condition sufficient to handle both these difficulties, which also leads to an interesting physical insight. From the obvious inequality

$$0 \le \mathrm{tr}\left[P_F(\partial_1 P_F \pm \mathrm{i}\partial_2 P_F)^*(\partial_1 P_F \pm \mathrm{i}\partial_2 P_F)\right] \quad [19]$$

$$= \mathrm{tr}\left[P_F\left((\partial_1 P_F)^2 + (\partial_2 P_F)^2\right)\right] \pm \mathrm{i}\,\mathrm{tr}(P_F[\partial_1 P_F, \partial_2 P_F]) \quad [20]$$

and the fact that $1 \ge P_F$, we deduce that

$$\mathrm{tr}\left[\left((\partial_1 P_F)^2 + (\partial_2 P_F)^2\right)\right] \ge \mathrm{tr}\left[P_F\left((\partial_1 P_F)^2 + (\partial_2 P_F)^2\right)\right] \ge |\mathrm{tr}(P_F[\partial_1 P_F, \partial_2 P_F])| \quad [21]$$

Thus, if $\mathrm{tr}[((\partial_1 P_F)^2 + (\partial_2 P_F)^2)]$ exists and is finite, then our expression for the conductivity is well defined. Mathematically, this is a Sobolev type condition. To see the physical significance, we recall that $\partial_k P_F = -\mathrm{i}[X_k, P_F]$, so that the condition is equivalent to the finiteness of $\mathrm{tr}[(X_1^2 + X_2^2)P_F{}^2] - \mathrm{tr}[(X_1 P_F)^2 + (X_2 P_F)^2]$.

This condition imposes a requirement for some localization in the system (when $P_F$ is a rank-1 projection, it reduces to the requirement that the variance $\langle X_1^2 + X_2^2\rangle - \langle X_1\rangle^2 - \langle X_2\rangle^2$ be finite). This links with a much older observation of Anderson that the interference caused by impurities in a crystal, which cancel at long range, should, at smaller distances, cause localized clumping. The mathematical development of this idea by Pastur provides an appropriate tool for handling the conditions for the valdiity of the conductivity formula. The impurities generating Anderson localization are provided in this model by the random potential in the Hamiltonian. It also leads us to restrict attention to the dense subalgebra $\mathcal{A}_0$ of $f \in \mathcal{A}$, where $\tau[(\partial_1 f)^*(\partial_1 f) + (\partial_2 f)^*(\partial_2 f)] < \infty$.

## The Integral Quantum Hall Effect

Having identified the features of physical interest, we can return to the abstract algebraic description with conductivity $\mathrm{i}(e^2/\hbar)\tau(p[\partial_j p, \partial_k p])$. The key observation is that this can be interpreted as the Connes pairing between a cyclic cocycle $c_\tau$ on $\mathcal{A}_0$ and the projection $p$ whose stable equivalence class represents an element of the $C^*$-algebraic $K$-theory, $K_0(\mathcal{A})$. Such pairings give noncommutative Chern characters. The cyclic cocycle is a trilinear form defined on elements $a_0, a_1, a_2 \in \mathcal{A}_0$ by

$$c_\tau(a_0, a_1, a_2) = \tau[a_0(\delta_1 a_1 \delta_2 a_2 - \delta_2 a_1 \delta_1 a_2)] \quad [22]$$

This is easily shown to be cyclic, $c_\tau(a_0, a_1, a_2) = c_\tau(a_1, a_2, a_0)$, and to satisfy the cyclic 2-cocycle condition

$$c_\tau(a_0 a_1, a_2, a_3) - c_\tau(a_0, a_1 a_2, a_3) + c_\tau(a_0, a_1, a_2 a_3) - c_\tau(a_3 a_0, a_1, a_2) = 0 \quad [23]$$

The Hall conductivity $\sigma_{21} = \mathrm{i}c_\tau(p, p, p)e^2/\hbar$ can now be interpreted as the noncommut ative Chern character defined by the projection $p$.

This interpretation of the Hall conductivity clears the way to prove that it is integral, and there are several different routes to this.

One approach is to identify the conductivity with some kind of index which is clearly integral. Bellissard worked with the Fredholm module where, by results of Connes, the Chern character is interpreted as the index of the Fredholm operator $\pi_\rho(p)F\pi_\rho(p)$. Avron, Seiler and Simon have interpreted the conductivity as a relative index $\dim[\ker(P_F - Q_F - 1)] - \dim[\ker(Q_F - P_F - 1)]$ of the projections $P_F$ and its conjugate $Q_F = uP_F u^*$ by an off-diagonal element $u$ of $F$. This is particularly interesting as the conjugation by $u$ can be interpreted as a nonsingular gauge transformation of exactly the kind introduced by Laughlin in his original explanation of the quantum Hall effect in terms of singular flux tubes piercing a cylindrical conductor.

Xia suggested another approach rewriting $\mathcal{A}$ as a repeated crossed product with $\boldsymbol{R}$, which allows us to calculate $K_0(\mathcal{A})$, using either Connes' Thom isomorphism theorem or the Takai duality theorem for stable algebras to get

$$K_0(\mathcal{A}) = K_0\left[C(\mathcal{A}_1, G, \lambda)\right] \cong K_0(\mathcal{A}_1) \quad [24]$$

which, when $\mathcal{A}_1 = C(\Omega)$, is just $K^0(\Omega)$, leading to identification as a topological index. For the simplest case of $\Omega = \boldsymbol{T}^2$, this gives $K^0(\Omega) \cong \boldsymbol{Z}^2$. The image of $\tau$, and so also $c_\tau$, actually sits in just one component, leading to quantization of the Hall conductivity.

The two questions posed in the introduction can now be answered as follows: The Hall conductivity can be identified with a topological index which can take only integer values, and therefore does not respond to continuous changes in any of the physical parameters until the change brings the system into a region where one of the background assumptions fails, such as a breakdown in the localization condition. The same conditions also ensure that the direct current vanishes. Roughly speaking, the

plateaus occur when the Fermi energy is in a gap in the extended (nonlocalized) spectrum.

This brief overview has omitted many of the interesting features of the detailed theory, which can be found in the surveys, such as the fact that low-lying energy levels do not contribute to the conductivity, and Shubin's theorem identifying $\tau(p)$ as the integrated density of states. Harper's equation describing a discrete lattice analog of the IQHE has been a test-bed for many of the ideas, and various results were first proved in that setting. The FQHE was discovered during an unsuccessful search for a Wigner crystal phase transition, but analysis of discrete models provides strong evidence that Hall conductors have very complicated phase diagrams.

## The Fractional Quantum Hall Effect

As mentioned in the introduction, by the time IQHE had been understood theoretically, it had been found that, with appropriate care, fractional conductivities could also be observed, although they were much less precise and stable than the integer values, and the plateaus less pronounced. Although there have been many phenomenological explanations, there is as yet no mathematical understanding from quantum field theory as compelling as that for the integer effect. We shall briefly summarize some of the main lines of attack.

The first explanation, again due to Laughlin, has also provided the basis for many subsequent treatments of the problem. The wave functions of the oscillator-like Landau Hamiltonian can conveniently be represented in the Bargmann–Segal Fock space of holomorphic functions $f$ on $\boldsymbol{R}^2 \sim \boldsymbol{C}$ which are square-integrable with respect to a Gaussian measure. Incorporating the measure into the functions, these have the form $f(z)\exp(-|z|^2/2)$. Many particle wave functions are similarly realized in terms of holomorphic functions on $\boldsymbol{C}^N$, and must be antisymmetric under odd permutations of the particles to describe fermions. This quickly leads one to consider functions of the form

$$\prod_{r<s}(z_r - z_s)^k \exp\left(-\sum_j |z_j|^2/2\right) \qquad [25]$$

for odd integers $k > 0$, and their multiples by even holomorphic functions. The lowest energy where such a wave function occurs is when $k = 1$, and larger values of $k$ have the effect of dividing the Hall conductivity by $k$, which produces fractional conductivities.

Halperin suggested quite early that counterflowing currents in the interior of a sample would tend to cancel, so that most of the current would be carried near the edge of the sample. There are several mathematical derivations of this, by, for example, Macris, Martin, and Pulé, and by Fröhlich, Graf, and Walcher. The $K$-theory of the boundary and bulk of a sample can be linked by exact sequences such as those of the commutative theory (Kellendonk *et al.* 2000), and even in the IQHE boundary and bulk conductivities can be used (Schulz-Baldes *et al.* 2002).

It has been fairly clear that whilst the IQHE can already be understood in terms of the motion of a single electron, the fractional effect is a many-body cooperative effect. One attempt to simplify the description is to work with an incompressible quantum fluid, and for edge currents one should study the boundary theory of such a fluid, in which the dominant contribution to the action is a Chern–Simons term, with conductivity as a coefficient. For an annular sample, this leads, in a suitable limit, to a chiral Luttinger model on the boundary circles, which can then be tackled mathematically using the representation theory of loop groups. This leads to some elegant mathematics, including extensions to multiple coupled bands, with conductivities described by Cartan matrices, as explained in the International Congress of Mathematicians (ICM) survey (Fröhlich 1995), and in the review by Fröhlich and Studer (1993).

The theory of composite fermions provides another physical approach in which field-theoretic effects result in the electrons sharing their charges in such a way as to produce fractional charges, and there is experimental evidence of such fractional charges in studies of tunneling from one edge to another. Then the FQHE is easily understood by simply replacing the electron charge $e$ by $e/k$ in the appropriate formulas.

Susskind has suggested combining noncommutative geometry with the theory of incompressible quantum fluids, an idea taken up by Polychronakos (2001). There are intriguing mathematical parallels with work by Berest and Wilson on ideals in the Weyl algebra and the Calogero–Moser model.

## Further Developments

Bellissard and others have extended the use of noncommutative geometrical methods into other parts of solid-state theory, where they clarify a number of the physical ideas. This is particularly useful in the case of quasicrystals, which are not easily handled by the conventional methods (Bellissard *et al.* 2000). Some ideas in string theory resemble higher-dimensional analogs, and higher-dimensional versions of the quantum Hall effect have also been studied by Hu and Zhang.

Finally, we conclude with some mathematical extensions of the theory. We have seen that, for periodic systems, the noncommutative Brillouin

zone can be a noncommutative torus, and it is possible to consider noncommutative versions of Riemann surfaces of higher genera. Carey *et al.* (1998) studied the effect in a noncommutative hyperbolic geometry with a discrete group action, generalizing the action of a Fuchsian group on the unit disc. This provides a tractable example in which one has an edge (albeit rather different from the normal physical situations) and also examples of a Hall effect in higher-genus noncommutative Riemann surfaces closely related to those of Klimek and Lesznewski. Natsumé and Nest have subsequently shown that these are deformation quantizations of the commutative Riemann surface theory in the sense of Rieffel. Coverings of noncommutative Riemann surfaces, which might provide an analoge of composite fermions, have been investigated by Marcolli and Mathai (1999, 2001).

# Quantum Mechanical Scattering Theory

**D R Yafaev**, Université de Rennes, Rennes, France

## Introduction

Scattering theory is concerned with the study of the large-time behavior of solutions of the time-dependent Schrödinger equation [1] for a system with a Hamiltonian $H$:

$$i\partial u/\partial t = Hu, \quad u(0) = f \qquad [1]$$

Being a part of the perturbation theory, scattering theory describes the asymptotics of $u(t)$ as $t \to +\infty$ or $t \to -\infty$ in terms of solutions of the Schrödinger equation for a "free" system with a Hamiltonian $H_0$. Of course, eqn [1] has a unique solution $u(t) = \exp(-iHt)f$, while the solution of the same equation with the operator $H_0$ and the initial data $u_0(0) = f_0$ is given by the formula $u_0(t) = \exp(-iH_0 t)f_0$. From the viewpoint of scattering theory, the function $u(t)$ has free asymptotics as $t \to \pm\infty$ if for appropriate initial data $f_0^{\pm}$ eqn [2] holds:

$$\lim_{t\to\pm\infty} \|u(t) - u_0^{\pm}(t)\| = 0 \qquad [2]$$

Here and throughout this article a relation containing the signs "±" is understood as two independent equalities. We emphasize that initial data $f_0^{\pm}$ are different for $t \to +\infty$ and $t \to -\infty$ and

$u_0^\pm(t) = \exp(-iH_0t)f_0^\pm$. Equation [2] leads to a connection between the corresponding initial data $f_0^\pm$ and $f$ given by

$$f = \lim_{t\to\pm\infty} \exp(iHt)\exp(-iH_0t)f_0^\pm \qquad [3]$$

If $f$ is an eigenvector of $H$, that is, $Hf = \lambda f$, then obviously $u(t) = e^{-i\lambda t}f$. On the contrary, if $f$ belongs to the (absolutely) continuous subspace of $H$, then necessarily $u(t)$ has the free asymptotics as $t \to \pm\infty$. This result is known as asymptotic completeness.

The Schrödinger operator $H = -\Delta + V(x)$ in the space $\mathcal{H} = L_2(\mathbb{R}^d)$ with a real potential $V$ decaying at infinity is a typical Hamiltonian of scattering theory. The operator $H$ describes a particle in an external potential $V$ or two interacting particles. Asymptotically (as $t \to +\infty$ or $t \to -\infty$), particles may either form a bound state or be free (a scattering state). Of course, a bound (scattering) state at $-\infty$ remains the same at $+\infty$. To be more precise, suppose that

$$|V(x)| \le C(1 + |x|)^{-\rho} \qquad [4]$$

where $\rho > 1$. Then relation [2] can be justified with the kinetic energy operator $H_0 = -\Delta$ playing the role of the unperturbed operator.

As discussed in Landau and Lifshitz (1965) (see also Amrein *et al.* (1977), Pearson (1988), and Yafaev (2000)), in scattering experiments one sends a beam of particles of energy $\lambda > 0$ in a direction $\omega$. Such a beam is described by the plane wave

$$\psi_0(x;\omega,\lambda) = \exp(ik\langle\omega, x\rangle), \quad \lambda = k^2 > 0$$

(which satisfies of course the free equation $-\Delta\psi_0 = \lambda\psi_0$). The scattered particles are described for large distances by the outgoing spherical wave

$$a(\hat{x},\omega;\lambda)|x|^{-(d-1)/2}\exp(ik|x|)$$

Here $\hat{x} = x|x|^{-1}$ is the direction of observation and the coefficient $a(\hat{x},\omega;\lambda)$ is known as the scattering amplitude. This means that quantum particles subject to a potential $V(x)$ are described by the solution $\psi$ of eqn [5] with asymptotics [6] at infinity:

$$-\Delta\psi + V(x)\psi = \lambda\psi \qquad [5]$$

$$\psi(x;\omega,\lambda) = \exp(ik\langle\omega,x\rangle) + a(\hat{x},\omega;\lambda)|x|^{-(d-1)/2}\exp(ik|x|) + o\left(|x|^{-(d-1)/2}\right) \qquad [6]$$

The existence of such solutions requires of course a proof. The differential scattering crosssection defined by eqn [7] gives us the part of particles scattered in a solid angle $d\hat{x}$:

$$d\sigma(\hat{x},\omega;\lambda) = |a(\hat{x},\omega;\lambda)|^2 d\hat{x} \qquad [7]$$

As discussed below, the temporal asymptotics of solutions of the time-dependent Schrödinger equation [1] are closely related to the asymptotics at large distances of solutions of the stationary Schrödinger equation [5].

## Time-Dependent Scattering Theory and Møller Operators

If $V(x) \to 0$ as $|x| \to \infty$, then the essential spectrum of the Schrödinger operator $H = -\Delta + V(x)$ covers the whole positive half-line, whereas the negative spectrum of $H$ consists of eigenvalues accumulating, perhaps, at the point zero only.

Scattering theory requires a more advanced classification of the spectrum based on measure theory. Consider a self-adjoint operator $H$ defined on domain $\mathcal{D}(H)$ in a Hilbert space $\mathcal{H}$. Let $E$ be its spectral family. Then the space $\mathcal{H}$ can be decomposed into the orthogonal sum of invariant subspaces $\mathcal{H}^{(p)}, \mathcal{H}^{(sc)}$ and $\mathcal{H}^{(ac)}$. The subspace $\mathcal{H}^{(p)}$ is spanned by eigenvectors of $H$ and the subspaces $\mathcal{H}^{(sc)}, \mathcal{H}^{(ac)}$ are distinguished by the condition that the measure $(E(X)f, f)$ (here $X \subset \mathbb{R}$ is a Borel set) is singularly or absolutely continuous with respect to the Lebesgue measure for all $f \in \mathcal{H}^{(sc)}$ or $f \in \mathcal{H}^{(ac)}$. Typically (in applications to quantum-mechanical problems) the singularly continuous part is absent, that is, $\mathcal{H}^{(sc)} = \{0\}$. We denote by $H^{(ac)}$ the restriction of $H$ on its absolutely continuous subspace $\mathcal{H}^{(ac)}$ and by $P^{(ac)}$ the orthogonal projection on this subspace. The same objects for the operator $H_0$ will be endowed with the index "0."

Equation [3] motivates the following fundamental definition. The wave, or Møller, operator $W_\pm = W_\pm(H, H_0)$ for a pair of self-adjoint operators $H_0$ and $H$ is defined by eqn [8] provided that the corresponding strong limit exists:

$$W_\pm = \operatorname*{s-lim}_{t\to\pm\infty} \exp(iHt)\exp(-iH_0t)P_0^{(ac)} \qquad [8]$$

The wave operator is isometric on $\mathcal{H}_0^{(ac)}$ and enjoys the intertwining property

$$HW_\pm = W_\pm H_0 \qquad [9]$$

Therefore, its range $\operatorname{Ran} W_\pm$ is contained in the absolutely continuous subspace $\mathcal{H}^{(ac)}$ of the operator $H$.

The operator $W_\pm(H, H_0)$ is said to be complete if eqn [10] holds:

$$\operatorname{Ran} W_\pm(H, H_0) = \mathcal{H}^{(ac)} \qquad [10]$$

It is easy to see that the completeness of $W_\pm(H, H_0)$ is equivalent to the existence of the "inverse" wave operator $W_\pm(H_0, H)$. Thus, if the wave operator $W_\pm(H, H_0)$ exists and is complete, then the operators $H_0^{(\mathrm{ac})}$ and $H^{(\mathrm{ac})}$ are unitarily equivalent. We emphasize that scattering theory studies not arbitrary unitary equivalence but only the "canonical" one realized by the wave operators.

Along with the wave operators an important role in scattering theory is played by the scattering operator defined by eqn [11] where $W_+^*$ is the operator adjoint to $W_+$:

$$S = S(H, H_0) = W_+^*(H, H_0)W_-(H, H_0) \qquad [11]$$

The operator $S$ commutes with $H_0$ and hence reduces to multiplication by the operator function $S(\lambda) = S(\lambda; H, H_0)$ in a representation of $\mathcal{H}_0^{(\mathrm{ac})}$ which is diagonal for $H_0^{(\mathrm{ac})}$. The operator $S(\lambda)$ is known as the scattering matrix. The scattering operator [11] is unitary on the subspace $\mathcal{H}_0^{(\mathrm{ac})}$ provided the wave operators $W_\pm(H, H_0)$ exist and are complete. The scattering operator $S(H, H_0)$ connects the asymptotics of the solutions of eqn [1] as $t \to -\infty$ and as $t \to +\infty$ in terms of the free problem, that is $S(H, H_0) : f_0^- \mapsto f_0^+$, where $f_0^\pm$ are the same as in eqn [2]. The scattering operator and the scattering matrix are usually of great interest in mathematical physics problems, because they connect the "initial" and the "final" characteristics of the process directly, bypassing its consideration for finite times.

The definition of the wave operators can be extended to self-adjoint operators acting in different spaces. Let $H_0$ and $H$ be self-adjoint operators in Hilbert spaces $\mathcal{H}_0$ and $\mathcal{H}$, respectively, and let "identification" $J : \mathcal{H}_0 \to \mathcal{H}$ be a bounded operator. Then the wave operator $W_\pm = W_\pm(H, H_0; J)$ for the triple $H_0, H$, and $J$ is defined by eqn [12] provided again that the strong limit there exists:

$$W_\pm = \operatorname*{s-lim}_{t\to\pm\infty} \exp(\mathrm{i}Ht)J\exp(-\mathrm{i}H_0t)P_0^{(\mathrm{ac})} \qquad [12]$$

Intertwining property [9] is preserved for wave operator [12]. This operator is isometric on $\mathcal{H}_0^{(\mathrm{ac})}$ if and only if

$$\lim_{t\to\pm\infty} \|J\exp(-\mathrm{i}H_0t)f_0\| = \|f_0\|$$

for all $f_0 \in \mathcal{H}_0^{(\mathrm{ac})}$. Since

$$\operatorname*{s-lim}_{|t|\to\infty} K\exp(-\mathrm{i}H_0t)P_0^{(\mathrm{ac})} = 0$$

for a compact operator $K$, wave operators [12] corresponding to identifications $J_1$ and $J_2$ coincide if $J_2 - J_1$ is compact or, at least, the operators $(J_2 - J_1)$ $E_0(X)$ are compact for all bounded intervals $X$. Consideration of wave operators [12] with $J \neq I$ may of course be of interest also in the case $\mathcal{H}_0 = \mathcal{H}$.

It suffices to verify the existence of limits [8] or [12] on some set dense in the absolutely continuous subspace $\mathcal{H}_0^{(\mathrm{ac})}$ of the operator $H_0$. The following simple but convenient condition for the existence of wave operators is usually called Cook's criterion. Suppose that $H_0 = H_0^{(\mathrm{ac})}$ and that the operator $J$ maps domain $\mathcal{D}(H_0)$ of the operator $H_0$ into $\mathcal{D}(H)$. Let

$$\int_0^{\pm\infty} \|(HJ - JH_0)\exp(-\mathrm{i}H_0t)f\|\mathrm{d}t < \infty$$

for all $f$ from some set $D_0 \subset \mathcal{D}(H_0)$ dense in $\mathcal{H}_0$. Then the wave operator $W_\pm(H, H_0; J)$ exists.

This result is often useful in applications since the operator $\exp(-\mathrm{i}H_0t)$ is known explicitly. For example, it works with $J = I$ for the pair

$$H_0 = -\Delta, \qquad H = H_0 + V(x) \qquad [13]$$

if $V(x)$ satisfies estimate [4] with $\rho > 1$. On the other hand, different proofs of the existence of the wave operators $W_\pm(H_0, H; J^*)$ require new mathematical tools. There are two essentially different approaches in scattering theory: the trace-class and smooth methods.

## Time-Independent Scattering Theory

The approach in scattering theory relying on definition [8] is called time dependent. An alternative possibility is to change the definition of wave operators replacing the unitary groups by the corresponding resolvents $R_0(z) = (H_0 - z)^{-1}$ and $R(z) = (H - z)^{-1}$. They are related by a simple identity

$$\begin{aligned} R(z) &= R_0(z) - R_0(z)VR(z) \\ &= R_0(z) - R(z)VR_0(z) \end{aligned} \qquad [14]$$

where $V = H - H_0$ and $\operatorname{Im} z \neq 0$. In the stationary approach in place of limits [8] one has to study the boundary values (in a suitable topology) of the resolvents as the spectral parameter $z$ tends to the real axis. An important advantage of the stationary approach is that it gives convenient formulas for the wave operators and the scattering matrix.

Let us discuss here the stationary formulation of the scattering problem for operators [13] in the Hilbert space $\mathcal{H} = L_2(\mathbb{R}^d)$ in terms of solutions of the Schrödinger equation [5]. If $V(x)$ satisfies estimate [4] with $\rho > (d+1)/2$, then for all $\lambda > 0$ and all unit vectors $\omega \in \mathbb{S}^{d-1}$, eqn [5] has the solution $\psi(x; \omega, \lambda)$ with asymptotics [6] as $|x| \to \infty$. Moreover, the scattering amplitude $a(\hat{x}, \omega; \lambda)$ belongs to the space

$L_2(\mathbb{S}^{d-1})$ in the variable $\hat{x}$ uniformly in $\omega \in \mathbb{S}^{d-1}$, and it can be expressed via $\psi(x;\omega,\lambda)$ by the formula

$$a(\theta,\omega;\lambda) = -\gamma_d(\lambda)\int_{\mathbb{R}^d} e^{-ik\langle\theta,x\rangle}V(x)\psi(x;\omega,\lambda)\,dx$$

where

$$\gamma_d(\lambda) = e^{-\pi i(d-3)/4}2^{-1}(2\pi)^{-(d-1)/2}\lambda^{(d-3)/4}$$

Let us define two sets of scattering solutions, or eigenfunctions of the continuous spectrum, by the formulas

$$\psi_-(x;\omega,\lambda) = \psi(x;\omega,\lambda) \text{ and } \psi_+(x;\omega,\lambda) = \overline{\psi(x;-\omega,\lambda)}$$

In terms of boundary values of the resolvent, the functions $\psi_\pm(\omega,\lambda)$ can be constructed by the formula

$$\psi_\pm(\omega,\lambda) = \psi_0(\omega,\lambda) - R(\lambda \mp i0)V\psi_0(\omega,\lambda) \qquad [15]$$

Obviously, functions [15] satisfy eqn [5]. Using resolvent identity [14], it is easy to derive the Lippmann–Schwinger equation

$$\psi_\pm(\omega,\lambda) = \psi_0(\omega,\lambda) - R_0(\lambda \mp i0)V\psi_\pm(\omega,\lambda)$$

for $\psi_\pm(\omega,\lambda)$. Asymptotics [6] can be deduced from the formula

$$(R_0(\lambda \pm i0)f)(x) = c_\pm(\lambda)(\Gamma_0(\lambda)f)(\pm\hat{x})|x|^{-(d-1)/2} \times \exp(\pm ik|x|) + O(|x|^{-(d+1)/2})$$

where $f \in C_0^\infty(\mathbb{R}^d)$, $c_\pm(\lambda) = \pi^{1/2}\lambda^{-1/4}e^{\mp i\pi(d-3)/4}$ and the operator $\Gamma_0(\lambda)$ defined by eqn [16] is (up to the numerical factor) the restriction of the Fourier transform $\hat{f} = \mathcal{F}_0 f$ onto the sphere of radius $\lambda^{1/2}$:

$$(\Gamma_0(\lambda)f)(\omega) = 2^{-1/2}\lambda^{(d-2)/4}\hat{f}(\lambda^{1/2}\omega), \quad \omega \in \mathbb{S}^{d-1} \qquad [16]$$

The wave operators $W_\pm(H,H_0)$ can be constructed in terms of the solutions $\psi_\pm$. Set $\xi = \lambda^{1/2}\omega$ ($\xi$ is the momentum variable), write $\psi_\pm(x,\xi)$ instead of $\psi_\pm(x;\omega,\lambda)$, and consider two transformations

$$(\mathcal{F}_\pm f)(\xi) = (2\pi)^{-d/2}\int_{\mathbb{R}^d}\overline{\psi_\pm(x,\xi)}f(x)\,dx \qquad [17]$$

(defined initially, e.g., on the Schwartz class $\mathcal{S}(\mathbb{R}^d)$) of the space $L_2(\mathbb{R}^d)$ into itself. The operators $\mathcal{F}_\pm$ can be regarded as generalized Fourier transforms, and both of them coincide with the usual Fourier transform $\mathcal{F}_0$ if $V=0$. It follows from eqns [5], [17] that under the action of $\mathcal{F}_\pm$ the operator $H$ goes over into multiplication by $|\xi|^2$, that is,

$$(\mathcal{F}_\pm Hf)(\xi) = |\xi|^2(\mathcal{F}_\pm f)(\xi)$$

Moreover, with the help of eqn [15], it can be shown that $\mathcal{F}_\pm$ is an isometry on $\mathcal{H}^{(ac)}$, it is zero on $\mathcal{H} \ominus \mathcal{H}^{(ac)}$, and its range Ran $\mathcal{F}_\pm = L_2(\mathbb{R}^d)$. This is equivalent to eqns [18]:

$$\mathcal{F}_\pm^*\mathcal{F}_\pm = P^{(ac)}, \qquad \mathcal{F}_\pm\mathcal{F}_\pm^* = I \qquad [18]$$

Hence any function $f \in \mathcal{H}^{(ac)}$ admits the expansion in the generalized Fourier integral

$$f(x) = (2\pi)^{-d/2}\int_{\mathbb{R}^d}\psi_\pm(x,\xi)(\mathcal{F}_\pm f)(\xi)\,d\xi$$

It can also be deduced from eqn [6] that the vector

$$(\mathcal{F}_\pm^* - \mathcal{F}_0^*)\exp(-i|\xi|^2t)\hat{f}$$

tends to zero as $t \to \pm\infty$ for an arbitrary $\hat{f} \in L_2(\mathbb{R}^d)$. This implies the existence of the wave operators $W_\pm = W_\pm(H,H_0)$ for pair [13] and gives the representation

$$W_\pm = \mathcal{F}_\pm^*\mathcal{F}_0 \qquad [19]$$

Completeness of $W_\pm$ follows from eqn [19] and the first equation in [18]. The second equality in [18] is equivalent to the isometricity of $W_\pm$. Formula [19] is an example of a stationary representation for the wave operator. It formally implies that

$$W_\pm\psi_0(\omega,\lambda) = \psi_\pm(\omega,\lambda)$$

which means that each wave operator establishes a one-to-one correspondence between eigenfunctions of the continuous spectrum of the operators $H_0$ and $H$.

The main ideas of the stationary approach go back to Friedrichs (1965), and Povzner. The inverse problem of reconstruction of a potential $V$ given the scattering amplitude $a$ (see eqn [6]) is treated in Faddeev (1976).

## The Trace-Class Method

Recall that the class $\mathfrak{S}_p, p \geq 1$, consists of compact operators $T$ such that the norm

$$\|T\|_p = \left(\sum_n \lambda_n^p(|T|)\right)^{1/p}, \quad |T| = (T^*T)^{1/2}$$

is finite. Eigenvalues $\lambda_n(|T|) =: s_n(T)$ of a non-negative operator $|T|$ are called singular numbers of $T$. In particular, $\mathfrak{S}_1$ is the trace class and $\mathfrak{S}_2$ is the Hilbert–Schmidt class.

The trace-class method (see Reed and Simon (1976) or Yafaev (1992) for a detailed presentation) makes no assumptions about the "unperturbed" operator $H_0$. Its basic result is the following theorem of Kato and Rosenblum. If $V = H - H_0$ belongs to the trace class

$\mathfrak{S}_1$, then the wave operators $W_\pm(H, H_0)$ exist and are complete. In particular, the operators $H_0^{(ac)}$ and $H^{(ac)}$ are unitarily equivalent. This can be considered as a far advanced extension of the H Weyl theorem, which states the stability of the essential spectrum under compact perturbations.

The condition $V \in \mathfrak{S}_1$ in the Kato–Rosenblum theorem cannot be relaxed in the framework of operator ideals $\mathfrak{S}_p$. This follows from the Weyl–von Neumann–Kuroda theorem. Let $H_0$ be an arbitrary self-adjoint operator. For any $p > 1$ and any $\varepsilon > 0$ there exists a self-adjoint operator $V$ such that $V \in \mathfrak{S}_p$, $\|V\|_p < \varepsilon$ and the operator $H = H_0 + V$ has purely point spectrum. Of course, such an operator $H$ has no absolutely continuous part. At the same time, the operator $H_0$ may be absolutely continuous. In this case, the wave operators $W_\pm(H, H_0)$ do not exist.

Although sharp in the abstract framework, the Kato–Rosenblum theorem cannot directly be applied to the theory of differential operators where a perturbation is usually an operator of multiplication and hence is not even compact. We mention its two generalizations applicable to this theory. The first, the Birman–Kato–Kreĭn theorem, claims that the wave operators $W_\pm(H, H_0)$ exist and are complete provided

$$R^n(z) - R_0^n(z) \in \mathfrak{S}_1$$

for some $n = 1, 2, \ldots$ and all $z$ with $\operatorname{Im} z \neq 0$. The second, the Birman theorem, asserts that the same is true if $\mathcal{D}(H) = \mathcal{D}(H_0)$ or $\mathcal{D}(|H|^{1/2}) = \mathcal{D}(|H_0|^{1/2})$ and

$$E(X)(H - H_0)E_0(X) \in \mathfrak{S}_1$$

for all bounded intervals $X$.

The wave operators enjoy the following property known as the Birman invariance principle. Suppose that $\varphi(H) - \varphi(H_0) \in \mathfrak{S}_1$ for a real function $\varphi$ such that its derivative $\varphi'$ is absolutely continuous and $\varphi'(\lambda) > 0$. Then the wave operators $W_\pm(H, H_0)$ exist and eqn [20] holds:

$$W_\pm(H, H_0) = W_\pm(\varphi(H), \varphi(H_0)) \qquad [20]$$

A direct generalization of the Kato–Rosenblum theorem to the operators acting in different spaces is due to Pearson. Suppose that $H_0$ and $H$ are self-adjoint operators in spaces $\mathcal{H}_0$ and $\mathcal{H}$, respectively, $J : \mathcal{H}_0 \to \mathcal{H}$ is a bounded operator and $V = HJ - JH_0 \in \mathfrak{S}_1$. Then the wave operators $W_\pm(H, H_0; J)$ and $W_\pm(H_0, H; J^*)$ exist.

Although rather sophisticated, the proof relies only on the following elementary lemma of Rosenblum. For a self-adjoint operator $H$, consider the set $\mathfrak{R} \subset \mathcal{H}^{(ac)}$ of elements $f$ such that

$$r_H^2(f) := \operatorname{ess\,sup}\, \mathrm{d}(E(\lambda)f, f)/\mathrm{d}\lambda < \infty$$

If $K : \mathcal{H} \to \mathcal{G}$ ($\mathcal{G}$ is some Hilbert space) is a Hilbert–Schmidt operator, then for all $f \in \mathfrak{R}$

$$\int_{-\infty}^{\infty} \|K \exp(-\mathrm{i}Ht)f\|^2 \,\mathrm{d}t \leq 2\pi r_H^2(f)\|K\|_2^2 \qquad [21]$$

Moreover, the set $\mathfrak{R}$ is dense in $\mathcal{H}^{(ac)}$.

The Pearson theorem allows to simplify considerably the original proofs of different generalizations of the Kato–Rosenblum theorem.

A typical application of the trace-class theory is the following result. Suppose that

$$\mathcal{H} = L_2(\mathbb{R}^d),\ H_0 = -\Delta + V_0(x),\ H = H_0 + V(x) \qquad [22]$$

where the functions $V_0$ and $V$ are real, $V_0 \in L_\infty(\mathbb{R}^d)$ and $V$ satisfies estimate [4] for some $\rho > d$. Then the wave operators $W_\pm(H, H_0)$ exist and are complete.

## The Smooth Method

The smooth method (see Kuroda (1978), Reed and Simon (1979), or Yafaev (1992), for a detailed presentation) relies on a certain regularity of the perturbation in the spectral representation of the operator $H_0$. There are different ways to understand regularity. For example, in the Friedrichs–Faddeev model $H_0$ acts as multiplication by independent variable in the space $\mathcal{H} = L_2(\Lambda; \mathfrak{N})$, where $\Lambda$ is an interval and $\mathfrak{N}$ is an auxiliary Hilbert space. The perturbation $V$ is an integral operator with sufficiently smooth kernel.

Another possibility is to use the concept of $H$-smoothness introduced by Kato. An $H$-bounded operator $K$ is called $H$-smooth if, for all $f \in \mathcal{D}(H)$,

$$\int_{-\infty}^{\infty} \|K \exp(-\mathrm{i}Ht)f\|^2 \,\mathrm{d}t \leq C\|f\|^2 \qquad [23]$$

(cf. eqns [21] and [23]). Here and below, $C$ are different positive numbers whose precise values are inessential. It is important that this definition admits equivalent reformulations in terms of the resolvent or of the spectral family. Thus, $K$ is $H$-smooth if and only if

$$\sup_{\lambda \in \mathbb{R}, \varepsilon > 0} \|K(R(\lambda + \mathrm{i}\varepsilon) - R(\lambda - \mathrm{i}\varepsilon))K^*\| < \infty$$

or if and only if

$$\sup |X|^{-1} \|KE(X)\|^2 < \infty$$

for all intervals $X \subset \mathbb{R}$.

In applications the assumption of $H$-smoothness of an operator $K$ imposes too stringent conditions on the operator $H$. In particular, the operator $H$ is necessarily absolutely continuous if kernel of $K$ is trivial. This assumption excludes eigenvalues and other singular points in the spectrum of $H$, for

example, the bottom of the continuous spectrum for the Schrödinger operator with decaying potential or edges of bands if the spectrum has the band structure. The notion of local $H$-smoothness suggested by Lavine is considerably more flexible. By definition, $K$ is called $H$-smooth on a Borel set $X \subset \mathbb{R}$ if the operator $KE(X)$ is $H$-smooth. Note that, under the assumption

$$\sup_{\lambda \in X, \varepsilon > 0} \| K(R(\lambda + \mathrm{i}\varepsilon) - R(\lambda - \mathrm{i}\varepsilon))K^* \| < \infty \qquad [24]$$

the operator $K$ is $H$-smooth on the closure of $X$.

The following Kato–Lavine theorem is simple but very useful. Suppose that

$$HJ - JH_0 = K^* K_0$$

where the operators $K_0$ and $K$ are $H_0$-smooth and $H$-smooth, respectively, on an arbitrary compact subinterval of some interval $\Lambda$. Then the wave operators

$$W_\pm(H, H_0; JE_0(\Lambda)) \text{ and } W_\pm(H_0, H; J^* E(\Lambda))$$

exist (and are adjoint to each other).

This result cannot usually be applied directly since the verification of $H_0$- and especially of $H$-smoothness may be a difficult problem. Let us briefly explain how it can be done on the example of pair [10], where the potential $V(x)$ satisfies estimate [4] for some $\rho > 1$. Let us start with the operator $H_0 = -\Delta$. Denote by $L_2^{(l)} = L_2^{(l)}(\mathbb{R}^d)$ the Hilbert space with the norm $\|f\|_l = \|\langle x \rangle^l f\|$, where $\langle x \rangle = (1 + |x|^2)^{1/2}$. Let the operator $\Gamma_0(\lambda)$ be defined by eqn [16], and let $X \subset (0, \infty)$ be some compact interval. Set $\mathfrak{N} = L_2(\mathbb{S}^{d-1})$. If $f \in L_2^{(l)}$ with $l > 1/2$, then, by the Sobolev trace theorem,

$$\begin{aligned} \|\Gamma_0(\lambda) f\|_{\mathfrak{N}} &\leq C \|f\|_l \\ \|\Gamma_0(\lambda) f - \Gamma_0(\lambda') f\|_{\mathfrak{N}} &\leq C |\lambda - \lambda'|^\alpha \|f\|_l \end{aligned} \qquad [25]$$

for an arbitrary $\alpha \leq l - 1/2, \alpha < 1$ and all $\lambda, \lambda' \in X$. These estimates imply that the function

$$(E_0(\lambda) f, f) = \int_{|\xi|^2 < \lambda} |\hat{f}(\xi)|^2 \, \mathrm{d}\xi \qquad [26]$$

is differentiable and the derivative

$$\mathrm{d}(E_0(\lambda) f, f)/\mathrm{d}\lambda = \|\Gamma_0(\lambda) f\|_{\mathfrak{N}}^2, \quad f \in L_2^{(l)}, \ l > 1/2$$

is Hölder-continuous in $\lambda > 0$ (uniformly in $f$, $\|f\|_l \leq 1$). Therefore, applying the Privalov theorem to the Cauchy integral

$$(R_0(z) f, f) = \int_0^\infty (\lambda - z)^{-1} \, \mathrm{d}(E_0(\lambda) f, f)$$

we obtain that the analytic operator function

$$\mathcal{R}_0(z) = \langle x \rangle^{-l} R_0(z) \langle x \rangle^{-l}, \quad l > 1/2$$

considered in the space $\mathcal{H}$, is continuous in norm in the closed complex plane $\mathbb{C}$ cut along $(0, \infty)$ with possible exception of the point $z = 0$. This implies $H_0$-smoothness of the operator $\langle x \rangle^{-l}, l > 1/2$, on all compact intervals $X \subset (0, \infty)$.

To obtain a similar result for the operator $H$, we proceed from the resolvent identity [14]. Let $\mathcal{R}(z) = \langle x \rangle^{-l} R(z) \langle x \rangle^{-l}$, and let $B$ be the operator of multiplication by the bounded function $(1 + |x|)^\rho V(x)$. If

$$f + \mathcal{R}_0(z) B f = 0$$

then $\psi = R_0(z) \langle x \rangle^{-l} B f$ satisfies the Schrödinger equation $H\psi = z\psi$. Since $H$ is self-adjoint, this implies that $\psi = 0$ and hence $f = 0$. Using eqn [14], we obtain that

$$\mathcal{R}(z) = (I + \mathcal{R}_0(z) B)^{-1} \mathcal{R}_0(z), \quad \operatorname{Im} z \neq 0 \qquad [27]$$

because the inverse operator here exists by the Fredholm alternative.

The operator function $(I + \mathcal{R}_0(z) B)^{-1}$ is analytic in the complex plane cut along $(0, \infty)$ with possible exception of poles (coinciding with eigenvalues of $H$) on the negative half-axis. Moreover, $(I + \mathcal{R}_0(z) B)^{-1}$ is continuous up to the cut except the set $\mathcal{N} \subset (0, \infty)$ of $\lambda$ where at least one of the homogeneous equations

$$f + \mathcal{R}_0(\lambda \pm \mathrm{i}0) B f = 0 \qquad [28]$$

has a nontrivial solution. It follows from eqn [27] that the same is true for the operator function $\mathcal{R}(z)$. It can be shown that the set $\mathcal{N}$ is closed and has the Lebesgue measure zero. Let $\Lambda = (0, \infty) \backslash \mathcal{N}$; then $\Lambda = \cup_n \Lambda_n$ where $\Lambda_n$ are disjoint open intervals. By condition [24], the operator $\langle x \rangle^{-l}, l > 1/2$, is $H$-smooth on any strictly interior subinterval of every $\Lambda_n$. Applying the Kato–Lavine theorem, we see that the wave operators $W_\pm(H, H_0; E_0(\Lambda_n))$ and $W_\pm(H_0, H; E(\Lambda_n))$ exist for all $n$. Since $E_0(\Lambda) = I$ and $E(\Lambda) = P^{(\mathrm{ac})}$, this implies the existence of $W_\pm(H, H_0)$ and $W_\pm(H_0, H)$. Thus, the wave operators $W_\pm(H, H_0)$ for pair [13] exist and are complete if estimate [4] holds for some $\rho > 1$.

Compared to the trace-class method, conditions on the perturbation $V(x)$ are less restrictive, while the class of admissible "free" problems is essentially more narrow (in eqn [22] $V_0(x)$ is an arbitrary bounded function). It is not known whether the wave operators $W_\pm(H, H_0)$ exist for all pairs [22] such that $V_0 \in L_\infty$ and $V$ satisfies [4] for some $\rho > 1$.

It is important that the smooth method allows one to prove the absence of the singular continuous spectrum. Note first that the continuity of $\mathcal{R}(z)$ implies that the operator $H$ is absolutely continuous on the subspace $E(\Lambda)\mathcal{H}$. Therefore, the singular

positive spectrum of $H$ is necessarily contained in $\mathcal{N}$. To prove that its continuous part is empty, it suffices to check that the set $\mathcal{N}$ consists of eigenvalues of the operator $H$. In terms of $u = \langle x \rangle^{-l} Bf, l = \rho/2$, eqn [28] can be rewritten as

$$u + VR_0(\lambda \pm i0)u = 0 \qquad [29]$$

Multiplying this equation by $R_0(\lambda \pm i0)u$ and taking the imaginary part of the scalar product, we see that

$$\pi\, d(E_0(\lambda)u, u)/d\lambda = \mathrm{Im}(R_0(\lambda \pm i0)u, u) = 0$$

According to eqn [26], this implies that

$$\hat{u}(\xi) = 0 \quad \text{for} \quad |\xi| = \lambda^{1/2} \qquad [30]$$

It follows from eqn [29] that

$$\psi = R_0(\lambda \pm i0)u \qquad [31]$$

that is, $\hat{\psi}(\xi) = (|\xi|^2 - \lambda \mp i0)^{-1}\hat{u}(\xi)$, is a formal (because of the singularity of the denominator) solution of Schrödinger equation [5]. Therefore, one needs only to verify that $\psi \in L_2(\mathbb{R}^d)$. Since $u \in L_2^{(l)}$, where $l = \rho/2$, this is a direct consequence of [25] and [30] if $\rho > 2$. In the general case, one uses that under assumption [30] the function $(|\xi|^2 - \lambda)^{-1}\hat{u}(\xi)$ belongs to the space $L_2^{(p)}$ for any $p < l - 1$. By virtue of condition [4] where $\rho > 1$, eqn [29] now shows that actually $u \in L_2^{(p)}$ for any $p < l + \rho - 1$. Repeating these arguments, we obtain, after $n$ steps, that $u \in L_2^{(p)}$ for any $p < l + n(\rho - 1)$. For $n$ large enough, this implies that $u \in L_2^{(p)}$ for $p > 1$, and consequently function [31] belongs to $L_2(\mathbb{R}^d)$.

Similar arguments show that eigenvalues of $H$ have finite multiplicity and do not have positive accumulation points. For the proof of boundedness of the set of eigenvalues, one uses additionally the estimate

$$\|\mathcal{R}_0(\lambda \pm i0)\| = O(\lambda^{-1/2}), \quad \lambda \to \infty \qquad [32]$$

Actually, according to Kato theorem the Schrödinger operator $H$ does not have positive eigenvalues.

There exists also a purely time-dependent approach, the Enss method (see Perry (1983)), which relies on an advanced study of the free evolution operator $\exp(-iH_0 t)$.

## The Scattering Matrix

The operator $H_0 = -\Delta$ can of course be diagonalized by the classical Fourier transform. To put it slightly differently, set

$$(F_0 f)(\lambda) = \Gamma_0(\lambda) f$$

where the operator $\Gamma_0(\lambda)$ is defined by eqn [16]. Then

$$F_0 : L_2(\mathbb{R}^d) \to L_2(\mathbb{R}_+; \mathfrak{N}), \quad \mathfrak{N} = L_2(\mathbb{S}^{d-1})$$

is a unitary operator and $(F_0 H_0 f)(\lambda) = \lambda (F_0 f)(\lambda)$.

Under assumption [4] where $\rho > 1$, the scattering operator $S$ for pair [13] is defined by eqn [11]. It is unitary on the space $\mathcal{H} = L_2(\mathbb{R}^d)$ and commutes with the operator $H_0$. It follows that $(F_0 S f)(\lambda) = S(\lambda)(F_0 f)(\lambda), \lambda > 0$, where the unitary operator $S(\lambda) : \mathfrak{N} \to \mathfrak{N}$ is known as the scattering matrix. The scattering matrix $S(\lambda)$ for the pair $H_0, H$ can be computed in terms of the scattering amplitude. Namely, $S(\lambda)$ acts in the space $L_2(\mathbb{S}^{d-1})$, and $S(\lambda) - I$ is the integral operator whose kernel is the scattering amplitude. More precisely,

$$(S(\lambda)f)(\theta) = f(\theta) + 2i\lambda^{1/2}\overline{\gamma_d(\lambda)} \int_{\mathbb{S}^{d-1}} a(\theta, \omega; \lambda) f(\omega)\, d\omega$$

In operator notation, this representation can be rewritten as

$$S(\lambda) = I - 2\pi i \Gamma_0(\lambda)(V - VR(\lambda + i0)V)\Gamma_0^*(\lambda) \qquad [33]$$

The right-hand side here is correctly defined as a bounded operator in the space $\mathfrak{N}$ and is continuous in $\lambda > 0$. Moreover, the operator $S(\lambda) - I$ is compact since $\Gamma_0(\lambda)\langle x \rangle^{-l} : \mathcal{H} \to \mathfrak{N}$ is compact for $l > 1/2$ by virtue of the Sobolev trace theorem.

It follows that the spectrum of the operator $S(\lambda)$ consists of eigenvalues of finite multiplicity, except possibly the point 1, lying on the unit circle and accumulating at the point 1 only. In the general case, eigenvalues of $S(\lambda)$ play the role of scattering phases or shifts considered often for radial potentials $V(x) = V(|x|)$.

The scattering amplitude is singular on the diagonal $\theta = \omega$ only. Moreover, this singularity is weaker for potentials with faster decay at infinity (for $\rho$ bigger). If $\rho > (d+1)/2$, then the operator $S(\lambda) - I$ belongs to the Hilbert–Schmidt class. In this case the total scattering cross section

$$\sigma(\omega; \lambda) = \int_{\mathbb{S}^{d-1}} |a(\theta, \omega; \lambda)|^2\, d\theta$$

is finite for all energies $\lambda > 0$ and all incident directions $\omega \in \mathbb{S}^{d-1}$. If $\rho > d$, then the operator $S(\lambda) - I$ belongs to the trace class. In this case, the scattering amplitude $a(\theta, \omega; \lambda)$ is a continuous function of $\theta, \omega \in \mathbb{S}^{d-1}$ (and $\lambda > 0$). The unitarity of the operator $S(\lambda)$ implies the optical theorem

$$\sigma(\omega; \lambda) = \lambda^{-1/2} \mathrm{Im}\big(\gamma_d^{-1}(\lambda) a(\omega, \omega; \lambda)\big)$$

Using resolvent identity [14], one deduces from eqn [33] the Born expansion

$$S(\lambda) = I - 2\pi \mathrm{i} \sum_{n=0}^{\infty} (-1)^n \Gamma_0(\lambda) V (R_0(\lambda + \mathrm{i}0) V)^n \Gamma_0^*(\lambda)$$

This series is norm-convergent for small potentials $V$ and according to estimate [32] for high energies $\lambda$.

## Long-Range Interactions

Potentials decaying at infinity as the Coulomb potential

$$V(x) = \gamma |x|^{-1}, \quad d \geq 3$$

or slower are called long-range. More precisely, it is required that

$$|\partial^\alpha V(x)| \leq C(1 + |x|)^{-\rho - |\alpha|}, \quad \rho \in (0, 1] \qquad [34]$$

for all derivatives of $V$ up to some order. In the long-range case, the wave operators $W_\pm(H, H_0)$ do not exist, and the asymptotic dynamics should be properly modified. It can be done in a time-dependent way either in the coordinate or momentum representations. For example, in the coordinate representation, the free evolution $\exp(-\mathrm{i}H_0 t)$ should be replaced in definition [8] of wave operators by unitary operators $U_0(t)$ defined by

$$(U_0(t)f)(x) = \exp(\mathrm{i}\,\Xi(x,t))(2\mathrm{i}t)^{-d/2} \hat{f}(x/(2t))$$

where $\hat{f}$ is the Fourier transform of $f$. For short-range potentials we can set $\Xi(x,t) = (4t)^{-1}|x|^2$. In the long-range case the phase function $\Xi(x,t)$ should be chosen as a (perhaps, approximate) solution of the eikonal equation

$$\partial\Xi/\partial t + |\nabla\Xi|^2 + V = 0$$

In particular, we can set

$$\Xi(x,t) = (4t)^{-1}|x|^2 - t \int_0^1 V(sx)\,\mathrm{d}s$$

if $\rho > 1/2$ in [34]. For the Coulomb potential,

$$\Xi(x,t) = (4t)^{-1}|x|^2 - \gamma t |x|^{-1} \ln|t|$$

(the singularity at $x = 0$ is inessential here). Thus, both in short- and long-range cases solutions of the time-dependent Schrödinger equation "live" in a region of the configuration space where $|x|$ is of order $|t|$. Long-range potentials change only asymptotic phases of these solutions.

Another possibility is a time-independent modification in the phase space. Let us consider wave operators $W_\pm(H, H_0; J)$, where $J$ is a pseudodifferential operator,

$$(Jf)(x) = (2\pi)^{-d/2} \int_{\mathbb{R}^d} \mathrm{e}^{\mathrm{i}\langle x,\xi\rangle}\, \mathrm{e}^{\mathrm{i}\Phi(x,\xi)} \zeta(x,\xi) \hat{f}(\xi)\,\mathrm{d}\xi$$

with oscillating symbol $\exp(\mathrm{i}\Phi(x,\xi))\zeta(x,\xi)$. Due to the conservation of energy, we may suppose that $\zeta(x,\xi)$ contains a factor $\psi(|\xi|^2)$ with $\psi \in C_0^\infty(0,\infty)$. Set

$$\varphi(x,\xi) = \langle x,\xi\rangle + \Phi(x,\xi)$$

The perturbation $HJ - JH_0$ is also a pseudodifferential operator, and its symbol is short-range (it is $O(|x|^{-1-\varepsilon}), \varepsilon > 0$, as $|x| \to \infty$) if $\exp(\mathrm{i}\varphi(x,\xi))$ is an approximate eigenfunction of the operator $H$ corresponding to the "eigenvalue" $|\xi|^2$. This leads to the eikonal equation

$$|\nabla_x \varphi(x,\xi)|^2 + V(x) = |\xi|^2$$

The notorious difficulty (for $d \geq 2$) of this method is that the eikonal equation does not have (even approximate) solutions such that $|\nabla_x \Phi(x,\xi)| \to 0$ as $|x| \to \infty$ and the arising error term is short-range. However, it is easy to construct functions $\varphi = \varphi_\pm$ satisfying these conditions if a conical neighborhood of the direction $\mp\xi$ is removed from $\mathbb{R}^d$. For example,

$$\Phi_\pm(x,\xi) = \pm 2^{-1} \int_0^\infty (V(x \pm \tau\xi) - V(\pm\tau\xi))\,\mathrm{d}\tau$$

if $\rho > 1/2$ in eqn [34]. Then the cutoff function $\zeta(x,\xi) = \zeta_\pm(x,\xi)$ should be homogeneous of order zero in the variable $x$ and it should be equal to zero in a neighborhood of the direction $\mp\xi$. We emphasize that now we have a couple of different identifications $J = J_\pm$.

The long-range problem is essentially more difficult than the short-range one. The limiting absorption principle remains true in this case, but its proof cannot be performed within perturbation theory. The simplest proof relies on the Mourre estimate (see Cycon *et al.* (1987)) for the commutator $\mathrm{i}[H, A]$ of $H$ with the generator of dilations

$$A = -\mathrm{i} \sum_{j=1}^{d} (x_j \partial_j + \partial_j x_j)$$

The Mourre estimate affirms that, for all $\lambda > 0$,

$$\mathrm{i}E(\Lambda_\lambda)[H, A]E(\Lambda_\lambda) \geq c(\lambda)E(\Lambda_\lambda), \quad c(\lambda) > 0 \qquad [35]$$

if $\Lambda_\lambda = (\lambda - \varepsilon, \lambda + \varepsilon)$ and $\varepsilon$ is small enough. For the free operator $H_0$, this estimate takes the form $\mathrm{i}[H_0, A] = 4H_0$ and can be regarded as a commutation relation. Estimate [35] means that the observable

$$(A\mathrm{e}^{-\mathrm{i}Ht} f,\ \mathrm{e}^{-\mathrm{i}Ht} f)$$

is a strictly increasing function of $t$ for all $f \in \mathcal{H}^{(ac)}$. The $H$-smoothness of the operator $\langle x \rangle^{-l}, l > 1/2$, is deduced from this fact by some arguments of abstract nature (they do not really use concrete forms of the operators $H$ and $A$).

However, the limiting absorption principle is not sufficient for construction of scattering theory in the long-range case, and it should be supplemented by an additional estimate. To formulate it, denote by

$$(\nabla^{\perp} u)(x) = (\nabla u)(x) - |x|^{-2} \langle (\nabla u)(x), x \rangle x$$

the orthonal projection of a vector $(\nabla u)(x)$ on the plane orthogonal to $x$. Then the operator $K = \langle x \rangle^{-1/2} \nabla^{\perp}$ is $H$-smooth on any compact $X \subset (0, \infty)$. This result is formulated as an estimate (either on the resolvent or on the unitary group of $H$), which we refer to as the radiation estimate. This estimate is not very astonishing from the viewpoint of analogy with the classical mechanics. Indeed, in the case of free motion, the vector $x(t)$ of the position of a particle is directed asymptotically as its momentum $\xi$. Regarded as a pseudodifferential operator, $\nabla^{\perp}$ has symbol $\xi - |x|^{-2} \langle \xi, x \rangle x$, which equals zero if $x = \gamma \xi$ for some $\gamma \in \mathbb{R}$. Thus, $\nabla^{\perp}$ removes the part of the phase space where a classical particle propagates. The proof of the radiation estimate is based on the inequality

$$K^* K \leq C_0 [H, \partial_r] + C_1 \langle x \rangle^{-1-\rho}, \quad \partial_r = \partial / \partial |x|$$

which can be obtained by a direct calculation. Since the integral

$$\begin{aligned} &\mathrm{i} \int_0^t ([H, \partial_r] \mathrm{e}^{-\mathrm{i}Hs} f, \, \mathrm{e}^{-\mathrm{i}Hs}) f) \, \mathrm{d}s \\ &\quad = (\partial_r \, \mathrm{e}^{-\mathrm{i}Ht} f, \, \mathrm{e}^{-\mathrm{i}Ht} f) - (\partial_r f, f) \end{aligned}$$

is bounded by $C(X) \|f\|^2$ for $f \in E(X) f$ and the operator $\langle x \rangle^{-(1+\rho)/2}$ is $H$-smooth on $X$, this implies $H$-smoothness of the operator $KE(X)$.

Calculating the perturbation $HJ_{\pm} - J_{\pm} H_0$, we see that it is a sum of two pseudodifferential operators. The first of them is short-range and thus can be taken into account by the limiting absorption principle. The symbol of the second one contains first derivatives (in the variable $x$) of the cutoff function $\zeta_{\pm}(x, \xi)$ and hence decreases at infinity as $|x|^{-1}$ only. This operator factorizes into a product of $H_0$- and $H$-smooth operators according to the radiation estimate. Thus, all wave operators $W_{\pm}(H, H_0; J_{\pm})$ and $W_{\pm}(H_0, H; J_{\pm}^*)$ exist. These operators are isometric since the operators $J_{\pm}$ are in some sense close to unitary operators. The isometricity of $W_{\pm}(H_0, H; J_{\pm}^*)$ is equivalent to the completeness of $W_{\pm}(H, H_0; J_{\pm})$.

Although the modified wave operators enjoy basically the same properties as in the short-range case, properties of the scattering matrices in the short- and long-range cases are drastically different. Here we note only that for long-range potentials, due to a wild diagonal singularity of kernel of the scattering matrix, its spectrum covers the whole unit circle.

Different aspects of long-range scattering are discussed in Dereziński and Gérard (1997), Pearson (1988), Saitō (1979), and Yafaev (2000).

## The Framework of Quantum Mechanics

In 1900, Max Planck initiated the quantum revolution by presenting the hypothesis that radiation is emitted or absorbed only in "quanta," each of energy $h\nu$, for frequency $\nu$ (where $h$ was a new fundamental constant of Nature). By this device, he explained the precise shape of the puzzling black-body spectrum. Then, in 1905, Albert Einstein introduced the concept of the photon, according to which light, of frequency $\nu$ would, in appropriate circumstances, behave as though it were constituted as individual particles, each of energy $h\nu$, rather than as continuous waves, and he was able to explain the conundrum posed by the photoelectric effect by this means. Later, in 1923, Prince Louis de Broglie proposed that, conversely, all particles behave like waves, the energy being Planck's $\hbar\nu$ and the momentum being $h\lambda^{-1}$, where $\lambda$ is the wavelength, which was later strikingly confirmed in a famous experiment of Davisson and Germer in 1927. Some years earlier, in 1913, Niels Bohr had used another aspect of this curious quantum "discreteness," explaining the stable electron orbits in hydrogen by the assumption that (orbital) angular momentum must be quantized in units of $\hbar(=h/2\pi)$.

All this provided a very remarkable collection of facts and concepts, albeit somewhat disjointed, explaining a variety of previously baffling physical phenomena, where a certain discreteness seemed to be entering Nature at a fundamental level, where previously there had been continuity, and where there was an overriding theme of a confusion as to whether – or in what circumstances – waves or particles provide better pictures of reality. Moreover, no clear and consistent picture of an actual "quantum-level reality" as yet seemed to arise out of all this. Then, in 1925, Heisenberg introduced his "matrix mechanics," subsequently developed into a more complete theory by Born, Heisenberg and Jordan, and then more fully by Dirac. Some six months after Heisenberg, in 1926, Schrödinger introduced his very different-looking "wave mechanics," which he subsequently showed was equivalent to Heisenberg's scheme. These became encompassed into a comprehensive framework through the transformation theory of Dirac, which he put together in his famous book *The Principles of Quantum Mechanics*, first published in 1930. Later, von Neumann set the framework on a more rigorous basis in his 1932 book, *Mathematische Grundlageen der Quantenmechanik* (later translated as *Mathematical Foundations of Quantum Mechanics*, 1955).

This formalism, now well known to physicists, is based on the presence of a quantum state $|\psi\rangle$ (Dirac's "ket" notation being adopted here). In Schrödinger's description, $|\psi\rangle$ is to evolve by unitary evolution, according to the Schrödinger equation

$$i\hbar\frac{\partial|\psi\rangle}{\partial t}=\mathtt{H}|\psi\rangle$$

where $\mathtt{H}$ is the quantum Hamiltonian. The totality of allowable states $|\psi\rangle$ constitutes a Hilbert space $\mathbf{H}$ and the Schrödinger equation provides a continuous one-parameter family of unitary transformations of $\mathbf{H}$. The letter $\boldsymbol{U}$ is used here for the "quantum-level" evolution whereby the state $|\psi\rangle$ evolves in time according to this unitary Schrödinger evolution. However, we must be careful not to demand an interpretation of this evolution similar to that which we adopt for a classical theory, such as is provided by Maxwell's equations for the electromagnetic field. In Maxwell's theory, the evolution that his equations provide is accepted as very closely mirroring the actual way in which a physically real electromagnetic field evolves with time. In quantum mechanics, however, it is a highly contentious matter how we should regard the "reality" of the unitarily evolving state $|\psi\rangle$.

One of the key difficulties resides in the fact that the world that we actually observe about us rather blatantly does not accord with such a unitarily evolving $|\psi\rangle$. Indeed, the standard way that the quantum formalism is to be interpreted is very far from the mere following of such a picture. So long as no "measurement" is deemed to have been taking place, this $\boldsymbol{U}$-evolution procedure would be adopted, but upon measurement, the state is taken to behave in a very different way, namely to "jump" instantaneously to some eigenstate $|\phi\rangle$ of the quantum operator $\boldsymbol{Q}$ which is taken to represent the measurement, with probability given by the Born rule

$$|\langle\phi|\psi\rangle|^2$$

if we assume that both $|\psi\rangle$ and $|\phi\rangle$ are normalized ($\langle\psi|\psi\rangle=1=\langle\phi|\phi\rangle$); otherwise we can express this probability simply as

$$\frac{\langle\phi|\psi\rangle\langle\psi|\phi\rangle}{\langle\psi|\psi\rangle\langle\phi|\phi\rangle}$$

(The operator $\boldsymbol{Q}$ is normally taken to be self-adjoint, so that $\boldsymbol{Q}=\boldsymbol{Q}^*$ and its eigenvalues are real, but more

generally complex eigenvalues are accommodated if we allow $\boldsymbol{Q}$ to be normal, that is, $\boldsymbol{Q}\boldsymbol{Q}^* = \boldsymbol{Q}^*\boldsymbol{Q}$. In each case we require the eigenvectors of $\boldsymbol{Q}$ to span the Hilbert space **H**.) This "evolution procedure" of the quantum state is very different from $\boldsymbol{U}$, owing both to its discontinuity and its indeterminacy. The letter $\boldsymbol{R}$ will be used for this, standing for the "reduction" of the quantum state (sometimes referred to as the "collapse of the wave function"). This strange hybrid, whereby $\boldsymbol{U}$ and $\boldsymbol{R}$ are alternated, with $\boldsymbol{U}$ holding between measurements and $\boldsymbol{R}$ holding at measurements, is the standard procedure that is pragmatically adopted in conventional quantum mechanics, and which works so marvelously well, with no known discrepancy between the theory and observation. (In his classic account, von Neumann (1932, 1955), "$\boldsymbol{R}$" is referred to as his "process I" and "$\boldsymbol{U}$" as his "process II.") However, there appears to be no consensus whatever about the relation between this mathematical procedure and what is "really" going on in the physical world. This is the kind of issue that will be of concern to us here.

## Quantum Reality

The discussion here will be given only in the Schrödinger picture, for the reason that the issues appear to be clearer with this description. In the Heisenberg picture, the state $|\psi\rangle$ does not evolve in time, and all dynamics is taken up in the time evolution of the dynamical variables. But this evolution does not refer to the evolution of specific systems, the "state" of any particular system being defined to remain constant in time. Since the Schrödinger and Heisenberg pictures are deemed to be equivalent (at least for the "normal" systems that are under consideration here), we do not lose anything substantial by sticking to Schrödinger's description, whereas there does seem to be a significant gain in understanding of what the formalism is actually telling us.

There are, however, many different attitudes that are expressed as to the "reality" of $|\psi\rangle$. (There is an unfortunate possibility of confusion here in the two uses of the word "real" that come into the discussion here. In the quantum formalism, the state is mathematically a "complex" rather than a "real" entity, whereas our present concern is not directly to do with this, but with the "ontology" of the quantum description.) According to what is commonly regarded as the standard – "Copenhagen" – interpretation of quantum mechanics (due primarily to Bohr, Heisenberg, and Pauli), the quantum state $|\psi\rangle$ is not taken as a description of a quantum-level reality at all, but merely as a description of the observer's knowledge of the of the quantum system under consideration. According to this view, the "jumping" that the quantum state undergoes is regarded as unsurprising, since it does not represent a sudden change in the reality of the situation, but merely in the observer's knowledge, as new information becomes available, when the result of some measurement becomes known to the observer. According to this view, there is no objective quantum reality described by $|\psi\rangle$. Whether or not there might be some objective quantum-level reality with some other mathematical description seems to be left open by this viewpoint, but the impression given is that there might well not be any such quantum-level reality at all, in the sense that it becomes meaningless to ask for a description of "actual reality" at quantum-relevant scales.

Of course some connection with the real world is necessary, in order that the quantum formalism can relate to the results of experiment. In the Copenhagen viewpoint, the experimenter's measuring apparatus is taken to be a classical-level entity, which can be ascribed a real ontological status. When the Geiger counter "clicks" or when the pointer "points" to some position on a dial, or when the track in the cloud chamber "becomes visible" – these are taken to be real events. The intervening description in terms of a quantum state vector $|\psi\rangle$ is not ascribed a reality. The role of $|\psi\rangle$ is merely to provide a calculational procedure whereby the different outcomes of an experiment can be assigned probabilities. Reality comes about only when the result of the measurement is manifested, not before.

A difficulty with this viewpoint is that it is hard to draw a clear line between those entities which are considered to have an actual reality, such as the experimental apparatus or a human observer, and the elemental constituents of those entities, which are such things as electrons or protons or neutrons or quarks, which are to be treated quantum mechanically and therefore, on the "Copenhagen" view, their mathematical descriptions are denied such an honored ontological status. Moreover, there is no limit to the number of particles that can partake in a quantum state. According to current quantum mechanics, the most accurate mathematical procedure for describing a system with a large number of particles would indeed be to use a unitarily evolving quantum state. What reasons can be presented for or against the viewpoint that this gives us a reasonable description of an actual reality? Can our perceived reality arise as some kind of statistical limit when very large numbers of constituents are involved?

Before entering into the more subtle and contentious issues of the nature of "quantum reality," it

is appropriate that one of the very basic mathematical aspects of the quantum formalism be addressed first. It is an accepted aspect of the quantum formalism that a state-vector such as $|\psi\rangle$ should not, in any case, be thought of as providing a unique mathematical description of a "physical reality" for the simple reason that $|\psi\rangle$ and $z|\psi\rangle$, where $z$ is any nonzero complex number, describe precisely the same physical situation. It is a common, but not really necessary, practice to demand that $|\psi\rangle$ be normalized to unity: $\langle\psi|\psi\rangle = 1$, in which case the freedom in $|\psi\rangle$ is reduced to the multiplication by a phase factor $|\psi\rangle \mapsto e^{i\theta}|\psi\rangle$. Either way, the physically distinguishable states constitute a projective Hilbert space $\mathbb{P}\mathbf{H}$, where each point of $\mathbb{P}\mathbf{H}$ corresponds to a one-dimensional linear subspace of the Hilbert space $\mathbf{H}$. The issue, therefore, is whether quantum reality can be described in terms of the points of a projective Hilbert space $\mathbb{P}\mathbf{H}$.

## Reality in Spin-1/2 Systems

As a general comment, it seems that for systems with a small number of degrees of freedom – that is, for a Hilbert space $\mathbf{H}^n$ of small finite dimension $n$ – it seems more reasonable to assign a reality to the elements of $\mathbb{P}\mathbf{H}^n$ than is the case when $n$ is large. Let us begin with a particularly simple case, where $n = 2$, and $\mathbf{H}^2$ describes the two-dimensional space of spin states of a massive particle of spin 1/2, such as an electron, proton, or quark, or suitable atom. Here we can take as an orthonormal pair of basis states $|\uparrow\rangle$ and $|\downarrow\rangle$, representing right-handed spin about the "up" and "down" directions, respectively. Clearly there is nothing special about these particular directions, so any other state of spin, of direction $|\nearrow\rangle$ say, is just as "real" as the original two. Indeed, we always find

$$|\nearrow\rangle = w|\uparrow\rangle + z|\downarrow\rangle$$

for some pair of complex numbers $z$ and $w$ (not both zero). The different possible ratios $z:w$ give us a complex plane (of $zw^{-1}$) compactified by a point at infinity (where $w = 0$) – a "Riemann sphere" – which is a realization of the complex projective 1-space $\mathbb{P}\mathbf{H}^2$.

There does indeed seem to be something "real" about the spin state of such a spin-1/2 particle or atom. We might imagine preparing the spin of a suitable spin-1/2 atom using a Stern–Gerlach apparatus (*see* Introductory Article: Quantum Mechanics) oriented in some chosen direction. The atom seems to "know" the direction of its spin, because if we measure it again in the same direction it has to be prepared to give us the answer "YES," to the second measurement, with certainty, and that direction for its spin state is the only one that can guarantee this answer. (We are, of course, considering only "ideal" measurements, for the purpose of argument.) Moreover, we could imagine that between the two measurements, some appropriate magnetic field had been introduced so as to rotate the spin direction in some very specific way, so that the spin state is now some other direction such as $|\searrow\rangle$. By rotating our second Stern–Gerlach apparatus to agree with this new direction, we must again get certainty for the YES answer, the guaranteeing of this by the rotated state seeming now to give a "reality" to this new state $|\searrow\rangle$. The quantum formalism does not allow us to ascertain an unknown direction of spin. But it does allow for us to "confirm" (or "refute") a proposed direction for the spin state, in the sense that if the proposed direction is incorrect, then there is a nonzero probability of refutation. Only the correct direction can be guaranteed to give the YES answer.

## EPR–Bohm and Bell's Theorem

For a pair of particles or atoms of spin 1/2, the issue of the "reality" of spin states becomes less clear. Consider, for example, the EPR–Bohm example (where "EPR" stands for Einstein–Podolski–Rosen) whereby an initial state of spin 0 decays into two spin-1/2 atoms, traveling in opposite directions (east E, and west W). If a suitable Stern–Gerlach apparatus is set up to measure the spin of the atom at E, finding an answer $|\searrow\rangle$, say, then this immediately ensures that the state at W is the oppositely pointing $|\nwarrow\rangle$, which can subsequently be "confirmed" by measurement at W. This, then, seems to provide a "reality" for the spin state $|\nwarrow\rangle$ at W as soon as the E measurement has been performed, but not before. Now, let us suppose that some orientation different from $\nwarrow$ had actually been set up for the measurement at W, namely that which would have given YES for the direction $\leftarrow$. This measurement can certainly give the answer YES upon encountering $|\nwarrow\rangle$ (with a certain nonzero probability, namely $(1 + \cos\theta)/2$, where $\theta$ is the angle between $\nwarrow$ and $\leftarrow$). So far, this provides us with no problem with the "reality" of the spin state of the atom at W, since it would have been $|\nwarrow\rangle$ before the measurement at W and would have "collapsed" (by the ***R***-process) to $|\leftarrow\rangle$ after the measurement. But now suppose that the measurement at W had actually been performed momentarily before the measurement at E, rather than just after it. Then there is no reason that the W-measurement would encounter $|\nwarrow\rangle$, rather than some other direction, but the result $|\leftarrow\rangle$ of the measurement at W now seems to force the state at E to be $|\rightarrow\rangle$. Indeed, the two measurements, at E and

at W, might have been spacelike separated, and because of the requirements of special relativity there would be no meaning to say which of the two measurements – at E or at W – had "actually" occurred first. One seems to obtain a different picture of "reality" depending on this ordering.

In fact, the calculations of probabilities come out the same whichever picture is used, so if one asks only for a calculational procedure for the probabilities, rather than an actual picture of quantum reality, these considerations are not problematic. But they do provide profound difficulties for any view of quantum reality that is entirely local. The difficulty is made particularly clear in a theorem due to John Bell (1964, 1966a, b) which showed that on the basis of the assumptions of local realism, there are particular relations between the conditional probabilities, which must hold in any situation of this kind; moreover, these inequalities can be violated in various situations in standard quantum mechanics. (See, most specifically, Clauser *et al.* (1969).) Several experiments that were subsequently performed (notably Aspect *et al.* (1982)) confirmed the expectations of quantum mechanics, thereby presenting profound difficulties for any local realistic model of the world. There are also situations of this kind which involve only yes/no questions, so that actual probabilities do not need to be considered, see Kochen and Specker (1967), Peres (1991), Hardy (1993), Conway and Kochen (2002). Basically: if one insists on realism, then one must give up locality. Moreover, nonlocal realistic models, consistent with the requirements of special relativity, are not easy to construct (*see* Quantum Mechanics: Generalizations), and have so far proved elusive.

## Other Aspects of Quantum Nonlocality

Problems of this kind occur even at the more elementary level of single particles, if one tries to consider that an ordinary particle wave function (position-space description of $|\psi\rangle$) might be just some kind of "local disturbance," like an ordinary classical wave. Consider the wave function spreading out from a localized source, to be detected at a perpendicular screen some distance away. The detection of the particle at any one place on the screen immediately forbids the detection of that particle at any other place on the screen, and if we are to think of this information as being transmitted as a classical signal to all other places on the screen, then we are confronted with problems of superluminary communication. Again, any "realistic" picture of this process would require nonlocal ingredients, which are difficult to square with the requirements of special relativity. (It is possible that these difficulties might be resolved within some kind of nonlocal geometry, such as that supplied by twistor theory (*see* Twistors; Twistor Theory: Some Applications); see, particularly, Penrose (2005).)

These types of issues are made even more dramatic and problematic in the procedure of "quantum teleportation," whereby the information in a quantum state (e.g., the unknown actual direction $\nearrow$ in some quantum state $|\nearrow\rangle$) can be transported from one experimenter A to another one B, by merely the sending of a small finite number of classical bits of information from A to B, where before this classical information is transmitted, A and B must each be in possession of one member of an EPR pair. More explicitly, we may suppose A (Alice) is presented with a spin-1/2 state $|\nearrow\rangle$, but is not told the direction $\nearrow$. She has in her possession another spin-1/2 state which is an EPR–Bohm partner of a spin-1/2 state in the possession of B (Bob). She combines this $|\nearrow\rangle$ with her EPR atom and then performs a measurement which distinguishes the four orthogonal "Bell states"

$$\begin{aligned}
0&: \ |\uparrow\rangle|\downarrow\rangle - |\downarrow\rangle|\uparrow\rangle \\
1&: \ |\uparrow\rangle|\uparrow\rangle - |\downarrow\rangle|\downarrow\rangle \\
2&: \ |\uparrow\rangle|\uparrow\rangle + |\downarrow\rangle|\downarrow\rangle \\
3&: \ |\uparrow\rangle|\downarrow\rangle + |\downarrow\rangle|\uparrow\rangle
\end{aligned}$$

where the first state in each product refers to her unknown state and the second refers to her EPR atom. The result of this measurement is conveyed to Bob by an ordinary classical signal, coded by the indicated numbers 0, 1, 2, 3. On receiving Alice's message, Bob takes the other member of the EPR pair and performs the following rotation on it:

0: leave alone
1: 180° about $x$-axis
2: 180° about $y$-axis
3: 180° about $z$-axis

This achieves the successful "teleporting" of $|\nearrow\rangle$ from A to B, despite the fact that only 2 bits of classical information have been signaled. It is the acausal EPR–Bohm connection that provides the transmission of "quantum information" in a classically acausal way. Again, we see the essentially nonlocal (or acausal) nature of any attempted "realistic" picture of quantum phenomena. It may be regarded as inappropriate to use the term "information" for something that is propagated acausally and cannot be directly used for signaling. It has been suggested, accordingly, that a term such as "quanglement" might be more appropriate to use for this concept; see Penrose (2002, 2004).

The preceding arguments illustrate how quantum systems involving even just a few particles can exhibit features quite unlike the ordinary behavior of classical particles. This was pointed out by Schrödinger (1935), and he referred to this key property of composite quantum systems as "entanglement." An entangled quantum state (vector) is an element of a product Hilbert space $\mathbf{H}^m \otimes \mathbf{H}^n$ which cannot be written as a tensor product of elements $|\psi\rangle|\phi\rangle$, with $|\psi\rangle \in \mathbf{H}^m$ and $|\phi\rangle \in \mathbf{H}^n$, where $\mathbf{H}^m$ refers to one part of the system and $\mathbf{H}^n$ refers to another part, usually taken to be physically widely separated from the first. EPR systems are a clear example, and we begin to see very nonclassical, effectively nonlocal behavior with entangled systems generally. A puzzling aspect of this is that the vast majority of states are indeed entangled, and the more parts that a system has, the more entangled it becomes (where the generalization of this notion to more than two parts is evident). One might have expected that "big" quantum systems with large numbers of parts ought to behave more and more like classical systems when they get larger and more complicated. However, we see that this is very far from being the case. There is no good reason why a large quantum system, left on its own to evolve simply according to $\boldsymbol{U}$ should actually resemble a classical system, except in very special circumstances. Something of the nature of the $\boldsymbol{R}$ process seems to be needed in order that classical behaviour can "emerge."

## Schrödinger's Cat

To clarify the nature of the problem we must consider a key feature of the $\boldsymbol{U}$ formalism, namely "linearity," which is supposed to hold no matter how large or complicated is the quantum system under consideration. Recall the quantum superposition principle, which allows us to construct arbitrary combinations of states

$$|\psi\rangle = w|\chi\rangle + z|\phi\rangle$$

from two given states $|\chi\rangle$ and $|\phi\rangle$. Quantum linearity tells us that if

$$|\chi\rangle \rightsquigarrow |\chi'\rangle \qquad \text{and} \qquad |\phi\rangle \rightsquigarrow |\phi'\rangle$$

where the symbol "$\rightsquigarrow$" expresses how a state will have evolved after a specified time period $T$, then

$$|\psi\rangle = w|\chi\rangle + z|\phi\rangle \rightsquigarrow |\psi'\rangle = w|\chi'\rangle + z|\phi'\rangle$$

Let us now consider how this might be applied in a particular, rather outlandish situation. Let us suppose that the $|\chi\rangle$-evolution consists of a photon going in one direction, encountering a detector, which is connected to some murderous device which kills a cat. The $|\phi\rangle$-evolution, on the other hand, consists of the photon going in some other direction, missing the detector so that the murderous device is not activated, and the cat is left alive. These two alternatives would each be perfectly plausible evolutions which might take place in the physical world. Now, by use of a beam splitter (effectively a "half-silvered mirror") we can easily arrange for the initial state of the photon to be the superposition $w|\chi\rangle + z|\phi\rangle$ of the two. Then by quantum linearity we find, as the final result, the superposed state $w|\chi'\rangle + z|\phi'\rangle$, in which the cat is in a superposition of life and death (a "Schrödinger's cat").

We note that the two individual final states $|\chi'\rangle$ and $|\phi'\rangle$ would each involve not just the cat but also its environment, fully entangled with the cat's state, and perhaps also some human observer looking at the cat. In the latter case, $|\chi'\rangle$ would involve the observer in a state of unhappily perceiving a dead cat, and $|\phi'\rangle$ happily perceiving a live one. Two of the "conventional standpoints" with regard to the measurement problem are of relevance here. According to the standpoint of environmental decoherence, the details of the environmental degrees of freedom are completely inaccessible, and it is deemed to be appropriate to construct a density matrix to describe the situation, which is a partial trace $\boldsymbol{D}$ of the quantity $|\psi\rangle\langle\psi|$, constructed by tracing out over all the environmental degrees of freedom:

$$\boldsymbol{D} = \text{trace over environment}\{|\psi\rangle\langle\psi|\}$$

The density matrix tends to be regarded as a more appropriate quantity than the ket $|\psi\rangle$ to represent the physical situation, although this represents something of an "ontology shift" from the point of view that was being held previously. Under appropriate assumptions, $\boldsymbol{D}$ may now be shown to attain a form that is close to being diagonal in a basis with respect to which the cat is either dead or alive, and then, by a second "ontology shift" $\boldsymbol{D}$ is re-read as describing a probability mixture of these two states.

According to the second "conventional standpoint" under consideration here, it is not logical to take this detour through a density-matrix description, and instead one should maintain a consistent ontology by following the evolution of the state $|\psi\rangle$ itself throughout. The "real" resulting physical state is then taken to be actually $|\psi'\rangle$, which involves the superposition of a dead and live cat. Of course this "reality" does not agree with the reality that we actually perceive, so the position is taken that a conscious mind would not actually be able to function in such a superposed condition, and would have to settle into a state of perception of either a dead cat or a live one, these two alternatives occurring with probabilities as given by the Born rule stated above. It may be argued that this conclusion depends

upon some appropriate theory of how conscious minds actually perceive things, and this appears to be lacking.

A good many physicists might argue that none of these attempts at resolution of the measurement problem is satisfactory, including "Copenhagen," although the latter at least has the advantage of offering a pragmatic, if not fully logical, stance. Such physicists might take the position that it is necessary to move away from the precise version of quantum theory that we have at present, and turn to one of its modifications. Some major candidates for modification are discussed in Quantum Mechanics: Generalizations. Most of these actually make predictions that, at some stage, would differ from those of standard quantum mechanics. So it becomes an experimental matter to ascertain the plausibility of these schemes. In addition, there are reinterpretations which do not change quantum theory's predictions, such as the de Broglie–Bohm model. In this, there are two levels of "reality," a firmer one with a particle or position-space ontology, and a secondary one containing waves which guide the behavior at the firmer level. It is clear, however, that these issues will remain the subject of debate for many years to come.

## Introduction

According to the so-called "Copenhagen Interpretation," standard quantum theory is limited to describing experimental situations. It is at once remarkably successful in its predictions, and remarkably ill-defined in its conceptual structure: what is an experiment? what physical objects do or do not require quantization? how are the states realized in nature to be characterized? how and when is the wave-function "collapse postulate" to be invoked? Because of its success, one may suspect that quantum theory can be promoted from a theory of measurement to a theory of reality. But, that requires there to be an unambiguous specification (S) of the possible real states of nature and their probabilities of being realized.

There are several approaches that attempt to achieve S. The more conservative approaches (e.g., consistent histories, environmental decoherence, many worlds) do not produce any predictions that differ from the standard ones because they do not tamper with the usual basic mathematical

formalism. Rather, they utilize structures compatible with standard quantum theory to elucidate S. These approaches, which will not be discussed in this article, have arguably been less successful so far at achieving S than approaches that introduce significant alterations to quantum theory.

This article will largely deal with the two most well-developed realistic models that reproduce quantum theory in some limit and yield potentially new and testable physics outside that limit. First, the pilot-wave model, which will be discussed in the broader context of "hidden-variables theories." Second, the continuous spontaneous localization (CSL) model, which describes wave-function collapse as a physical process. Other related models will also be discussed briefly.

Due to bibliographic space limitations, this article contains a number of uncited references, of the form "[author] in [year]." Those in the next section can be found in Valentini (2002b, 2004a,b) or at www.arxiv.org. Those in the subsequent sections can be found in Adler (2004), Bassi and Ghirardi (2003), Pearle (1999) (or in subsequent papers by these authors, or directly, at www.arxiv.org), and in Wallstrom (1994).

## Hidden Variables and Quantum Nonequilibrium

A deterministic hidden-variables theory defines a mapping $\omega = \omega(M, \lambda)$ from initial hidden parameters $\lambda$ (defined, e.g., at the time of preparation of a quantum state) to final outcomes $\omega$ of quantum measurements. The mapping depends on macroscopic experimental settings $M$, and fixes the outcome for each run of the experiment. Bell's theorem of 1964 shows that, for entangled quantum states of widely separated systems, the mapping must be nonlocal: some outcomes for (at least) one system must depend on the setting for another distant system.

In a viable theory, the statistics of quantum measurement outcomes – over an ensemble of experimental trials with fixed settings $M$ – will agree with quantum theory for some special distribution $\rho_{\mathrm{QT}}(\lambda)$ of hidden variables. For example, expectation values will coincide with the predictions of the Born rule

$$\langle \omega \rangle_{\mathrm{QT}} \equiv \int \mathrm{d}\lambda\, \rho_{\mathrm{QT}}(\lambda)\omega(M, \lambda) = \mathrm{tr}(\hat{\rho}\hat{\Omega})$$

for an appropriate density operator $\hat{\rho}$ and Hermitian observable $\hat{\Omega}$. (As is customary in this context, $\int \mathrm{d}\lambda$ is to be understood as a generalized sum.) However, given the mapping $\omega = \omega(M, \lambda)$ for individual trials, one may, in principle, consider nonstandard distributions $\rho(\lambda) \neq \rho_{\mathrm{QT}}(\lambda)$ that yield statistics outside the domain of ordinary quantum theory (Valentini 1991, 2002a). We may say that such distributions correspond to a state of quantum nonequilibrium.

Quantum nonequilibrium is characterized by the breakdown of a number of basic quantum constraints. In particular, nonlocal signals appear at the statistical level. We shall first illustrate this for the hidden-variables model of de Broglie and Bohm. Then we shall generalize the discussion to all (deterministic) hidden-variables theories.

At present there is no experimental evidence for quantum nonequilibrium in nature. However, from a hidden-variables perspective, it is natural to explore the theoretical properties of nonequilibrium distributions, and to search experimentally for the statistical anomalies associated with them.

From this point of view, quantum theory is a special case of a wider physics, much as thermal physics is a special case of a wider (nonequilibrium) physics. (The special distribution $\rho_{\mathrm{QT}}(\lambda)$ is analogous to, say, Maxwell's distribution of molecular speeds.) Quantum physics may be compared with the physics of global thermal equilibrium, which is characterized by constraints – such as the impossibility of converting heat into work (in the absence of temperature differences) – that are not fundamental but contingent on the state. Similarly, quantum constraints such as statistical locality (the impossibility of converting entanglement into a practical signal) are seen as contingencies of $\rho_{\mathrm{QT}}(\lambda)$.

### Pilot-Wave Theory

The de Broglie–Bohm "pilot-wave theory" – as it was originally called by de Broglie, who first presented it at the Fifth Solvay Congress in 1927 – is the classic example of a deterministic hidden-variables theory of broad scope (Bohm 1952, Bell 1987, Holland 1993). We shall use it to illustrate the above ideas. Later, the discussion will be generalized to arbitrary theories.

In pilot-wave dynamics, an individual closed system with (configuration-space) wave function $\Psi(X, t)$ satisfying the Schrödinger equation

$$\mathrm{i}\hbar \frac{\partial \Psi}{\partial t} = \hat{H}\Psi \qquad [1]$$

has an actual configuration $X(t)$ with velocity

$$\dot{X}(t) = \frac{J(X, t)}{|\Psi(X, t)|^2} \qquad [2]$$

where $J = J[\Psi] = J(X, t)$ satisfies the continuity equation

$$\frac{\partial |\Psi|^2}{\partial t} + \nabla \cdot J = 0 \qquad [3]$$

(which follows from [1]). In quantum theory, $J$ is the "probability current." In pilot-wave theory, $\Psi$ is an objective physical field (on configuration space) guiding the motion of an individual system.

Here, the objective state (or ontology) for a closed system is given by $\Psi$ and $X$. A probability distribution for $X$ – discussed below – completes an unambiguous specification S (as mentioned in the introduction).

Pilot-wave dynamics may be applied to any quantum system with a locally conserved current in configuration space. Thus, $X$ may represent a many-body system, or the configuration of a continuous field, or perhaps some other entity.

For example, at low energies, for a system of $N$ particles with positions $\boldsymbol{x}_i(t)$ and masses $m_i\,(i = 1, 2, \ldots, N)$, with an external potential $V$, [1] (with $X \equiv (\boldsymbol{x}_1, \boldsymbol{x}_2, \ldots, \boldsymbol{x}_N)$) reads

$$i\hbar \frac{\partial \Psi}{\partial t} = \sum_{i=1}^{N} -\frac{\hbar^2}{2m_i} \nabla_i^2 \Psi + V\Psi \qquad [4]$$

while [2] has components

$$\frac{d\boldsymbol{x}_i}{dt} = \frac{\hbar}{m_i} \mathrm{Im}\left(\frac{\nabla_i \Psi}{\Psi}\right) = \frac{\nabla_i S}{m_i} \qquad [5]$$

(where $\Psi = |\Psi| e^{(i/\hbar)S}$).

In general, [1] and [2] determine $X(t)$ for an individual system, given the initial conditions $X(0), \Psi(X, 0)$ at $t = 0$. For an arbitrary initial distribution $P(X, 0)$, over an ensemble with the same wave function $\Psi(X, 0)$, the evolution $P(X, t)$ of the distribution is given by the continuity equation

$$\frac{\partial P}{\partial t} + \nabla \cdot (P\dot{X}) = 0 \qquad [6]$$

The outcome of an experiment is determined by $X(0), \Psi(X, 0)$, which may be identified with $\lambda$. For an ensemble with the same $\Psi(X, 0)$, we have $\lambda = X(0)$.

**Quantum equilibrium** From [3] and [6], if we assume $P(X, 0) = |\Psi(X, 0)|^2$ at $t = 0$, we obtain $P(X, t) = |\Psi(X, t)|^2$ – the Born-rule distribution of configurations – at all times $t$.

Quantum measurements are, like any other process, described and explained in terms of evolving configurations. For measurement devices whose pointer readings reduce to configurations, the distribution of outcomes of quantum measurements will match the statistical predictions of quantum theory (Bohm 1952, Bell 1987, Dürr *et al.* 2003). Thus, quantum theory emerges phenomenologically for a "quantum equilibrium" ensemble with distribution $P(X, t) = |\Psi(X, t)|^2$ (or $\rho(\lambda) = \rho_{\mathrm{QT}}(\lambda)$).

**Quantum nonequilibrium** In principle, as we saw for general hidden-variables theories, we may consider a nonequilibrium distribution $P(X, 0) \neq |\Psi(X, 0)|^2$ of initial configurations while retaining the same deterministic dynamics [1], [2] for individual systems (Valentini 1991). The time evolution of $P(X, t)$ will be determined by [6].

As we shall see, in appropriate circumstances (with a sufficiently complicated velocity field $\dot{X}$), [6] generates relaxation $P \to |\Psi|^2$ on a coarse-grained level, much as the analogous classical evolution on phase space generates thermal relaxation. But for as long as the ensemble is in nonequilibrium, the statistics of outcomes of quantum measurements will disagree with quantum theory.

Quantum nonequilibrium may have existed in the very early universe, with relaxation to equilibrium occurring soon after the big bang. Thus, a hidden-variables analog of the classical thermodynamic "heat death of the universe" may have actually taken place (Valentini 1991). Even so, relic cosmological particles that decoupled sufficiently early could still be in nonequilibrium today, as suggested by Valentini in 1996 and 2001. It has also been speculated that nonequilibrium could be generated in systems entangled with degrees of freedom behind a black-hole event horizon (Valentini 2004a).

Experimental searches for nonequilibrium have been proposed. Nonequilibrium could be detected by the statistical analysis of random samples of particles taken from a parent population of (for example) relics from the early universe. Once the parent distribution is known, the rest of the population could be used as a resource, to perform tasks that are currently impossible (Valentini 2002b).

### *H*-Theorem: Relaxation to Equilibrium

Before discussing the potential uses of nonequilibrium, we should first explain why all systems probed so far have been found in the equilibrium state $P = |\Psi|^2$. This distribution may be accounted for along the lines of classical statistical mechanics, noting that all currently accessible systems have had a long and violent astrophysical history.

Dividing configuration space into small cells, and introducing coarse-grained quantities $\bar{P}, \overline{|\Psi|^2}$, a general argument for relaxation $\bar{P} \to \overline{|\Psi|^2}$ is based on an

analog of the classical coarse-graining $H$-theorem. The coarse-grained $H$-function

$$\bar{H} = \int dX \ \bar{P} \ln(\bar{P}/\overline{|\Psi|^2}) \qquad [7]$$

(minus the relative entropy of $\bar{P}$ with respect to $|\Psi|^2$) obeys the $H$-theorem (Valentini 1991)

$$\bar{H}(t) \leq \bar{H}(0)$$

(assuming no initial fine-grained microstructure in $P$ and $|\Psi|^2$). Here, $\bar{H} \geq 0$ for all $\bar{P}, \overline{|\Psi|^2}$ and $\bar{H} = 0$ if and only if $\bar{P} = \overline{|\Psi|^2}$ everywhere.

The $H$-theorem expresses the fact that $P$ and $|\Psi|^2$ behave like two "fluids" that are "stirred" by the same velocity field $\dot{X}$, so that $P$ and $|\Psi|^2$ tend to become indistinguishable on a coarse-grained level. Like its classical analog, the theorem provides a general understanding of how equilibrium is approached, while not proving that equilibrium is actually reached. (And of course, for some simple systems – such as a particle in the ground state of a box, for which the velocity field $\nabla S/m$ vanishes – there is no relaxation at all.) A strict decrease of $\bar{H}(t)$ immediately after $t = 0$ is guaranteed if $\dot{X}_0 \cdot \nabla(P_0/|\Psi_0|^2)$ has nonzero spatial variance over a coarse-graining cell, as shown by Valentini in 1992 and 2001.

A relaxation timescale $\tau$ may be defined by $1/\tau^2 \equiv -(d^2\bar{H}/dt^2)_0/\bar{H}_0$. For a single particle with quantum energy spread $\Delta E$, a crude estimate given by Valentini in 2001 yields $\tau \sim (1/\varepsilon)\hbar^2/m^{1/2}(\Delta E)^{3/2}$, where $\varepsilon$ is the coarse-graining length. For wave functions that are superpositions of many energy eigenfunctions, the velocity field (generally) varies rapidly, and detailed numerical simulations (in two dimensions) show that relaxation occurs with an approximately exponential decay $\bar{H}(t) \approx \bar{H}_0 e^{-t/t_c}$, with a time constant $t_c$ of order $\tau$ (Valentini and Westman 2005).

Equilibrium is then to be expected for particles emerging from the violence of the big bang. The possibility is still open that relics from very early times may not have reached equilibrium before decoupling.

## Nonlocal Signaling

We now show how nonequilibrium, if it were ever discovered, could be used for nonlocal signaling.

Pilot-wave dynamics is nonlocal. For a pair of particles $A$, $B$ with entangled wave function $\Psi(\boldsymbol{x}_A, \boldsymbol{x}_B, t)$, the velocity $\dot{\boldsymbol{x}}_A(t) = \nabla_A S(\boldsymbol{x}_A, \boldsymbol{x}_B, t)/m_A$ of $A$ depends instantaneously on $\boldsymbol{x}_B$, and local operations at $B$ – such as switching on a potential – instantaneously affect the motion of $A$. For an ensemble $P(\boldsymbol{x}_A, \boldsymbol{x}_B, t) = |\Psi(\boldsymbol{x}_A, \boldsymbol{x}_B, t)|^2$, local operations at $B$ have no statistical effect at $A$: the individual nonlocal effects vanish upon averaging over an equilibrium ensemble.

Nonlocality is (generally) hidden by statistical noise only in quantum equilibrium. If instead $P(\boldsymbol{x}_A, \boldsymbol{x}_B, 0) \neq |\Psi(\boldsymbol{x}_A, \boldsymbol{x}_B, 0)|^2$, a local change in the Hamiltonian at $B$ generally induces an instantaneous change in the marginal $p_A(\boldsymbol{x}_A, t) \equiv \int d^3\boldsymbol{x}_B P(\boldsymbol{x}_A, \boldsymbol{x}_B, t)$ at $A$. For example, in one dimension a sudden change $\hat{H}_B \to \hat{H}'_B$ in the Hamiltonian at $B$ induces a change $\Delta p_A \equiv p_A(x_A, t) - p_A(x_A, 0)$ (for small $t$) (Valentini 1991),

$$\Delta p_A = -\frac{t^2}{4m}\frac{\partial}{\partial x_A}\left(a(x_A)\int dx_B \ b(x_B) \times \frac{P(x_A, x_B, 0) - |\Psi(x_A, x_B, 0)|^2}{|\Psi(x_A, x_B, 0)|^2}\right) \qquad [8]$$

(Here $m_A = m_B = m$, $a(x_A)$ depends on $\Psi(x_A, x_B, 0)$, while $b(x_B)$ also depends on $\hat{H}'_B$ and vanishes if $\hat{H}'_B = \hat{H}_B$.) The signal is generally nonzero if $P_0 \neq |\Psi_0|^2$.

Nonlocal signals do not lead to causal paradoxes if, at the hidden-variable level, there is a preferred foliation of spacetime with a time parameter that defines a fundamental causal sequence. Such signals, if they were observed, would define an absolute simultaneity as discussed by Valentini in 1992 and 2005. Note that in pilot-wave field theory, Lorentz invariance emerges as a phenomenological symmetry of the equilibrium state, conditional on the structure of the field-theoretical Hamiltonian (as discussed by Bohm and Hiley in 1984, Bohm, Hiley and Kaloyerou in 1987, and Valentini in 1992 and 1996).

## Subquantum Measurement

In principle, nonequilibrium particles could also be used to perform "subquantum measurements" on ordinary, equilibrium systems. We illustrate this with an exactly solvable one-dimensional model (Valentini 2002b).

Consider an apparatus "pointer" coordinate $y$, with known wave function $g_0(y)$ and known (ensemble) distribution $\pi_0(y) \neq |g_0(y)|^2$, where $\pi_0(y)$ has been deduced by statistical analysis of random samples from a parent population with known wave function $g_0(y)$. (We assume that relaxation may be neglected: for example, if $g_0$ is a box ground state, $\dot{y} = 0$ and $\pi_0(y)$ is static.) Consider also a "system" coordinate $x$ with known wave function $\psi_0(x)$ and known distribution $\rho_0(x) = |\psi_0(x)|^2$. If $\pi_0(y)$ is arbitrarily narrow, $x_0$ can be measured without

disturbing $\psi_0(x)$, to arbitrary accuracy (violating the uncertainty principle).

To do this, at $t = 0$ we switch on an interaction Hamiltonian $\hat{H} = a\hat{x}\hat{p}_y$, where $a$ is a constant and $p_y$ is canonically conjugate to $y$. For relatively large $a$, we may neglect the Hamiltonians of $x$ and $y$. For $\Psi = \Psi(x, y, t)$, we then have $\partial\Psi/\partial t = -ax\partial\Psi/\partial y$. For $|\Psi|^2$ we have the continuity equation $\partial|\Psi|^2/\partial t = -ax\partial|\Psi|^2/\partial y$, which implies the hidden-variable velocity fields $\dot{x} = 0, \dot{y} = ax$ and trajectories $x(t) = x_0$, $y(t) = y_0 + ax_0t$.

The initial product $\Psi_0(x, y) = \psi_0(x)g_0(y)$ evolves into $\Psi(x, y, t) = \psi_0(x)g_0(y - axt)$. For $at \to 0$ (with $a$ large but fixed), $\Psi(x, y, t) \to \psi_0(x)g_0(y)$ and $\psi_0(x)$ is undisturbed: for small $at$, a standard quantum pointer with the coordinate $y$ would yield negligible information about $x_0$. Yet, for arbitrarily small $at$, the hidden-variable pointer coordinate $y(t) = y_0 + ax_0t$ does contain complete information about $x_0$ (and $x(t) = x_0$). This "subquantum" information will be visible to us if $\pi_0(y)$ is sufficiently narrow.

For, over an ensemble of similar experiments, with initial joint distribution $P_0(x, y) = |\psi_0(x)|^2\pi_0(y)$ (equilibrium for $x$ and nonequilibrium for $y$), the continuity equation $\partial P/\partial t = -ax\partial P/\partial y$ implies that $P(x, y, t) = |\psi_0(x)|^2\pi_0(y - axt)$. If $\pi_0(y)$ is localized around $y = 0$ ($\pi_0(y) = 0$ for $|y| > w/2$), then a standard (faithful) measurement of $y$ with result $y_{\text{meas}}$ will imply that $x$ lies in the interval ($y_{\text{meas}}/at - w/2at$, $y_{\text{meas}}/at + w/2at$) (so that $P(x, y, t) \neq 0$). Taking the simultaneous limits $at \to 0$, $w \to 0$, with $w/at \to 0$, the midpoint $y_{\text{meas}}/at \to x_0$ (since $y_{\text{meas}} = y_0 + ax_0t$ and $|y_0| \leq w/2$), while the error $w/2at \to 0$.

If $w$ is arbitrarily small, a sequence of such measurements will determine the hidden trajectory $x(t)$ without disturbing $\psi(x, t)$, to arbitrary accuracy.

### Subquantum Information and Computation

From a hidden-variables perspective, immense physical resources are hidden from us by equilibrium statistical noise. Quantum nonequilibrium would probably be as useful technologically as thermal or chemical nonequilibrium.

**Distinguishing nonorthogonal states** In quantum theory, nonorthogonal states $|\psi_1\rangle, |\psi_2\rangle$ ($\langle\psi_1|\psi_2\rangle \neq 0$) cannot be distinguished without disturbing them. This theorem breaks down in quantum nonequilibrium (Valentini 2002b). For example, if $|\psi_1\rangle, |\psi_2\rangle$ are distinct states of a single spinless particle, then the associated de Broglie–Bohm velocity fields will in general be different, even if $\langle\psi_1|\psi_2\rangle \neq 0$, and so will the hidden-variable trajectories. Subquantum measurement of the trajectories could then distinguish the states $|\psi_1\rangle, |\psi_2\rangle$.

**Breaking quantum cryptography** The security of standard protocols for quantum key distribution depends on the validity of the laws of quantum theory. These protocols would become insecure given the availability of nonequilibrium systems (Valentini 2002b).

The protocols known as BB84 and B92 depend on the impossibility of distinguishing nonorthogonal quantum states without disturbing them. An eavesdropper in possession of nonequilibrium particles could distinguish the nonorthogonal states being transmitted between two parties, and so read the supposedly secret key. Further, if subquantum measurements allow an eavesdropper to predict quantum measurement outcomes at each "wing" of a (bipartite) entangled state, then the EPR (Einstein–Podolsky–Rosen) protocol also becomes insecure.

**Subquantum computation** It has been suggested that nonequilibrium physics would be computationally more powerful than quantum theory, because of the ability to distinguish nonorthogonal states (Valentini 2002b). However, this ability depends on the (less-than-quantum) dispersion $w$ of the nonequilibrium ensemble. A well-defined model of computational complexity requires that the resources be quantified in some way. Here, a key question is how the required $w$ scales with the size of the computational task. So far, no rigorous results are known.

### Extension to All Deterministic Hidden-Variables Theories

Let us now discuss arbitrary (deterministic) theories.

**Nonlocal signaling** Consider a pair of two-state quantum systems $A$ and $B$, which are widely separated and in the singlet state. Quantum measurements of observables $\hat{\sigma}_A \equiv \boldsymbol{m}_A \cdot \hat{\boldsymbol{\sigma}}_A, \hat{\sigma}_B \equiv \boldsymbol{m}_B \cdot \hat{\boldsymbol{\sigma}}_B$ (where $\boldsymbol{m}_A, \boldsymbol{m}_B$ are unit vectors in Bloch space and $\hat{\boldsymbol{\sigma}}_A, \hat{\boldsymbol{\sigma}}_B$ are Pauli spin operators) yield outcomes $\sigma_A, \sigma_B = \pm 1$, in the ratio $1:1$ at each wing, with a correlation $\langle\hat{\sigma}_A\hat{\sigma}_B\rangle = -\boldsymbol{m}_A \cdot \boldsymbol{m}_B$. Bell's theorem shows that for a hidden-variables theory to reproduce this correlation – upon averaging over an equilibrium ensemble with distribution $\rho_{\text{QT}}(\lambda)$ – it must take the nonlocal form

$$\sigma_A = \sigma_A(\boldsymbol{m}_A, \boldsymbol{m}_B, \lambda), \qquad \sigma_B = \sigma_B(\boldsymbol{m}_A, \boldsymbol{m}_B, \lambda) \qquad [9]$$

More precisely, to obtain $\langle\sigma_A\sigma_B\rangle_{\text{QT}} = -\boldsymbol{m}_A \cdot \boldsymbol{m}_B$ (where $\langle\sigma_A\sigma_B\rangle_{\text{QT}} \equiv \int d\lambda\rho_{\text{QT}}(\lambda)\sigma_A\sigma_B$), at least one of

$\sigma_A, \sigma_B$ must depend on the measurement setting at the distant wing. Without loss of generality, we assume that $\sigma_A$ depends on $\boldsymbol{m}_B$.

For an arbitrary nonequilibrium ensemble with distribution $\rho(\lambda) \neq \rho_{\mathrm{QT}}(\lambda)$, in general $\langle \sigma_A \sigma_B \rangle \equiv \int \mathrm{d}\lambda\, \rho(\lambda) \sigma_A \sigma_B$ differs from $-\boldsymbol{m}_A \cdot \boldsymbol{m}_B$, and the outcomes $\sigma_A, \sigma_B = \pm 1$ occur in a ratio different from $1:1$. Further, a change of setting $\boldsymbol{m}_B \to \boldsymbol{m}'_B$ at $B$ will generally induce a change in the outcome statistics at $A$, yielding a nonlocal signal at the statistical level. To see this, note that, in a nonlocal theory, the "transition sets"

$$T_A(-,+) \equiv \{\lambda | \sigma_A(\boldsymbol{m}_A, \boldsymbol{m}_B, \lambda) = -1, \; \sigma_A(\boldsymbol{m}_A, \boldsymbol{m}'_B, \lambda) = +1\}$$
$$T_A(+,-) \equiv \{\lambda | \sigma_A(\boldsymbol{m}_A, \boldsymbol{m}_B, \lambda) = +1, \; \sigma_A(\boldsymbol{m}_A, \boldsymbol{m}'_B, \lambda) = -1\}$$

cannot be empty for arbitrary settings. Yet, in quantum equilibrium, the outcomes $\sigma_A = \pm 1$ occur in the ratio $1:1$ for all settings, so the transition sets must have equal equilibrium measure, $\mu_{\mathrm{QT}}[T_A(-,+)] = \mu_{\mathrm{QT}}[T_A(+,-)]$ ($\mathrm{d}\mu_{\mathrm{QT}} \equiv \rho_{\mathrm{QT}}(\lambda)\mathrm{d}\lambda$). That is, the fraction of the equilibrium ensemble making the transition $\sigma_A = -1 \to \sigma_A = +1$ under $\boldsymbol{m}_B \to \boldsymbol{m}'_B$ must equal the fraction making the reverse transition $\sigma_A = +1 \to \sigma_A = -1$. (This "detailed balancing" is analogous to the principle of detailed balance in statistical mechanics.) Since $T_A(-,+), T_A(+,-)$ are fixed by the deterministic mapping, they are independent of the ensemble distribution $\rho(\lambda)$. Thus, for $\rho(\lambda) \neq \rho_{\mathrm{QT}}(\lambda)$, in general $\mu[T_A(-,+)] \neq \mu[T_A(+,-)]$ ($\mathrm{d}\mu \equiv \rho(\lambda) d\lambda$): the fraction of the nonequilibrium ensemble making the transition $\sigma_A = -1 \to \sigma_A = +1$ will not in general balance the fraction making the reverse transition. The outcome ratio at $A$ will then change under $\boldsymbol{m}_B \to \boldsymbol{m}'_B$ and there will be an instantaneous signal at the statistical level from $B$ to $A$ (Valentini 2002a).

Thus, in any deterministic hidden-variables theory, nonequilibrium distributions $\rho(\lambda) \neq \rho_{\mathrm{QT}}(\lambda)$ generally allow entanglement to be used for nonlocal signalling (just as, in ordinary statistical physics, differences of temperature make it possible to convert heat into work).

**Experimental signature of nonequilibrium** Quantum expectations are additive, $\langle c_1 \hat{\Omega}_1 + c_2 \hat{\Omega}_2 \rangle = c_1 \langle \hat{\Omega}_1 \rangle + c_2 \langle \hat{\Omega}_2 \rangle$, even for noncommuting observables ($[\hat{\Omega}_1, \hat{\Omega}_2] \neq 0$, with $c_1$, $c_2$ real). As emphasized by Bell in 1966, this seemingly trivial consequence of the (linearity of the) Born rule $\langle \hat{\Omega} \rangle = \mathrm{tr}(\hat{\rho}\hat{\Omega})$ is remarkable because it relates statistics from distinct, "incompatible" experiments. In nonequilibrium, such additivity generically breaks down (Valentini 2004b).

Further, for a two-state system with observables $\boldsymbol{m} \cdot \hat{\boldsymbol{\sigma}}$, the "dot-product" structure of the quantum expectation $\langle \boldsymbol{m} \cdot \hat{\boldsymbol{\sigma}} \rangle = \mathrm{tr}(\hat{\rho} \boldsymbol{m} \cdot \hat{\boldsymbol{\sigma}}) = \boldsymbol{m} \cdot \boldsymbol{P}$ (for some Bloch vector $\boldsymbol{P}$) is equivalent to expectation additivity (Valentini 2004b). Nonadditive expectations then provide a convenient signature of nonequilibrium for any two-state system. For example, the sinusoidal modulation of the quantum transmission probability for a single photon through a polarizer

$$p^{+}_{\mathrm{QT}}(\Theta) = \tfrac{1}{2}(1 + \langle \boldsymbol{m} \cdot \hat{\boldsymbol{\sigma}} \rangle) = \tfrac{1}{2}(1 + P \cos 2\Theta) \qquad [10]$$

(where an angle $\theta$ on the Bloch sphere corresponds to a physical angle $\Theta = \theta/2$) will generically break down in nonequilibrium. Deviations from [10] would provide an unambiguous violation of quantum theory (Valentini 2004b).

Such deviations were searched for by Papaliolios in 1967, using laboratory photons and successive polarization measurements over very short times, to test a hidden-variables theory (distinct from pilot-wave theory) due to Bohm and Bub (1966), in which quantum measurements generate nonequilibrium for short times. Experimentally, successive measurements over timescales $\sim 10^{-13}$ s agreed with the (quantum) sinusoidal modulation $\cos^2 \Theta$ to $\lesssim 1\%$. Similar tests might be performed with photons of a more exotic origin.

## Continuous Spontaneous Localization Model (CSL)

The basic postulate of CSL is that the state vector $|\psi, t\rangle$ represents reality. Since, for example, in describing a measurement, the usual Schrödinger evolution readily takes a real state into a nonreal state, that is, into a superposition of real states (such as apparatus states describing different experimental outcomes), CSL requires a modification of Schrödinger's evolution. To the Hamiltonian is added a term which depends upon a classical randomly fluctuating field $w(\boldsymbol{x}, t)$ and a mass-density operator $\hat{A}(\boldsymbol{x}, t)$. This term acts to collapse a superposition of states, which differ in their spatial distribution of mass density, to one of these states. The rate of collapse is very slow for a superposition involving a few particles, but very fast for a superposition of macroscopically different states. Thus, very rapidly, what you see (in nature) is what you get (from the theory). Each state vector evolving under each $w(\boldsymbol{x}, t)$ corresponds to a realizable state, and a rule is given for how to associate a probability with each. In this way, an

unambiguous specification S, as mentioned in the introduction, is achieved.

### Requirements for Stochastic Collapse Dynamics

Consider a normalized state vector $|\psi, t\rangle = \sum_n \alpha_n(t)|a_n\rangle (\langle a_n|a_{n'}\rangle = \delta_{nn'})$ which undergoes a stochastic dynamical collapse process. This means that, starting from the initial superposition at $t=0$, for each run of the process, the squared amplitudes $x_n(t) \equiv |\alpha_n(t)|^2$ fluctuate until all but one vanish, that is, $x_m(\infty)=1, (x_{\neq m}(\infty)=0)$ with probability $x_m(0)$.

This may be achieved simply, assuming negligible effect of the usual Schrödinger evolution, if the stochastic process enjoys the following properties (Pearle 1979):

$$\sum_n x_n(t) = 1 \quad [11a]$$

$$\overline{x_n(t)} = x_n(0) \quad [11b]$$

$$\overline{x_n(\infty)x_m(\infty)} = 0 \quad \text{for } m \neq n \quad [11c]$$

where the overbar indicates the ensemble average at the indicated time. The only way that a sum of products of non-negative terms can vanish is for at least one term in each product to vanish. Thus, according to [11c], for each run, at least one of each pair $\{x_n(\infty), x_m(\infty)\}(n \neq m)$ must vanish. This means that at most one $x_n(\infty)$ might not vanish and, by [11a], applied at $t=\infty$, one $x_n(\infty)$ must not vanish and, in fact, must equal 1: hence, each run produces collapse. Now, let the probability of the outcome $\{x_n(\infty)=1, x_{\neq n}(\infty)=0\}$ be denoted $P_n$. Since $\overline{x_n(\infty)} = 1 \cdot P_n + \sum_{m \neq n} 0 \cdot P_m = P_n$ then, according to the Martingale property [11b], applied at $t=\infty, P_n = x_n(0)$: hence, the ensemble of runs produces the probability postulated by the usual "collapse rule" of standard quantum theory.

A (nonquantum) stochastic process which obeys these equations is the gambler's ruin game. Suppose one gambler initially possesses the fraction $x_1(0)$ of their joint wealth, and the other has the fraction $x_2(0)$. They toss a coin: heads, a dollar goes from gambler 1 to gambler 2, tails the dollar goes the other way. [11a] is satisfied since the sum of money in the game remains constant, [11b] holds because it is a fair game, and [11c] holds because each game eventually ends. Thus, gambler $i$ wins all the money with probability $x_i(0)$.

### CSL in Essence

Consider the (nonunitary) Schrödinger picture evolution equation

$$|\psi, t\rangle_w = \mathcal{T} \exp\left(-\int_0^t \mathrm{d}t' \{i\hat{H} + (4\lambda)^{-1}[w(t') - 2\lambda\hat{A}]^2\}\right)|\psi, 0\rangle \quad [12]$$

where $\hat{H}$ is the usual Hamiltonian, $w(t')$ is an arbitrary function of white noise class, $\hat{A}$ is a Hermitian operator $(\hat{A}|a_n\rangle = a_n|a_n\rangle), \lambda$ is a collapse rate parameter, $\mathcal{T}$ is the time-ordering operator and $\hbar=1$. Associated with this, the probability rule

$$P_t(w)Dw \equiv {}_w\langle\psi, t|\psi, t\rangle_w \prod_{j=0}^{t/\mathrm{d}t} \mathrm{d}w(t_j)/(2\pi\lambda/\mathrm{d}t)^{1/2} \quad [13]$$

is defined, which gives the probability that nature chooses a noise which lies in the range $\{w(t'), w(t') + \mathrm{d}w(t')\}$ for $0 \leq t' \leq t$ (for calculational purposes, time is discretized, with $t_0=0$).

Equations [12] and [13] contain the essential features of CSL, and are all that is needed to discuss the simplest collapse behavior. Set $\hat{H}=0$, so there is no competition between collapse and the usual Schrödinger evolution, and let the initial state vector be $|\psi, 0\rangle = \sum_n \alpha_n|a_n\rangle$. Equations [12] and [13] become

$$|\psi, t\rangle_w = \sum_n \alpha_n|a_n\rangle \exp\left(-(4\lambda)^{-1}\int_0^t \mathrm{d}t'[w(t') - 2\lambda a_n]^2\right) \quad [14a]$$

$$P_t(w) = \sum_n |\alpha_n|^2 \exp\left(-(2\lambda)^{-1}\int_0^t \mathrm{d}t'[w(t') - 2\lambda a_n]^2\right) \quad [14b]$$

When the unnormalized state vector in [14a] is divided by $P_t^{1/2}(w)$ and so normalized, the squared amplitudes are

$$x_n(t) = |\alpha_n|^2 \exp\left(-(2\lambda)^{-1} \times \int_0^t \mathrm{d}t'[w(t') - 2\lambda a_n]^2\right)/P_t(w)$$

which are readily shown to satisfy [11a], [11b], and [11c] in the form $\overline{x_n^{1/2}(\infty)x_m^{1/2}(\infty)} = 0 (m \neq n)$ (which does not change the argument in the last subsection, but makes for an easier calculation). Thus, [14a] and [14b] describe collapse dynamics.

To describe collapse to a joint eigenstate of a set of mutually commuting operators $\hat{A}^r$, replace $(4\lambda)^{-1}[w(t') - 2\lambda\hat{A}]^2$ in the exponent of [12] by $\sum_r (4\lambda)^{-1}[w^r(t') - 2\lambda\hat{A}^r]^2$. The interaction picture state vector in this case is [12] multiplied by $\exp(\mathrm{i}\hat{H}t)$:

$$|\psi, t\rangle_w = \mathcal{T}\exp\left(-(4\lambda)^{-1}\int_0^l \mathrm{d}t' \times \sum_r [w^r(t') - 2\lambda\hat{A}^r(t')]^2\right)|\psi, 0\rangle \quad [15]$$

where $\hat{A}^r(t') \equiv \exp(\mathrm{i}\hat{H}t')\hat{A}^r\exp(-\mathrm{i}\hat{H}t')$. The density matrix follows from [15], and [13]:

$$\hat{\rho}(t) \equiv \int P_t(w)Dw|\psi, t\rangle_{w\,w}\langle\psi, t|/P_t(w) = \mathcal{T}\exp\left(-\lambda/2\int_0^t \mathrm{d}t' \times \sum_r [\hat{A}^r_{\mathrm{L}}(t') - \hat{A}^r_{\mathrm{R}}(t')]^2\right)\hat{\rho}(0) \quad [16]$$

where $\hat{A}^r_{\mathrm{L}}(t')(\hat{A}^r_{\mathrm{R}}(t'))$ appears to the left (right) of $\hat{\rho}(0)$, and is time-ordered (time reverse-ordered). In the example described by [14], the density matrix [16] is

$$\hat{\rho}(t) = \sum_{n,m} \mathrm{e}^{-(\lambda t/2)(a_n - a_m)^2}\alpha_n\alpha_m^*|a_n\rangle\langle a_m|$$

which encapsulates the ensemble's collapse behavior.

### CSL

The CSL proposal (Pearle 1989) is that collapse is engendered by distinctions between states at each point of space, so the index $r$ of $\hat{A}^r$ in [15] becomes $\boldsymbol{x}$,

$$|\psi, t\rangle_w = \mathcal{T}\exp\left(-(4\lambda)^{-1}\int_0^t\int \mathrm{d}t'\,\mathrm{d}\boldsymbol{x}' \times [w(\boldsymbol{x}', t') - 2\lambda\hat{A}(\boldsymbol{x}', t')]^2\right)|\psi, 0\rangle \quad [17]$$

and the distinction looked at is mass density. However, one cannot make the choice $\hat{A}(\boldsymbol{x}, 0) = \hat{M}(\boldsymbol{x})$, where $\hat{M}(\boldsymbol{x}) = \sum_i m_i\hat{\xi}_i^\dagger(\boldsymbol{x})\hat{\xi}_i(\boldsymbol{x})$ is the mass-density operator ($m_i$ is the mass of the $i$th type of particle, so $m_{\mathrm{e}}, m_{\mathrm{p}}, m_{\mathrm{n}}, \ldots$ are the masses, respectively, of electrons, protons, neutrons…, and $\hat{\xi}_i^\dagger(\boldsymbol{x})$ is the creation operator for such a particle at location $\boldsymbol{x}$), because this entails an infinite rate of energy increase of particles ([23] with $a = 0$). Instead, adapting a "Gaussian smearing" idea from the Ghirardi *et al.* (1986) spontaneous localization (SL) model (see the subsection "Spontaneous localization model"), choose $\hat{A}^{\boldsymbol{x}}$ as, essentially, proportional to the mass in a sphere of radius $a$ about $\boldsymbol{x}$:

$$\hat{A}(\boldsymbol{x}, t) \equiv \mathrm{e}^{\mathrm{i}\hat{H}t}\frac{1}{(\pi a^2)^{3/4}} \times \int \mathrm{d}\boldsymbol{z}\frac{\hat{M}(\boldsymbol{z})}{m_{\mathrm{p}}}\mathrm{e}^{-(2a^2)^{-1}(\boldsymbol{x}-\boldsymbol{z})^2}\mathrm{e}^{-\mathrm{i}\hat{H}t} \quad [18]$$

The parameter value choices of SL, $\lambda \approx 10^{-16}\,\mathrm{s}^{-1}$ (according to [17] and [18], the collapse rate for protons) and $a \approx 10^{-5}$ cm are, so far, consistent with experiment (see the next subsection), and will be adopted here.

The density matrix associated with [17] is, as in [16],

$$\hat{\rho}(t) = \mathcal{T}\exp\left(-(\lambda/2)\int_0^t \mathrm{d}t'\,\mathrm{d}\boldsymbol{x}'[\hat{A}_{\mathrm{L}}(\boldsymbol{x}', t') - \hat{A}_{\mathrm{R}}(\boldsymbol{x}', t')]^2\right)\hat{\rho}(0) \quad [19]$$

which satisfies the differential equation

$$\frac{\mathrm{d}\hat{\rho}(t)}{\mathrm{d}t} = -\frac{\lambda}{2}\int \mathrm{d}\boldsymbol{x}'[\hat{A}(\boldsymbol{x}', t), [\hat{A}(\boldsymbol{x}', t), \hat{\rho}(t)]] \quad [20]$$

of Lindblad–Kossakowski form.

### Consequences of CSL

Since the state vector dynamics of CSL is different from that of standard quantum theory, there are phenomena for which the two make different predictions, allowing for experimental tests. Consider an $N$-particle system with position operators $\hat{\boldsymbol{X}}_i(\hat{\boldsymbol{X}}_i|\boldsymbol{x}\rangle = \boldsymbol{x}_i|\boldsymbol{x}\rangle)$. Substitution of $\hat{A}(\boldsymbol{x}')$ from [18] in the Schrödinger picture version of [20], integration over $\boldsymbol{x}'$, and utilization of

$$f(\boldsymbol{z})\hat{M}(\boldsymbol{z})|\boldsymbol{x}\rangle = \sum_{i=1}^N m_i f(\hat{\boldsymbol{X}}_i)\delta(\boldsymbol{z} - \hat{\boldsymbol{X}}_i)|\boldsymbol{x}\rangle$$

results in

$$\frac{\mathrm{d}\hat{\rho}(t)}{\mathrm{d}t} = -\mathrm{i}[\hat{\rho}(t), \hat{H}] - \frac{\lambda}{2}\sum_{i=1}^N\sum_{j=1}^N \frac{m_i}{m_{\mathrm{p}}}\frac{m_j}{m_{\mathrm{p}}} \times \left[\mathrm{e}^{-(4a^2)^{-1}(\hat{\boldsymbol{X}}_{\mathrm{L}i} - \hat{\boldsymbol{X}}_{\mathrm{L}j})^2} + \mathrm{e}^{-(4a^2)^{-1}(\hat{\boldsymbol{X}}_{\mathrm{R}i} - \hat{\boldsymbol{X}}_{\mathrm{R}j})^2} - 2\mathrm{e}^{-(4a^2)^{-1}(\hat{\boldsymbol{X}}_{\mathrm{L}i} - \hat{\boldsymbol{X}}_{\mathrm{R}j})^2}\right]\hat{\rho}(t) \quad [21]$$

which is a useful form for calculations first suggested by Pearle and Squires in 1994.

**Interference** Consider the collapse rate of an initial state $|\phi\rangle = \alpha_1|1\rangle + \alpha_2|2\rangle$, where $|1\rangle, |2\rangle$ describe a

clump of matter, of size $\ll a$, at different locations with separation $\gg a$. Electrons may be neglected because of their small collapse rate compared to the much more massive nucleons, and the nucleon mass difference may be neglected. In using [21] to calculate $\mathrm{d}\langle 1|\hat{\rho}(t)|2\rangle/\mathrm{d}t$, since $\exp[-(4a^2)^{-1}(\hat{\boldsymbol{X}}_i - \hat{\boldsymbol{X}}_j)^2] \approx 1$ when acting on state $|1\rangle$ or $|2\rangle$, and $\approx 0$ when $\hat{\boldsymbol{X}}_i$ acts on $|1\rangle$ and $\hat{\boldsymbol{X}}_j$ acts on $|2\rangle$, [21] yields, for $N$ nucleons, the collapse rate $\lambda N^2$:

$$\frac{\mathrm{d}\langle 1|\hat{\rho}(t)|2\rangle}{\mathrm{d}t} = -\mathrm{i}\langle 1|[\hat{\rho}(t), \hat{H}]|2\rangle - \lambda N^2\langle 1|\hat{\rho}(t)|2\rangle \quad [22]$$

If the clump undergoes a two-slit interference experiment, where the size and separation conditions above are satisfied for a time $\Delta T$, and if the result agrees with the standard quantum theory prediction to 1%, it also agrees with CSL provided $\lambda^{-1} > 100N^2\Delta T$. So far, interference experiments with $N$ as large as $\approx 10^3$ have been performed, by Nairz, Arndt, and Zeilinger in 2000. The SL value of $\lambda^{-1} \approx 10^{16}$ would be testable, that is, the quantum-predicted interference pattern would be "washed out" to 1% accuracy, if the clump were an $\approx 10^{-6}$ cm radius sphere of mercury, which contains $N \approx 10^8$ nucleons, interfered for $\Delta T = 0.01$ s. Currently envisioned but not yet performed experiments (e.g., by Marshall, Simon, Penrose, and Bouwmester in 2003) have been analyzed (e.g., by Bassi, Ippoliti, and Adler in 2004 and by Adler in 2005), which involve a superposition of a larger clump of matter in slightly displaced positions, entangled with a photon whose interference pattern is measured: these proposed experiments are still too crude to detect the SL value of $\lambda$, or the gravitationally based collapse rate proposed by Penrose in 1996 (see the next section and papers by Christian in 1999 and 2005).

**Bound state excitation** Collapse narrows wave packets, thereby imparting energy to particles. If $\hat{H} = \sum_{i=1}^{N} \hat{\boldsymbol{P}}_i^2/2m_i + \hat{V}(\boldsymbol{x}_1, \ldots, \boldsymbol{x}_N)$, it is straightforward to calculate from [21] that

$$\frac{\mathrm{d}}{\mathrm{d}t}\langle\hat{H}\rangle \equiv \frac{\mathrm{d}}{\mathrm{d}t}\mathrm{tr}[\hat{H}\hat{\rho}(t)] = \sum_{i=1}^{N} \frac{3\lambda\hbar^2}{4m_i a^2} \quad [23]$$

For a nucleon, the mean rate of energy increase is quite small, $\approx 3 \times 10^{-25}$ eV s$^{-1}$. However, deviations from the mean can be significantly greater.

Equation [21] predicts excitation of atoms and nuclei. Let $|E_0\rangle$ be an initial bound energy eigenstate. Expanding [21] in a power series in (bound state size/$a$)$^2$, the excitation rate of state $|E\rangle$ is

$$\Gamma \equiv \frac{\mathrm{d}\langle E|\hat{\rho}(t)|E\rangle}{\mathrm{d}t}\Big|_{t=0} = \frac{\lambda}{2a^2}\left\langle E\Big|\sum_{i=1}^{N}\frac{m_i}{m_\mathrm{p}}\hat{\boldsymbol{X}}_i\Big|E_0\right\rangle\left\langle E_0\Big|\sum_{i=1}^{N}\frac{m_i}{m_\mathrm{p}}\hat{\boldsymbol{X}}_i\Big|E\right\rangle + \mathrm{O}(\mathrm{size}/a)^4 \quad [24]$$

Since $|E_0\rangle, |E\rangle$ are eigenstates of the center-of-mass operator $\sum_{i=1}^{N} m_i\hat{\boldsymbol{X}}_i/\sum_{i=1}^{N} m_i$ with eigenvalue 0, the dipole contribution explicitly given in [24] vanishes identically. This leaves the quadrupole contribution as the leading term, which is too small to be measured at present.

However, the choice of $\hat{A}(\boldsymbol{x})$ as mass-density operator was made only after experimental indication. Let $g_i$ replace $m_i/m_\mathrm{p}$ in [21] and [24], so that $\lambda g_i^2$ is the collapse rate for the $i$th particle. Then, experiments looking for the radiation expected from "spontaneously" excited atoms and nuclei, in large amounts of matter for a long time, as shown by Collett, Pearle, Avignone, and Nussinov in 1995, Pearle, Ring, Collar, and Avignone in 1999, and Jones, Pearle, and Ring in 2004, have placed the following limits:

$$\left|\frac{g_\mathrm{e}}{g_\mathrm{p}} - \frac{m_\mathrm{e}}{m_\mathrm{p}}\right| < \frac{12m_\mathrm{e}}{m_\mathrm{p}}, \quad \left|\frac{g_\mathrm{n}}{g_\mathrm{p}} - \frac{m_\mathrm{n}}{m_\mathrm{p}}\right| < \frac{3(m_\mathrm{n} - m_\mathrm{p})}{m_\mathrm{p}}$$

**Random walk** According to [17] and [13], the center-of-mass wave packet, of a piece of matter of size $\approx a$ or smaller, containing $N$ nucleons, achieves equilibrium size $s$ in a characteristic time $\tau_s$, and undergoes a random walk through a root-mean-square distance $\Delta Q$:

$$s \approx \left[\frac{a^2\hbar}{\lambda m_\mathrm{p}N^3}\right]^{1/4}, \qquad \tau_s \approx \frac{Nm_\mathrm{p}s^2}{\hbar}$$
$$\Delta Q \approx \frac{\hbar\lambda^{1/2}t^{3/2}}{m_\mathrm{p}a} \quad [25]$$

The results in [25] were obtained by Collett and Pearle in 2003. These quantitative results can be qualitatively understood as follows.

In time $\Delta t$, the usual Schrödinger equation expands a wave packet of size $s$ to $\approx s + (\hbar/Nm_\mathrm{p}s)\Delta t$. CSL collapse, by itself, narrows the wave packet to $\approx s[1 - \lambda N^2(s/a)^2\Delta t]$. The condition of no change in $s$ is the result quoted above. $\tau_s$ is the time it takes the Schrödinger evolution to expand a wave packet near size $s$ to size $s$: $(\hbar/Nm_\mathrm{p}s)\tau_s \approx s$.

The $t^{3/2}$ dependence of $\Delta Q$ arises because this is a random walk without damping (unlike Brownian motion, where $\Delta Q \sim t^{1/2}$). The mean energy increase $\approx \lambda N \hbar^2 m_p^{-1} a^{-2} t$ of [23] implies the root-mean-square velocity increase $\approx [\lambda \hbar^2 m_p^{-2} a^{-2} t]^{1/2}$, whose product with $t$ is $\Delta Q$.

For example, a sphere of density $1\,\text{cm}^{-3}$ and radius $10^{-5}$ cm has $s \approx 4 \times 10^{-7}$ cm, $\tau_s \approx 0.6$ s and $\Delta Q \approx 5[t \text{ in days}]^{3/2}$ cm. At the low pressure of $5 \times 10^{-17}$ torr at 4.2 K reported by Gabrielse's group in 1990, the mean collision time with gas molecules is $\approx$80 min, over which $\Delta Q \approx 0.7$ mm. Thus, observation of this effect should be feasible.

### Further Remarks

It is possible to define energy for the $w(\boldsymbol{x}, t)$ field so that total energy is conserved: as the particles gain energy, the $w$-field loses energy, as shown by Pearle in 2005.

Attempts to construct a special-relativistic CSL-type model have not yet succeeded, although Pearle in 1990, 1992, and 1999, Ghirardi, Grassi, and Pearle in 1990, and Nicrosini and Rimini in 2003 have made valiant attempts. The problem is that the white noise field $w(\boldsymbol{x}, t)$ contains all wavelengths and frequencies, exciting the vacuum in lowest order in $\lambda$ to produce particles at the unacceptable rate of infinite energy/per second per cubic centimeter. Collapse models which utilize a colored noise field $w$ have a similar problem in higher orders. In 2005, Pearle suggested a quasirelativistic model which reduces to CSL in the low-speed limit.

CSL is a phenomenological model which describes dynamical collapse so as to achieve S. Besides needing decisive experimental verification, it needs identification of the $w(\boldsymbol{x}, t)$ field with a physical entity.

Other collapse models which have been investigated are briefly described below.

### Spontaneous Localization Model

The SL model of Ghirardi *et al.* (1986), although superseded by CSL, is historically important and conceptually valuable. Let $\hat{H} = 0$ for simplicity, and consider a single particle whose wave function at time $t$ is $\psi(\boldsymbol{x}, t)$. Over the next interval d$t$, with probability $1 - \lambda \mathrm{d}t$, it does not change. With probability $\lambda \mathrm{d}t$ it does change, by being "spontaneously localized" or "hit." A hit means that the new (unnormalized) wave function suddenly becomes

$$\psi(\boldsymbol{x}, t + \mathrm{d}t) = \psi(\boldsymbol{x}, t)(\pi a^2)^{-3/4}\, \mathrm{e}^{-(2a^2)^{-1}(\boldsymbol{x}-\boldsymbol{z})^2}$$

with probability

$$\lambda \mathrm{d}t\, \mathrm{d}\boldsymbol{z} \int \mathrm{d}\boldsymbol{x} |\psi(\boldsymbol{x}, t + \mathrm{d}t)|^2$$

Thus $\boldsymbol{z}$, the "center" of the hit, is most likely to be located where the wave function is large. For a single particle in the superposition described in the subsection "Interference," a single hit is overwhelmingly likely to reduce the wave function to one or the other location, with total probability $|\alpha_i|^2$, at the rate $\lambda$.

For an $N$-particle clump, it is considered that each particle has the same independent probability, $\lambda \mathrm{d}t$, of being hit. But, for the example in the subsection "Interference," a single hit on any particle in one location of the clump has the effect of multiplying the wave function part describing the clump in the other location by the tail of the Gaussian, thereby collapsing the wave function at the rate $\lambda N$.

By use of the Gaussian hit rather than a delta-function hit, SL solves the problem of giving too much energy to particles as mentioned in the subsection "CSL." By the hypothesis of independent particle hits, SL also solves the problem of achieving a slow collapse rate for a superposition of small objects and a fast collapse rate for a superposition of large objects. However, the hits on individual particles destroys the (anti-) symmetry of wave functions. The CSL collapse toward mass density eigenstates removes that problem. Also, while SL modifies the Schrödinger evolution of a wave function, it involves discontinuous dynamics and so is not described by a modified Schrödinger equation as is CSL.

## Other Models

For a single (low-energy) particle, the polar decomposition $\Psi = R\mathrm{e}^{(\mathrm{i}/\hbar)S}$ of the Schrödinger equation implies two real equations,

$$\frac{\partial R^2}{\partial t} + \boldsymbol{\nabla} \cdot \left( R^2 \frac{\boldsymbol{\nabla} S}{m} \right) = 0 \qquad [26]$$

(the continuity equation for $R^2 = |\Psi|^2$) and

$$\frac{\partial S}{\partial t} + \frac{(\boldsymbol{\nabla} S)^2}{2m} + V + Q = 0 \qquad [27]$$

where $Q \equiv -(\hbar^2/2m)\nabla^2 R/R$ is the "quantum potential." (These equations have an obvious generalisation to higher-dimensional configuration space.) In 1926, Madelung proposed that one should start from [26] and [27] – regarded as hydrodynamical equations for a classical charged fluid with mass density $mR^2$ and fluid velocity $\boldsymbol{\nabla} S/m$ – and construct $\Psi = R\mathrm{e}^{(\mathrm{i}/\hbar)S}$ from the solutions.

This "hydrodynamical" interpretation suffers from many difficulties, especially for many-body systems. In any case, a criticism by Wallstrom (1994) seems decisive: [26] and [27] (and their higher-dimensional analogs) are not, in fact, equivalent to the Schrödinger equation. For, as usually understood, the quantum wave function $\Psi$ is a single-valued and continuous complex field, which typically possesses nodes ($\Psi = 0$), in the neighborhood of which the phase $S$ is multivalued, with values differing by integral multiples of $2\pi\hbar$. If one allows $S$ in [26], [27] to be multivalued, there is no reason why the allowed values should differ by integral multiples of $2\pi\hbar$, and in general $\Psi$ will not be single-valued. On the other hand, if one restricts $S$ in [26], [27] to be single-valued, one will exclude wave functions – such as those of nonzero angular momentum – with a multivalued phase. (This problem does not exist in pilot-wave theory as we have presented it here, where $\Psi$ is regarded as a basic entity.)

Stochastic mechanics, introduced by Fényes in 1952 and Nelson (1966), has particle trajectories $\boldsymbol{x}(t)$ obeying a "forward" stochastic differential equation $\mathrm{d}\boldsymbol{x}(t) = \boldsymbol{b}(\boldsymbol{x}(t), t)\mathrm{d}t + \mathrm{d}\boldsymbol{w}(t)$, where $\boldsymbol{b}$ is a drift (equal to the mean forward velocity) and $\boldsymbol{w}$ a Wiener process, and also a similar "backward" equation. Defining the "current velocity" $\boldsymbol{v} = (1/2)(\boldsymbol{b} + \boldsymbol{b}_*)$, where $\boldsymbol{b}_*$ is the mean backward velocity, and using an appropriate time-symmetric definition of mean acceleration, one may impose a stochastic version of Newton's second law. If one assumes, in addition, that $\boldsymbol{v}$ is a gradient ($\boldsymbol{v} = \nabla S/m$ for some $S$), then one obtains [26], [27] with $R \equiv \sqrt{\rho}$, where $\rho$ is the particle density. Defining $\Psi \equiv \sqrt{\rho}\mathrm{e}^{(\mathrm{i}/\hbar)S}$, it appears that one recovers the Schrödinger equation for the derived quantity $\Psi$. However, again, there is no reason why $S$ should have the specific multivalued structure required for the phase of a single-valued complex field. It then seems that, despite appearances, quantum theory cannot in fact be recovered from stochastic mechanics (Wallstrom 1994). The same problem occurs in models that use stochastic mechanics as an intermediate step (e.g., Markopoulou and Smolin in 2004): the Schrödinger equation is obtained only for exceptional, nodeless wave functions.

Bohm and Bub (1966) first proposed dynamical wave-function collapse through deterministic evolution. Their collapse outcome is determined by the value of a Wiener–Siegel hidden variable (a variable distributed uniformly over the unit hypersphere in a Hilbert space identical to that of the state vector). In 1976, Pearle proposed dynamical wave-function collapse equations where the collapse outcome is determined by a random variable, and suggested (Pearle 1979) that the modified Schrödinger equation be formulated as an Itô stochastic differential equation, a suggestion which has been widely followed. (The equation for the state vector given here, which is physically more transparent, has its time derivative equivalent to a Stratonovich stochastic differential equation, which is readily converted to the Itô form.) The importance of requiring that the density matrix describing collapse be of the Lindblad–Kossakowski form was emphasized by Gisin in 1984 and Diosi in 1988. The stochastic differential Schrödinger equation that achieves this was found independently by Diosi in 1988 and by Belavkin, Gisin, and Pearle in separate papers in 1989 (see Ghirardi *et al.* 1990).

A gravitationally motivated stochastic collapse dynamics was proposed by Diosi in 1989 (and somewhat corrected by Ghirardi *et al.* in 1990). Penrose emphasized in 1996 that a quantum state, such as that describing a mass in a superposition of two places, puts the associated spacetime geometry also in a superposition, and has argued that this should lead to wave-function collapse. He suggests that the collapse time should be $\sim\hbar/\Delta E$, where $\Delta E$ is the gravitational potential energy change obtained by actually displacing two such masses: for example, the collapse time $\approx\hbar/(Gm^2/R)$, where the mass is $m$, its size is $R$, and the displacement is $\approx R$ or larger. No specific dynamics is offered, just the vision that this will be a property of a correct future quantum theory of gravity.

Collapse to energy eigenstates was first proposed by Bedford and Wang in 1975 and 1977 and, in the context of stochastic collapse (e.g., [11] with $\hat{A} = \hat{H}$), by Milburn in 1991 and Hughston in 1996, but it has been argued by Finkelstein in 1993 and Pearle in 2004 that such energy-driven collapse cannot give a satisfactory picture of the macroscopic world. Percival in 1995 and in a 1998 book, and Fivel in 1997 have discussed energy-driven collapse for microscopic situations.

Adler (2004) has presented a classical theory (a hidden-variables theory) from which it is argued that quantum theory "emerges" at the ensemble level. The classical variables are $N \times N$ matrix field amplitudes at points of space. They obey appropriate classical Hamiltonian dynamical equations which he calls "trace dynamics," since the expressions for Hamiltonian, Lagrangian, Poisson bracket, etc., have the form of the trace of products of matrices and their sums with constant coefficients. Using classical statistical mechanics, canonical ensemble averages of (suitably projected) products of fields are analyzed and it is argued that they obey all the properties associated with Wightman functions, from which quantum field theory, and its nonrelativistic-limit quantum mechanics, may be derived. As well as obtaining the algebra of quantum theory in this way,

it is argued that statistical fluctuations around the canonical ensemble can give rise to the behavior of wave-function collapse, of the kind discussed here, both energy-driven and CSL-type mass-density-driven collapse so that, with the latter, comes the Born probability interpretation of the algebra. The Hamiltonian needed for this theory to work is not provided but, as the argument progresses, its necessary features are delimited.

# Quantum Mechanics: Weak Measurements

**L Diósi**, Research Institute for Particle and Nuclear Physics, Budapest, Hungary

## Introduction

In quantum theory, the mean value of a certain observable $\hat{A}$ in a (pure) quantum state $|i\rangle$ is defined by the quadratic form:

$$\langle \hat{A} \rangle_i =: \langle i|\hat{A}|i\rangle \qquad [1]$$

Here $\hat{A}$ is Hermitian operator on the Hilbert space $\mathcal{H}$ of states. We use Dirac formalism. The above mean is interpreted statistically. No other forms had been known to possess a statistical interpretation in standard quantum theory. One can, nonetheless, try to extend the notion of mean for normalized bilinear expressions (Aharonov *et al.* 1988):

$$A_{\mathrm{w}} =: \frac{\langle f|\hat{A}|i\rangle}{\langle f|i\rangle} \qquad [2]$$

However unusual is this structure, standard quantum theory provides a plausible statistical interpretation for it, too. The two pure states $|i\rangle, |f\rangle$ play the roles of the prepared initial and the postselected final states, respectively. The statistical interpretation relies upon the concept of weak measurement. In a single weak measurement, the notorious decoherence is chosen asymptotically small. In physical terms, the coupling between the measured state and the meter is assumed asymptotically weak. The novel mean value [2] is called the (complex) weak value.

The concept of quantum weak measurement (Aharonov *et al.* 1988) provides particular

conclusions on postselected ensembles. Weak measurements have been instrumental in the interpretation of time-continuous quantum measurements on single states as well. Yet, weak measurement itself can properly be illuminated in the context of classical statistics. Classical weak measurement as well as postselection and time-continuous measurement are straightforward concepts leading to conclusions that are natural in classical statistics. In quantum context, the case is radically different and certain paradoxical conclusions follow from weak measurements. Therefore, we first introduce the classical notion of weak measurement on postselected ensembles and, alternatively, in time-continuous measurement on a single state. Certain idioms from statistical physics will be borrowed and certain not genuinely quantum notions from quantum theory will be anticipated. The quantum counterpart of weak measurement, postselection, and continuous measurement will be presented afterwards. The apparent redundancy of the parallel presentations is of reason: the reader can separate what is common in classical and quantum weak measurements from what is genuinely quantum.

## Classical Weak Measurement

Given a normalized probability density $\rho(X)$ over the phase space $\{X\}$, which we call the state, the mean value of a real function $A(X)$ is defined as

$$\langle A\rangle_\rho =: \int \mathrm{d}X\, A\rho \qquad [3]$$

Let the outcome of an (unbiased) measurement of $A$ be denoted by $a$. Its stochastic expectation value $E[a]$ coincides with the mean [3]:

$$E[a] = \langle A\rangle_\rho \qquad [4]$$

Performing a large number $N$ of independent measurements of $A$ on the elements of the ensemble of identically prepared states, the arithmetic mean $\bar{a}$ of the outcomes yields a reliable estimate of $E[a]$ and, this way, of the theoretical mean $\langle A\rangle_\rho$.

Suppose, for concreteness, the measurement outcome $a$ is subject to a Gaussian stochastic error of standard dispersion $\sigma > 0$. The probability distribution of $a$ and the update of the state corresponding to the Bayesian inference are described as

$$p(a) = \langle G_\sigma(a - A)\rangle_\rho \qquad [5]$$

$$\rho \to \frac{1}{p(a)} G_\sigma(a - A)\rho \qquad [6]$$

respectively. Here $G_\sigma$ is the central Gaussian distribution of variance $\sigma$. Note that, as expected, eqn [5] implies eqn [4]. Nonzero $\sigma$ means that the measurement is nonideal, yet the expectation value $E[a]$ remains calculable reliably if the statistics $N$ is suitably large.

Suppose the spread of $A$ in state $\rho$ is finite:

$$\Delta_\rho^2 A =: \langle A^2\rangle_\rho - \langle A\rangle_\rho^2 < \infty \qquad [7]$$

Weak measurement will be defined in the asymptotic limit (eqns [8] and [9]) where both the stochastic error of the measurement and the measurement statistics go to infinity. It is crucial that their rate is kept constant:

$$\sigma, N \to \infty \qquad [8]$$

$$\Delta^2 =: \frac{\sigma^2}{N} = \text{const.} \qquad [9]$$

Obviously for asymptotically large $\sigma$, the precision of individual measurements becomes extremely weak. This incapacity is fully compensated by the asymptotically large statistics $N$. In the weak measurement limit (eqns [8] and [9]), the probability distribution $p_\mathrm{w}$ of the arithmetic mean $\bar{a}$ of the $N$ independent outcomes converges to a Gaussian distribution:

$$p_\mathrm{w}(\bar{a}) \to G_\Delta\left(\bar{a} - \langle A\rangle_\rho\right) \qquad [10]$$

The Gaussian is centered at the mean $\langle A\rangle_\rho$, and the variance of the Gaussian is given by the constant rate [9]. Consequently, the mean [3] is reliably calculable on a statistics $N$ growing like $\sim\sigma^2$.

With an eye on quantum theory, we consider two situations – postselection and time-continuous measurement – of weak measurement in classical statistics.

### Postselection

For the preselected state $\rho$, we introduce postselection via the real function $\Pi(X)$, where $0 \le \Pi \le 1$. The postselected mean value of a certain real function $A(X)$ is defined by

$$_\Pi\langle A\rangle_\rho =: \frac{\langle \Pi A\rangle_\rho}{\langle \Pi\rangle_\rho} \qquad [11]$$

where $\langle \Pi\rangle_\rho$ is the rate of postselection. Postselection means that after having obtained the outcome $a$ regarding the measurement of $A$, we measure the function $\Pi$, too, in ideal measurement with random outcome $\pi$ upon which we base the following random decision. With probability $\pi$, we include the current $a$ into the statistics and we discard it

with probability $1-\pi$. Then the coincidence of $E[a]$ and ${}_\Pi\langle A\rangle_\rho$, as in eqn [4], remains valid:

$$E[a] = {}_\Pi\langle A\rangle_\rho \qquad [12]$$

Therefore, a large ensemble of postselected states allows one to estimate the postselected mean ${}_\Pi\langle A\rangle_\rho$.

Classical postselection allows introducing the effective postselected state:

$$\rho_\Pi =: \frac{\Pi\rho}{\langle\Pi\rangle_\rho} \qquad [13]$$

Then the postselected mean [11] of $A$ in state $\rho$ can, by eqn [14], be expressed as the common mean of $A$ in the effective postselected state $\rho_\Pi$:

$$_\Pi\langle A\rangle_\rho = \langle A\rangle_{\rho_\Pi} \qquad [14]$$

As we shall see later, quantum postselection is more subtle and cannot be reduced to common statistics, that is, to that without postselection. The quantum counterpart of postselected mean does not exist unless we combine postselection and weak measurement.

### Time-Continuous Measurement

For time-continuous measurement, one abandons the ensemble of identical states. One supposes that a single time-dependent state $\rho_t$ is undergoing an infinite sequence of measurements (eqns [5] and [6]) of $A$ employed at times $t=\delta t, t=2\delta t, t=3\delta t, \ldots$ . The rate $\nu =: 1/\delta t$ goes to infinity together with the mean squared error $\sigma^2$. Their rate is kept constant:

$$\sigma, \nu \to \infty \qquad [15]$$

$$g^2 =: \frac{\sigma^2}{\nu} = \text{const.} \qquad [16]$$

In the weak measurement limit (eqns [15] and [16]), the infinite frequent weak measurements of $A$ constitute the model of time-continuous measurement. Even the weak measurements will significantly influence the original state $\rho_0$, due to the accumulated effect of the infinitely many Bayesian updates [6]. The resulting theory of time-continuous measurement is described by coupled Gaussian processes [17] and [18] for the primitive function $\alpha_t$ of the time-dependent measurement outcome and, respectively, for the time-dependent Bayesian conditional state $\rho_t$:

$$d\alpha_t = \langle A\rangle_{\rho_t} dt + g\, dW_t \qquad [17]$$

$$d\rho_t = g^{-1}\left(A - \langle A\rangle_{\rho_t}\right)\rho_t\, dW_t \qquad [18]$$

Here $dW_t$ is the Itô differential of the Wiener process.

Equations [17] and [18] are the special case of the Kushner–Stratonovich equations of time-continuous Bayesian inference conditioned on the continuous measurement of $A$ yielding the time-dependent outcome value $a_t$. Formal time derivatives of both sides of eqn [17] yield the heuristic equation

$$a_t = \langle A\rangle_{\rho_t} + g\xi_t \qquad [19]$$

Accordingly, the current measurement outcome is always equal to the current mean plus a term proportional to standard white noise $\xi_t$. This plausible feature of the model survives in the quantum context as well. As for the other equation [18], it describes the gradual concentration of the distribution $\rho_t$ in such a way that the variance $\Delta_{\rho_t}A$ tends to zero while $\langle A\rangle_{\rho_t}$ tends to a random asymptotic value. The details of the convergence depend on the character of the continuously measured function $A(X)$. Consider a stepwise $A(X)$:

$$A(X) = \sum_\lambda a^\lambda P^\lambda(X) \qquad [20]$$

The real values $a^\lambda$ are step heights all differing from each other. The indicator functions $P^\lambda$ take values 0 or 1 and form a complete set of pairwise disjoint functions on the phase space:

$$\sum_\lambda P^\lambda \equiv 1 \qquad [21]$$

$$P^\lambda P^\mu = \delta_{\lambda\mu} P^\lambda \qquad [22]$$

In a single ideal measurement of $A$, the outcome $a$ is one of the $a^\lambda$'s singled out at random. The probability distribution of the measurement outcome and the corresponding Bayesian update of the state are given by

$$p^\lambda = \langle P^\lambda\rangle_{\rho_0} \qquad [23]$$

$$\rho_0 \to \frac{1}{p^\lambda} P^\lambda \rho_0 =: \rho^\lambda \qquad [24]$$

respectively. Equations [17] and [18] of time-continuous measurement are a connatural time-continuous resolution of the "sudden" ideal measurement (eqns [23] and [24]) in a sense that they reproduce it in the limit $t\to\infty$. The states $\rho^\lambda$ are trivial stationary states of the eqn [18]. It can be shown that they are indeed approached with probability $p^\lambda$ for $t\to\infty$.

## Quantum Weak Measurement

In quantum theory, states in a given complex Hilbert space $\mathcal{H}$ are represented by non-negative density operators $\hat\rho$, normalized by $\mathrm{tr}\,\hat\rho = 1$. Like the

classical states $\rho$, the quantum state $\hat{\rho}$ is interpreted statistically, referring to an ensemble of states with the same $\hat{\rho}$. Given a Hermitian operator $\hat{A}$, called observable, its theoretical mean value in state $\hat{\rho}$ is defined by

$$\langle \hat{A} \rangle_{\hat{\rho}} = \mathrm{tr}(\hat{A}\hat{\rho}) \qquad [25]$$

Let the outcome of an (unbiased) quantum measurement of $\hat{A}$ be denoted by $a$. Its stochastic expectation value $E[a]$ coincides with the mean [25]:

$$E[a] = \langle \hat{A} \rangle_{\hat{\rho}} \qquad [26]$$

Performing a large number $N$ of independent measurements of $\hat{A}$ on the elements of the ensemble of identically prepared states, the arithmetic mean $\bar{a}$ of the outcomes yields a reliable estimate of $E[a]$ and, this way, of the theoretical mean $\langle \hat{A} \rangle_{\hat{\rho}}$. If the measurement outcome $a$ contains a Gaussian stochastic error of standard dispersion $\sigma$, then the probability distribution of $a$ and the update, called collapse in quantum theory, of the state are described by eqns [27] and [28], respectively. (We adopt the notational convenience of physics literature to omit the unit operator $\hat{I}$ from trivial expressions like $a\hat{I}$.)

$$p(a) = \left\langle G_\sigma(a - \hat{A}) \right\rangle_{\hat{\rho}} \qquad [27]$$

$$\hat{\rho} \to \frac{1}{p(a)} G_\sigma^{1/2}(a - \hat{A})\hat{\rho}G_\sigma^{1/2}(a - \hat{A}) \qquad [28]$$

Nonzero $\sigma$ means that the measurement is nonideal, but the expectation value $E[a]$ remains calculable reliably if $N$ is suitably large.

Weak quantum measurement, like its classical counterpart, requires finite spread of the observable $\hat{A}$ on state $\hat{\rho}$:

$$\Delta_{\hat{\rho}}^2 \hat{A} =: \langle \hat{A}^2 \rangle_{\hat{\rho}} - \langle \hat{A} \rangle_{\hat{\rho}}^2 < \infty \qquad [29]$$

Weak quantum measurement, too, will be defined in the asymptotic limit [8] introduced for classical weak measurement. Single quantum measurements can no more distinguish between the eigenvalues of $\hat{A}$. Yet, the expectation value $E[a]$ of the outcome $a$ remains calculable on a statistics $N$ growing like $\sim\sigma^2$.

Both in quantum theory and classical statistics, the emergence of nonideal measurements from ideal ones is guaranteed by general theorems. For completeness of this article, we prove the emergence of the nonideal quantum measurement (eqns [27] and [28]) from the standard von Neumann theory of ideal quantum measurements (von Neumann 1955). The source of the statistical error of dispersion $\sigma$ is associated with the state $\hat{\rho}_M$ in the complex Hilbert space $\mathcal{L}^2$ of a hypothetic meter. Suppose $R \in (-\infty, \infty)$ is the position of the "pointer." Let its initial state $\hat{\rho}_M$ be a pure central Gaussian state of width $\sigma$; then the density operator $\hat{\rho}_M$ in Dirac position basis takes the form

$$\hat{\rho}_M = \int \mathrm{d}R \int \mathrm{d}R' G_\sigma^{1/2}(R) G_\sigma^{1/2}(R') |R\rangle\langle R'| \qquad [30]$$

We are looking for a certain dynamical interaction to transmit the "value" of the observable $\hat{A}$ onto the pointer position $\hat{R}$. To model the interaction, we define the unitary transformation [31] to act on the tensor space $\mathcal{H} \otimes \mathcal{L}^2$:

$$\hat{U} = \exp(\mathrm{i}\hat{A} \otimes \hat{K}) \qquad [31]$$

Here $\hat{K}$ is the canonical momentum operator conjugated to $\hat{R}$:

$$\exp(\mathrm{i}a\hat{K})|R\rangle = |R + a\rangle \qquad [32]$$

The unitary operator $\hat{U}$ transforms the initial uncorrelated quantum state into the desired correlated composite state:

$$\hat{\Sigma} =: \hat{U}\hat{\rho} \otimes \hat{\rho}_M \hat{U}^\dagger \qquad [33]$$

Equations [30]–[33] yield the expression [34] for the state $\hat{\Sigma}$:

$$\hat{\Sigma} = \int \mathrm{d}R \int \mathrm{d}R' G_\sigma^{1/2}(R - \hat{A})\hat{\rho}G_\sigma^{1/2} \times (R' - \hat{A}) \otimes |R\rangle\langle R'| \qquad [34]$$

Let us write the pointer's coordinate operator $\hat{R}$ into the standard form [35] in Dirac position basis:

$$\hat{R} = \int \mathrm{d}a |a\rangle\langle a| \qquad [35]$$

The notation anticipates that, when pointer $\hat{R}$ is measured ideally, the outcome $a$ plays the role of the nonideally measured value of the observable $\hat{A}$. Indeed, let us consider the ideal von Neumann measurement of the pointer position on the correlated composite state $\hat{\Sigma}$. The probability of the outcome $a$ and the collapse of the composite state are given by the following standard equations:

$$p(a) = \mathrm{tr}\left[(\hat{I} \otimes |a\rangle\langle a|)\hat{\Sigma}\right] \qquad [36]$$

$$\hat{\Sigma} \to \frac{1}{p(a)} \left[(\hat{I} \otimes |a\rangle\langle a|)\hat{\Sigma}(\hat{I} \otimes |a\rangle\langle a|)\right] \qquad [37]$$

respectively. We insert eqn [34] into eqns [36] and [37]. Furthermore, we take the trace over $\mathcal{L}^2$ of both sides of eqn [37]. In such a way, as expected, eqns [36] and [37] of ideal measurement of $\hat{R}$ yield the

earlier postulated eqns [27] and [28] of nonideal measurement of $\hat{A}$.

### Quantum Postselection

A quantum postselection is defined by a Hermitian operator satisfying $\hat{0} \leq \hat{\Pi} \leq \hat{I}$. The corresponding postselected mean value of a certain observable $\hat{A}$ is defined by

$$ {}_{\hat{\Pi}}\langle \hat{A} \rangle_{\hat{\rho}} =: \mathrm{Re}\frac{\langle \hat{\Pi}\hat{A} \rangle_{\hat{\rho}}}{\langle \hat{\Pi} \rangle_{\hat{\rho}}} \qquad [38] $$

The denominator $\langle \hat{\Pi} \rangle_{\hat{\rho}}$ is the rate of quantum postselection. Quantum postselection means that after the measurement of $\hat{A}$, we measure the observable $\hat{\Pi}$ in ideal quantum measurement and we make a statistical decision on the basis of the outcome $\pi$. With probability $\pi$, we include the case in question into the statistics while we discard it with probability $1-\pi$. By analogy with the classical case [12], one may ask whether the stochastic expectation value $E[a]$ of the postselected measurement outcome does coincide with

$$ E[a] \stackrel{?}{=} {}_{\hat{\Pi}}\langle \hat{A} \rangle_{\hat{\rho}} \qquad [39] $$

Contrary to the classical case, the quantum equation [39] does not hold. The quantum counterparts of classical equations [12]–[14] do not exist at all. Nonetheless, the quantum postselected mean ${}_{\hat{\Pi}}\langle \hat{A} \rangle_{\hat{\rho}}$ possesses statistical interpretation although restricted to the context of weak quantum measurements. In the weak measurement limit (eqns [8] and [9]), a postselected analog of classical equation [10] holds for the arithmetic mean $\bar{a}$ of postselected weak quantum measurements:

$$ p_{\mathrm{w}}(\bar{a}) \rightarrow G_{\Delta}\left(\bar{a} - {}_{\hat{\Pi}}\langle \hat{A} \rangle_{\hat{\rho}}\right) \qquad [40] $$

The Gaussian is centered at the postselected mean ${}_{\hat{\Pi}}\langle \hat{A} \rangle_{\hat{\rho}}$, and the variance of the Gaussian is given by the constant rate [9]. Consequently, the mean [38] becomes calculable on a statistics $N$ growing like $\sim\sigma^2$.

Since the statistical interpretation of the postselected quantum mean [38] is only possible for weak measurements, therefore ${}_{\hat{\Pi}}\langle \hat{A} \rangle_{\hat{\rho}}$ is called the (real) weak value of $\hat{A}$. Consider the special case when both the state $\hat{\rho} = |i\rangle\langle i|$ and the postselected operator $\hat{\Pi} = |f\rangle\langle f|$ are pure states. Then the weak value ${}_{\hat{\Pi}}\langle \hat{A} \rangle_{\hat{\rho}}$ takes, in usual notations, a particular form [41] yielding the real part of the complex weak value $A_{\mathrm{w}}$ [1]:

$$ {}_f\langle \hat{A} \rangle_i =: \mathrm{Re}\frac{\langle f|\hat{A}|i\rangle}{\langle f|i\rangle} \qquad [41] $$

The interpretation of postselection itself reduces to a simple procedure. One performs the von Neumann ideal measurement of the Hermitian projector $|f\rangle\langle f|$, then includes the case if the outcome is 1 and discards it if the outcome is 0. The rate of postselection is $|\langle f|i\rangle|^2$. We note that a certain statistical interpretation of $\mathrm{Im}\, A_{\mathrm{w}}$, too, exists although it relies upon the details of the "meter."

We outline a heuristic proof of the central equation [40]. One considers the nonideal measurement (eqns [27] and [28]) of $\hat{A}$ followed by the ideal measurement of $\hat{\Pi}$. Then the joint distribution of the corresponding outcomes is given by eqn [42]. The probability distribution of the postselected outcomes $a$ is defined by eqn [43], and takes the concrete form [44]. The constant $\mathcal{N}$ assures normalization:

$$ p(\pi, a) = \mathrm{tr}\left(\delta(\pi - \hat{\Pi}) G_{\sigma}^{1/2}(a - \hat{A}) \hat{\rho} G_{\sigma}^{1/2}(a - \hat{A})\right) \qquad [42] $$

$$ p(a) =: \frac{1}{\mathcal{N}} \int \pi p(\pi, a)\, \mathrm{d}\pi \qquad [43] $$

$$ p(a) =: \frac{1}{\mathcal{N}} \left\langle G_{\sigma}^{1/2}(a - \hat{A}) \hat{\Pi} G_{\sigma}^{1/2}(a - \hat{A}) \right\rangle_{\hat{\rho}} \qquad [44] $$

Suppose, for simplicity, that $\hat{A}$ is bounded. When $\sigma \rightarrow \infty$, eqn [44] yields the first two moments of the outcome $a$:

$$ E[a] \rightarrow {}_{\hat{\Pi}}\langle \hat{A} \rangle_{\hat{\rho}} \qquad [45] $$

$$ E[a^2] \sim \sigma^2 \qquad [46] $$

Hence, by virtue of the central limit theorem, the probability distribution [40] follows for the average $\bar{a}$ of postselected outcomes in the weak measurement limit (eqns [8] and [9]).

### Quantum Weak-Value Anomaly

Unlike in classical postselection, effective postselected quantum states cannot be introduced. We can ask whether eqn [47] defines a correct postselected quantum state:

$$ \hat{\rho}_{\hat{\Pi}}^{?} =: \mathrm{Herm}\frac{\hat{\Pi}\hat{\rho}}{\langle \hat{\Pi} \rangle_{\hat{\rho}}} \qquad [47] $$

This pseudo-state satisfies the quantum counterpart of the classical equation [14]:

$$ {}_{\hat{\Pi}}\langle \hat{A} \rangle_{\hat{\rho}} = \mathrm{tr}\left(\hat{A}\hat{\rho}_{\hat{\Pi}}^{?}\right) \qquad [48] $$

In general, however, the operator $\hat{\rho}_{\hat{\Pi}}^{?}$ is not a density operator since it may be indefinite. Therefore, eqn [47] does not define a quantum state. Equation [48] does not guarantee that the quantum weak value

${}_{\Pi}\langle\hat{A}\rangle_{\hat{\rho}}$ lies within the range of the eigenvalues of the observable $\hat{A}$.

Let us see a simple example for such anomalous weak values in the two-dimensional Hilbert space. Consider the pure initial state given by eqn [49] and the postselected pure state by eqn [50], where $\phi \in [0, \pi]$ is a certain angular parameter.

$$|i\rangle = \frac{1}{\sqrt{2}}\begin{bmatrix} e^{i\phi/2} \\ e^{-i\phi/2} \end{bmatrix} \quad [49]$$

$$|f\rangle = \frac{1}{\sqrt{2}}\begin{bmatrix} e^{-i\phi/2} \\ e^{i\phi/2} \end{bmatrix} \quad [50]$$

The probability of successful postselection is $\cos^2\phi$. If $\phi \neq \pi/2$, then the postselected pseudo-state follows from eqn [47]:

$$\hat{\rho}^{?}_{\Pi} = \frac{1}{2}\begin{bmatrix} 1 & \cos^{-1}\phi \\ \cos^{-1}\phi & 1 \end{bmatrix} \quad [51]$$

This matrix is indefinite unless $\phi = 0$, its two eigenvalues are $1 \pm \cos^{-1}\phi$. The smaller the post-selection rate $\cos^2\phi$, the larger is the violation of the positivity of the pseudo-density operator. Let the weakly measured observable take the form

$$\hat{A} = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix} \quad [52]$$

Its eigenvalues are $\pm 1$. We express its weak value from eqns [41], [49], and [50] or, equivalently, from eqns [48] and [51]:

$${}_{f}\langle\hat{A}\rangle_{i} = \frac{1}{\cos\phi} \quad [53]$$

This weak value of $\hat{A}$ lies outside the range of the eigenvalues of $\hat{A}$. The anomaly can be arbitrarily large if the rate $\cos^2\phi$ of postselection decreases.

Striking consequences follow from this anomaly if we turn to the statistical interpretation. For concreteness, suppose $\phi = 2\pi/3$ so that ${}_{f}\langle\hat{A}\rangle_{i} = 2$. On average, 75% of the statistics $N$ will be lost in postselection. We learnt from eqn [40] that the arithmetic mean $\bar{a}$ of the postselected outcomes of independent weak measurements converges stochastically to the weak value upto the Gaussian fluctuation $\Delta$, as expressed symbolically by

$$\bar{a} = 2 \pm \Delta \quad [54]$$

Let us approximate the asymptotically large error $\sigma$ of our weak measurements by $\sigma = 10$ which is already well beyond the scale of the eigenvalues $\pm 1$ of the observable $\hat{A}$. The Gaussian error $\Delta$ derives from eqn [9] after replacing $N$ by the size of the postselected statistics which is approximately $N/4$:

$$\Delta^2 = 400/N \quad [55]$$

Accordingly, if $N = 3600$ independent quantum measurements of precision $\sigma = 10$ are performed regarding the observable $\hat{A}$, then the arithmetic mean $\bar{a}$ of the $\sim 900$ postselected outcomes $a$ will be $2 \pm 0.33$. This exceeds significantly the largest eigenvalue of the measured observable $\hat{A}$. Quantum postselection appears to bias the otherwise unbiased nonideal weak measurements.

### Quantum Time-Continuous Measurement

The mathematical construction of time-continuous quantum measurement is similar to the classical one. We consider the weak measurement limit (eqns [15] and [16]) of an infinite sequence of nonideal quantum measurements of the observable $\hat{A}$ at $t = \delta t, 2\delta t, \ldots$, on the time-dependent state $\hat{\rho}_t$. The resulting theory of time-continuous quantum measurement is incorporated in the coupled stochastic equations [56] and [57] for the primitive function $\alpha_t$ of the time-dependent outcome and the conditional time-dependent state $\hat{\rho}_t$, respectively (Diósi 1988):

$$d\alpha_t = \langle\hat{A}\rangle_{\hat{\rho}_t}\, dt + g dW_t \quad [56]$$

$$d\hat{\rho}_t = -\tfrac{1}{8}\, g^{-2}[\hat{A}, [\hat{A}, \hat{\rho}_t]]\, dt + g^{-1}\,\mathrm{Herm}\left(\hat{A} - \langle\hat{A}\rangle_{\hat{\rho}_t}\right)\hat{\rho}_t\, dW_t \quad [57]$$

Equation [56] and its classical counterpart [17] are perfectly similar. There is a remarkable difference between eqn [57] and its classical counterpart [18]. In the latter, the stochastic average of the state is constant: $E[d\rho_t] = 0$, expressing the fact that classical measurements do not alter the original ensemble if we "ignore" the outcomes of the measurements. On the contrary, quantum measurements introduce irreversible changes to the original ensemble, a phenomenon called decoherence in the physics literature. Equation [57] implies the closed linear first-order differential equation [58] for the stochastic average of the quantum state $\hat{\rho}_t$ under time-continuous measurement of the observable $\hat{A}$:

$$\frac{dE[\hat{\rho}_t]}{dt} = -\tfrac{1}{8}g^{-2}[\hat{A}, [\hat{A}, E[\hat{\rho}_t]]] \quad [58]$$

This is the basic irreversible equation to model the gradual loss of quantum coherence (decoherence) under time-continuous measurement. In fact, the very equation models decoherence under the influence of a large class of interactions, for example, with thermal reservoirs or complex environments. In

two-dimensional Hilbert space, for instance, we can consider the initial pure state $\langle i| =: [\cos\phi, \sin\phi]$ and the time-continuous measurement of the diagonal observable [59] on it. The solution of eqn [58] is given by eqn [60]:

$$\hat{A} = \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix} \quad [59]$$

$$E[\hat{\rho}_t] = \begin{bmatrix} \cos^2\phi & e^{-t/4g^2}\cos\phi\sin\phi \\ e^{-t/4g^2}\cos\phi\sin\phi & \sin^2\phi \end{bmatrix} \quad [60]$$

The off-diagonal elements of this density matrix go to zero, that is, the coherent superposition represented by the initial pure state becomes an incoherent mixture represented by the diagonal density matrix $\hat{\rho}_\infty$.

Apart from the phenomenon of decoherence, the stochastic equations show remarkable similarity with the classical equations of time-continuous measurement. The heuristic form of eqn [56] is eqn [61] of invariable interpretation with respect to the classical equation [19]:

$$a_t = \langle\hat{A}\rangle_{\hat{\rho}_t} + g\xi_t \quad [61]$$

Equation [57] describes what is called the time-continuous collapse of the quantum state under time-continuous quantum measurement of $\hat{A}$. For concreteness, we assume discrete spectrum for $\hat{A}$ and consider the spectral expansion

$$\hat{A} = \sum_\lambda a^\lambda \hat{P}^\lambda \quad [62]$$

The real values $a^\lambda$ are nondegenerate eigenvalues. The Hermitian projectors $\hat{P}^\lambda$ form a complete orthogonal set:

$$\sum_\lambda \hat{P}^\lambda \equiv \hat{I} \quad [63]$$

$$\hat{P}^\lambda \hat{P}^\mu = \delta_{\lambda\mu}\hat{P}^\lambda \quad [64]$$

In a single ideal measurement of $\hat{A}$, the outcome $a$ is one of the $a^\lambda$'s singled out at random. The probability distribution of the measurement outcome and the corresponding collapse of the state are given by

$$p^\lambda = \langle\hat{P}^\lambda\rangle_{\hat{\rho}_0} \quad [65]$$

$$\hat{\rho}_0 \to \frac{1}{p^\lambda}\hat{P}^\lambda\hat{\rho}_0\hat{P}^\lambda =: \hat{\rho}^\lambda \quad [66]$$

respectively. Equations [56] and [57] of continuous measurements are an obvious time-continuous resolution of the "sudden" ideal quantum measurement (eqns [65] and [66]) in a sense that they reproduce it in the limit $t \to \infty$. The states $\hat{\rho}^\lambda$ are stationary states of eqn [57]. It can be shown that they are indeed approached with probability $p^\lambda$ for $t \to \infty$ (Gisin 1984).

## Related Contexts

In addition to the two particular examples as in postselection and in time-continuous measurement, respectively, presented above, the weak measurement limit itself has further variants. A most natural example is the usual thermodynamic limit in standard statistical physics. Then weak measurements concern a certain additive microscopic observable (e.g., the spin) of each constituent and the weak value represents the corresponding additive macroscopic parameter (e.g., the magnetization) in the infinite volume limit. This example indicates that weak values have natural interpretation despite the apparent artificial conditions of their definition. It is important that the weak value, with or without postselection, plays the physical role similar to that of the common mean $\langle\hat{A}\rangle_{\hat{\rho}}$. If, between their pre- and postselection, the states $\hat{\rho}$ become weakly coupled with the state of another quantum system via the observable $\hat{A}$, their average influence will be as if $\hat{A}$ took the weak value ${}_{\hat{\Pi}}\langle\hat{A}\rangle_{\hat{\rho}}$. Weak measurements also open a specific loophole to circumvent quantum limitations related to the irreversible disturbances that quantum measurements cause to the measured state. Noncommuting observables become simultaneously measurable in the weak limit: simultaneous weak values of noncommuting observables will exist.

Literally, weak measurement had been coined in 1988 for quantum measurements with (pre- and) postselection, and became the tool of a certain time-symmetric statistical interpretation of quantum states. Foundational applications target the paradoxical problem of pre- and retrodiction in quantum theory. In a broad sense, however, the very principle of weak measurement encapsulates the trade between asymptotically weak precision and asymptotically large statistics. Its relevance in different fields has not yet been fully explored and a growing number of foundational, theoretical, and experimental applications are being considered in the literature – predominantly in the context of quantum physics. Since specialized monographs or textbooks on quantum weak measurement are not yet available, the reader is mostly referred to research articles, like the recent one by Aharonov and Botero (2005), covering many topics of postselected quantum weak values.

## Nomenclature

| | |
|---|---|
| $a$ | measurement outcome |

# Quantum *n*-Body Problem

**R G Littlejohn**, University of California at Berkeley, Berkeley, CA, USA

## Introduction

This article concerns the nonrelativistic quantum mechanics of isolated systems of $n$ particles interacting by means of a scalar potential, what we shall call the "quantum $n$-body problem." Such systems are described by the kinetic-plus-potential Hamiltonian,

$$H = T + V = \sum_{\alpha=1}^{n} \frac{|\boldsymbol{P}_\alpha|^2}{2m_\alpha} + V(\boldsymbol{R}_1, \ldots, \boldsymbol{R}_n) \qquad [1]$$

where $\boldsymbol{R}_\alpha, \boldsymbol{P}_\alpha, \alpha = 1, \ldots, n$ are the positions and momenta of the $n$ particles in three-dimensional space, $m_\alpha$ are the masses, and $V$ is the potential energy. This Hamiltonian also occurs in the "classical $n$-body problem," in which $V$ is usually assumed to consist of the sum of the pairwise gravitational interactions of the particles. In this article, we shall only assume that $V$ (hence $H$) is invariant under translations, proper rotations, parity, and permutations of identical particles. The Hamiltonian $H$ is also invariant under time reversal. This Hamiltonian describes the dynamics of isolated atoms, molecules, and nuclei, with varying degrees of approximation, including the case of molecules in the Born–Oppenheimer approximation, in which $V$ is the Born–Oppenheimer potential. We shall ignore the spin of the particles, and treat the wave function $\Psi$ as a scalar. We assume that $\Psi$ is an eigenfunction of $H$, $H\Psi = E\Psi$. In practice, the value of $n$ typically ranges from 2 to several hundred. Often the cases $n = 3$ and $n = 4$ are of special interest. In this article, we shall assume that $n \geq 3$, since $n = 2$ is the trivial case of central-force motion. The quantum $n$-body problem is not to be confused with the "quantum

many-body problem," which usually refers to the quantum mechanics of large numbers of identical particles, such as the electrons in a solid.

Of particular interest is the "reduction" of the Hamiltonian [1], that is, the elimination of those degrees of freedom that can be eliminated due to the continuous symmetries of translations and rotations. A basic problem is to write down the reduced Hamiltonian and to make its analytical and geometrical properties clear. In the following we shall present this reduction in two stages, dealing first with the translations and second with the proper rotations. In each stage, we shall describe the reduction first in coordinate language and then in geometrical language. The discrete symmetries of parity, time reversal, and permutation of identical particles are handled by standard methods of group representation theory, and will not be discussed here.

There has been considerable interest in mathematical circles in recent years in the reduction of dynamical systems with symmetry, and the quantum $n$-body problem is one of the most important such systems from a physical standpoint. As such, the basic theory of the quantum $n$-body problem has received considerable attention in the physical literature going back to the birth of quantum mechanics, and continues to be of great practical importance. This article and the bibliography attempt to bridge these two centers of interest.

## Reduction by Translations: Coordinate Description

We begin with a coordinate description of the reduction of the system [1] by translations. The coordinates $(\boldsymbol{R}_1, \ldots, \boldsymbol{R}_n)$ are coordinates on the configuration space of the system, called the "original configuration space" or OCS. The OCS is $\mathbb{R}^{3n}$. The original system has $3n$ degrees of freedom. The translation group acts on configuration space by $\boldsymbol{R}_\alpha \mapsto \boldsymbol{R}_\alpha + \xi$, for $\alpha = 1, \ldots, n$, where $\xi$ is a displacement vector. It acts on wave functions by $\Psi(\boldsymbol{R}_1, \ldots, \boldsymbol{R}_n) \mapsto \Psi(\boldsymbol{R}_1 - \xi, \ldots, \boldsymbol{R}_n - \xi)$.

To reduce the system by translations, we perform a linear coordinate transformation on the OCS, taking us from the original vectors $(\boldsymbol{R}_1, \ldots, \boldsymbol{R}_n)$ to a new set of $n$ vectors $(\boldsymbol{r}_1, \ldots, \boldsymbol{r}_{n-1}, \boldsymbol{R}_{\mathrm{CM}})$, where $\boldsymbol{R}_{\mathrm{CM}}$ is the center-of-mass position,

$$\boldsymbol{R}_{\mathrm{CM}} = \frac{1}{M} \sum_{\alpha=1}^{n} m_\alpha \boldsymbol{R}_\alpha \qquad [2]$$

where $M = \sum_\alpha m_\alpha$ is the total mass of the system, and the other $n-1$ vectors of the new coordinate system, $(\boldsymbol{r}_1, \ldots, \boldsymbol{r}_{n-1})$, are required to be translationally invariant, that is, independent linear functions of the relative particle positions $\boldsymbol{R}_\alpha - \boldsymbol{R}_\beta$. We denote the momenta conjugate to $(\boldsymbol{r}_1, \ldots, \boldsymbol{r}_{n-1}, \boldsymbol{R}_{\mathrm{CM}})$ by $(\boldsymbol{p}_1, \ldots, \boldsymbol{p}_{n-1}, \boldsymbol{P}_{\mathrm{CM}})$, of which $\boldsymbol{P}_{\mathrm{CM}}$ turns out to be the total momentum of the system,

$$\boldsymbol{P}_{\mathrm{CM}} = \sum_{\alpha=1}^{n} \boldsymbol{P}_\alpha \qquad [3]$$

Under such a coordinate transformation, the potential energy becomes simply a function of the $n-1$ relative vectors, $V(\boldsymbol{r}_1, \ldots, \boldsymbol{r}_{n-1})$, whereas the kinetic energy becomes

$$T = \frac{|\boldsymbol{P}_{\mathrm{CM}}|^2}{2M} + \frac{1}{2} \sum_{\alpha,\beta=1}^{n-1} K^{\alpha\beta} \boldsymbol{p}_\alpha \cdot \boldsymbol{p}_\beta \qquad [4]$$

where $K^{\alpha\beta}$ is a symmetric tensor (the "inverse mass tensor").

The vectors $(\boldsymbol{r}_1, \ldots, \boldsymbol{r}_{n-1})$ specify the positions of $n$ particles relative to their center of mass. As described so far, these vectors need only be independent, translationally invariant linear combinations of the particle postitions. However, it is convenient to choose them so that the inverse mass tensor becomes proportional to the identity, $K^{\alpha\beta} = (1/M)\delta_{\alpha\beta}$. An elegant way of doing this is the method of Jacobi vectors, which involves splitting the original set of particles into two nonempty subsets, which are then split into smaller subsets, etc., until only subsets of a single particle remain. The process can be represented by a tree growing downward, with the original $n$ particles as the root, and the ends of the branches at the bottom each containing one particle. Then the vectors $(\boldsymbol{r}_1, \ldots, \boldsymbol{r}_{n-1})$ (the Jacobi vectors) are chosen to be proportional to the differences between the centers of mass of the two subsets at each splitting. With the right constants of proportionality, the kinetic energy becomes

$$T = \frac{1}{2M} |\boldsymbol{P}_{\mathrm{CM}}|^2 + \frac{1}{2M} \sum_{\alpha=0}^{n-1} |\boldsymbol{p}_\alpha|^2 \qquad [5]$$

Henceforth, we shall assume that the vectors $(\boldsymbol{r}_1, \ldots, \boldsymbol{r}_{n-1})$ are Jacobi vectors with conjugate momenta $(\boldsymbol{p}_1, \ldots, \boldsymbol{p}_{n-1})$.

The choice of Jacobi vectors is not unique. In the first place, there is a discrete set of possible ways of splitting the original set of $n$ particles into subsets (of forming trees), each of which leads to the same form [5] of the kinetic energy. More generally, the kinetic energy [5] is invariant under transformations

$$\boldsymbol{r}'_\alpha = \sum_{\beta=1}^{n-1} Q_{\alpha\beta} \boldsymbol{r}_\beta \qquad [6]$$

where $Q_{\alpha\beta}$ is an orthogonal matrix, $Q \in O(n-1)$. Such transformations are called "kinematic rotations." The discrete choices of trees in forming the Jacobi vectors are equivalent to a discrete set of kinematic rotations $Q_{\alpha\beta}$ that map one standard choice of Jacobi vectors into the others.

Since the momentum $\boldsymbol{P}_{\mathrm{CM}}$ of the center of mass commutes with $H$, the eigenfunctions $\Psi$ of $H$ can be chosen to have the form

$$\Psi(\boldsymbol{R}_1, \ldots, \boldsymbol{R}_n) = \exp(\mathrm{i}\boldsymbol{R}_{\mathrm{CM}} \cdot \boldsymbol{P}_{\mathrm{CM}}/\hbar)\psi(\boldsymbol{r}_1, \ldots, \boldsymbol{r}_{n-1}) \qquad [7]$$

This causes $\psi$ to be an eigenfunction of the "translation-reduced Hamiltonian," $H_{\mathrm{tr}}\psi = E_{\mathrm{tr}}\psi$, where

$$H_{\mathrm{tr}} = \frac{1}{2M}\sum_{\alpha=0}^{n-1} |\boldsymbol{p}_\alpha|^2 + V(\boldsymbol{r}_1, \ldots, \boldsymbol{r}_{n-1}) \qquad [8]$$

The kinetic energy of the center of mass, $|\boldsymbol{P}_{\mathrm{CM}}|^2/2M$, has been discarded from both $H_{\mathrm{tr}}$ and $E_{\mathrm{tr}}$, which represent physically the energy of the system about its center of mass.

## Reduction by Translations: Geometrical Description

The kinetic energy $T$ in eqn [1] specifies a metric $\mathrm{d}s^2 = \sum_\alpha m_\alpha |\mathrm{d}\boldsymbol{R}_\alpha|^2$ on the OCS ($=\mathbb{R}^{3n}$). The translation group ($=\mathbb{R}^3$) acts freely on the OCS, with an action that is generated by $\boldsymbol{P}_{\mathrm{CM}}$. This action defines an orthogonal decomposition of the OCS, $\mathbb{R}^{3n} = \mathbb{R}^3 \oplus \mathbb{R}^{3n-3}$, where $\mathbb{R}^3$ is the orbit of the origin (the other orbits of the translation group action are parallel spaces), and $\mathbb{R}^{3n-3}$ is the orthogonal subspace (henceforth the "translation-reduced configuration space" or TRCS for short). The TRCS is physically the space of configurations relative to the center of mass. The vectors $(\boldsymbol{r}_1, \ldots, \boldsymbol{r}_{n-1})$ are coordinates on the TRCS. The TRCS possesses a metric which is the projection of the metric on the OCS onto the TRCS by means of the translation group action. The metric can be projected because translations preserve the original metric (they are isometries). Jacobi vectors are Euclidean coordinates on the TRCS with respect to this metric.

The tree method of constructing Jacobi vectors can be understood in terms of certain group actions which take place as each subset of particles is split into two further subsets. The group action in question leaves the center of mass of the original subset invariant, while moving the two new subsets apart along a line. This motion in the configuration space is orthogonal to all the other group actions that are created in the process of splitting subsets of particles, including the original action of the translation group. Thus, each splitting of a subset of particles generates a three-dimensional subspace of the OCS, on which one of the $\boldsymbol{r}_\alpha$ are coordinates. The conjugate momentum $\boldsymbol{p}_\alpha$ is the generator of the group action moving the two new subsets apart. The final result is that the OCS is decomposed into $n$ orthogonal, three-dimensional subspaces, one of which contains the action of the original translation group, and the others of which represent the decomposition of the TRCS into $n-1$, three-dimensional orthogonal subspaces.

The TRCS can also be seen as a global section of a flat, trivial, principal fiber bundle created by the action of the translation group on the OCS. Alternatively, the TRCS can be seen as the quotient space, $\mathbb{R}^{3n}/\mathbb{R}^3$. The construction is fairly simple because the translation group is Abelian.

The wave function $\psi$ can be seen as a member of the Hilbert space of wave functions on the TRCS, upon which the reduced Hamiltonian $H_{\mathrm{tr}}$ of eqn [8] acts. Alternatively, it can be seen as the function obtained by restricting $\Psi$ on the OCS to the TRCS, where $\Psi$ has a dependence along the orbits of the translation group given by $\exp(\mathrm{i}\boldsymbol{R}_{\mathrm{CM}} \cdot \boldsymbol{P}_{\mathrm{CM}}/\hbar)$, that is, by an irreducible representation (irrep) of the translation group.

## Reduction by Rotations: Coordinate Description

The Hamiltonian $H_{\mathrm{tr}}$ acts on wave functions $\psi$ defined on the TRCS and has $3n-3$ degrees of freedom. Consider a coordinate transformation to eliminate further degrees of freedom due to the rotational invariance. This coordinate transformation takes us from the Jacobi vectors $\{\boldsymbol{r}_\alpha, \alpha = 1, \ldots, n-1\}$ to orientational and shape coordinates. Shape coordinates are a set of $3n-6$ coordinates $\{q^\mu, \mu = 1, \ldots, 3n-6\}$ that specify the shape of the $n$-particle system, that is, they are $3n-6$ independent functions of the interparticle distances (hence rotationally invariant). We will call the space upon which the $q^\mu$ are coordinates "shape space." For example, in the case of the three-body problem, shape space is the space of all triangles.

As for orientational coordinates, to define them it is necessary first to define a "body frame." We assume we are already given one frame, the "space frame," a fixed inertial frame. The body frame is a 3-frame attached in a conventional way to each shape of the system of particles, which rotates with the particles. The orientational coordinates, to be

denoted by $\{\theta^i, i = 1, 2, 3\}$, are three coordinates (e.g., Euler angles) specifying the SO(3) rotation that maps the space frame into the body frame. We shall write the new coordinates collectively as $\{\theta^i, q^\mu\}$.

There is a great deal of arbitrariness in the choice of a body frame, since for a given shape a body frame can be attached in many ways, the different choices being related by proper rotations. The only requirement is that the body frame should change smoothly as the shape changes. Popular choices for the body frame are the principal axis and Eckart frames.

When the potential energy is transformed to the new coordinates, it becomes a function only of the $\{q^\mu\}$, that is, of the shape. The potential can be written as $V = V(q)$. $V$ is a scalar field on shape space.

The transformation of the kinetic energy is more complicated. When the (Euclidean) metric tensor on the TRCS is transformed to orientational and shape coordinates there results a $(3n-3)\times(3n-3)$ component matrix which may be partitioned into blocks according to the coordinates $\{\theta^i, q^\mu\}$, that is, according to $3n-3 = 3+(3n-6)$. This matrix cannot be made diagonal or even block diagonal by any choice of orientational or shape coordinates, or by any choice of body frame.

The components of the metric tensor in the new coordinates are conveniently expressed in terms of three fields on shape space. The first is the moment-of-inertia tensor $\mathsf{E}$, which describes the $3\times 3$ upper block of the metric tensor. Its components are given by

$$E_{ij} = M\sum_{\alpha=1}^{n-1}\left(|\boldsymbol{r}_\alpha|^2\,\delta_{ij} - r_{\alpha i}r_{\alpha j}\right) \qquad [9]$$

The vectors and tensors in this equation can be referred either to the space frame or the body frame, but the body frame is more convenient because then the components of the vectors $r_\alpha$ are functions only of the shape coordinates $q^\mu$. Thus, the body frame components $E_{ij}$ of the moment-of-inertia tensor define a field on shape space.

The second field is the "gauge potential" $\boldsymbol{A}_\mu$, an object with $3(3n-6)$ components $A^i_\mu, i = 1, 2, 3, \mu = 1, \ldots, 3n-6$, which describes the off-diagonal blocks of the metric tensor. It is defined by

$$\boldsymbol{A}_\mu = \mathsf{E}^{-1}\left(M\sum_{\alpha=1}^{n-1}\boldsymbol{r}_\alpha \times \frac{\partial \boldsymbol{r}_\alpha}{\partial q^\mu}\right) \qquad [10]$$

in which all vectors are understood to be referred to the body frame (so the partial derivatives make sense). The gauge potential $\boldsymbol{A}_\mu$ is responsible for the "falling cat" phenomenon, in which a flexible body of zero angular momentum nevertheless manages to rotate.

The third field is the $(3n-6)\times(3n-6)$ lower block of the metric tensor on the TRCS, an object with two shape indices. It is given by

$$g_{\mu\nu} = M\sum_{\alpha=1}^{n-1}\left(\frac{\partial \boldsymbol{r}_\alpha}{\partial q^\mu}\cdot\frac{\partial \boldsymbol{r}_\alpha}{\partial q^\nu}\right) - \boldsymbol{A}_\mu\cdot\mathsf{E}\cdot\boldsymbol{A}_\nu \qquad [11]$$

where again the vectors are referred to the body frame. The notation suggests (correctly) that $g_{\mu\nu}$ is the metric tensor on shape space.

On transforming the wave function from the Jacobi vectors to coordinates $(\theta^i, q^\mu)$, it is convenient to introduce a Jacobian factor, $\psi(\boldsymbol{r}_1, \ldots, \boldsymbol{r}_{n-1}) = D^{1/4}\phi(\theta^i, q^\mu)$, where $D = (\det \mathsf{E})(\det g_{\mu\nu})$. This causes the new wave function $\phi$ to have the normalization

$$\int \mathrm{d}\mathsf{R}\left(\prod_{\mu=1}^{3n-6}\mathrm{d}q^\mu\right)|\phi|^2 \qquad [12]$$

where $\mathrm{d}\mathsf{R}$ is the Haar measure on the group SO(3). The factor $D$ depends only on the $q^\mu$, not the $\theta^i$. Then the Schrödinger equation can be written as $H_{\mathrm{tr}}\phi = E_{\mathrm{tr}}\phi$, where $H_{\mathrm{tr}}$ is a differential operator involving $\partial/\partial\theta^i$ and $\partial/\partial q^\mu$.

The orientational derivatives $\partial/\partial\theta^i$ in $H_{\mathrm{tr}}$ are conveniently expressed in terms of the angular momentum operator $\boldsymbol{L}$. When acting on the original wave function $\Psi$ on the OCS, the angular momentum is

$$\boldsymbol{L} = \sum_{\alpha=1}^{n}\boldsymbol{R}_\alpha \times \boldsymbol{P}_\alpha \qquad [13]$$

When this is transformed to the coordinates $(\boldsymbol{r}_1, \ldots, \boldsymbol{r}_{n-1}, \boldsymbol{R}_{\mathrm{CM}})$, it becomes $\boldsymbol{L} = \boldsymbol{L}_{\mathrm{CM}} + \boldsymbol{L}_{\mathrm{tr}}$, where $\boldsymbol{L}_{\mathrm{CM}} = \boldsymbol{R}_{\mathrm{CM}}\times\boldsymbol{P}_{\mathrm{CM}}$, and

$$\boldsymbol{L}_{\mathrm{tr}} = \sum_{\alpha=1}^{n-1}\boldsymbol{r}_\alpha \times \boldsymbol{p}_\alpha \qquad [14]$$

Physically, $\boldsymbol{L}_{\mathrm{tr}}$ is the angular momentum of the system about the center of mass.

We shall henceforth drop the "tr" on $H_{\mathrm{tr}}, E_{\mathrm{tr}}$, and $\boldsymbol{L}_{\mathrm{tr}}$, thereby restricting attention to the energy and angular momentum about the center of mass.

The angular momentum $\boldsymbol{L}$, when acting on wave functions $\psi(\boldsymbol{r}_1, \ldots, \boldsymbol{r}_{n-1})$ on the TRCS, is a vector of differential operators involving $\partial/\partial\boldsymbol{r}_\alpha$. When these are transformed to orientational and shape coordinates, the components of $\boldsymbol{L}$ become differential operators involving only orientational derivatives, $\partial/\partial\theta^i$. There are no shape derivatives, $\partial/\partial q^\mu$, since $\boldsymbol{L}$ generates rotations, that is, changes in orientation, not shape. Thus, one can solve for the operators $\partial/\partial\theta^i$ in terms of the components of $\boldsymbol{L}$. This is true

both for the space and the body components of $\boldsymbol{L}$, although the differential operators are not the same in the two cases. The space components of $\boldsymbol{L}$ satisfy the usual angular momentum commutation relations, $[L_i, L_j] = i\hbar\epsilon_{ijk} L_k$, while the body components of satisfy $[L_i, L_j] = -i\hbar\epsilon_{ijk} L_k$ (with a minus sign relative to the space commutation relations).

Thus, the Hamiltonian can be expressed in terms of $\boldsymbol{L}$ and the shape momentum operators, $p_\mu = -i\hbar\partial/\partial q^\mu$. The result is

$$H = \frac{1}{2}\boldsymbol{L}\cdot\mathsf{E}^{-1}\cdot\boldsymbol{L} + \frac{1}{2}(p_\mu - \boldsymbol{L}\cdot\boldsymbol{A}_\mu)g^{\mu\nu}(p_\nu - \boldsymbol{L}\cdot\boldsymbol{A}_\nu) + V_2(q) + V(q) \qquad [15]$$

where all vectors are referred to the body frame, where $g^{\mu\nu}$ is the contravariant metric tensor on shape space, and where $V_2$ is given by

$$V_2 = \frac{\hbar^2}{2} D^{-1/4} \frac{\partial}{\partial q^\mu}\left(g^{\mu\nu}\frac{\partial D^{1/4}}{\partial q^\nu}\right) \qquad [16]$$

$V_2$ looks like a potential (it is a function of only $q$), hence the notation, but physically it belongs to the kinetic energy. It is sometimes called an "extrapotential." It arises from nonclassical commutators in the transformation of the kinetic energy (hence the $\hbar^2$ dependence). The first term of eqn [15] is the kinetic energy of rotation, also called the "vertical" kinetic energy, the next two terms are the remainder of the kinetic energy, somewhat imprecisely thought of as the kinetic energy of vibrations or changes in shape, also called the "horizontal kinetic energy," and the final term is the (true) potential, discussed above.

Since the Hamiltonian commutes with the angular momentum, $[H, \boldsymbol{L}] = 0$, $\phi$ can be chosen to be simultaneous eigenfunctions of $L^2$ and $L_z$ (the latter being the space component), as well as of energy. Let $\phi_{lm}$ be these eigenfunctions, where $l$ and $m$ are the quantum numbers of $L^2$ and $L_z$, respectively. Then by the transformation properties of $\phi$ under rotations, we can write

$$\phi_{lm}(\theta^i, q^\mu) = \sum_{k=-l}^{+l} \chi_{lk}(q^\mu)\, D^l_{km}(\theta^i) \qquad [17]$$

where $D$ is a standard rotation matrix and $\chi_{lk}$ are functions only of $q^\mu$. In these equations we use the phase and other standard conventions of the theory of rotations. The wave function $\chi$ is a function only of $q^\mu$ and can loosely be thought of as the wave function on shape space. It is not a scalar like $\Psi$, $\psi$, or $\phi$, but rather has $2l+1$ components indexed by $k$.

The Schrödinger equation for $\chi$ can be written as $H\chi = E\chi$, where $H$ has the same form as in eqn [15], except that now the components of the angular momentum $L_i$ are interpreted, no longer as differential operators in $\theta^i$, but as $(2l+1)\times(2l+1)$ matrices that act on the "spinor" $\chi$. These matrices are the transposes of the usual angular momentum matrices in angular momentum theory, that is, $(L_i)_{kk'} = \langle k'|L_i|k\rangle$.

This is the final form of the Schrödinger equation after all reductions by all continuous symmetries have been carried out. The fully reduced system has $3n-5$ degrees of freedom ($3n-6$ for the shape coordinates, and one for the "spinor" index $k$).

## Reduction by Rotations: Geometrical Description

The proper rotation group SO(3) acts on the OCS by $\boldsymbol{R}_\alpha \mapsto \mathsf{R}\boldsymbol{R}_\alpha$, and on the TRCS by $\boldsymbol{r}_\alpha \mapsto \mathsf{R}\boldsymbol{r}_\alpha$, where $\mathsf{R} \in SO(3)$. Rotations acting on the OCS do not commute with translations, but the action preserves the translation fibers, and thus can be projected onto the TRCS.

The action of SO(3) on the TRCS is effective but not free, that is, most orbits are diffeomorphic to SO(3), but a subset of measure zero (the "singular" orbits) are diffeomorphic to $S^2$ or a single point. Configurations of the $n$-particle system in which the particles do not lie on a line ("noncollinear shapes") have SO(3) orbits, those in which the particles do lie on a line but are not coincident have $S^2$ orbits, and the $n$-body collision (a single shape) has an orbit that is a single point. Thus, the action of SO(3) on the TRCS foliates the TRCS into a $(3n-6)$-parameter family of copies of SO(3), plus the singular orbits. If we exclude the singular orbits, then the TRCS has the structure of an SO(3) principal fiber bundle. In general, the bundle is not trivial. Shape space may be defined as the quotient space under the SO(3) action. Omitting the singular shapes, shape space is the base space of the bundle. The coordinates $q^\mu$ introduced above are coordinates on shape space. The singular shapes and orbits are physically accessible, and there are important questions regarding the behavior of the system in their neighborhood.

The definition of a body frame is equivalent to the choice of a section of the fiber bundle, generally only locally defined over some region of shape space. A configuration (a point in the TRCS) on the section defines an orientation of the $n$-particle system for the given shape, which serves as a reference orientation to which others can be referred. We think of the reference orientation as one in which the space and body frames coincide; in other orientations of the same shape, the body frame has been rotated with the body to a new orientation. The choice of the section (body frame) allows us to

impose coordinates on each (nonsingular) rotation fiber, that is, we label points on the fiber by the rotation that takes us from the section to the actual configuration in question. This is why a choice of body frame is necessary before defining orientational coordinates. Sections are only defined locally. Popular choices of body frame, such as the principal axis frame, imply multivalued sections, unless branch cuts are introduced. Orientational coordinates are simply coordinates on the group manifold SO(3), transferred to the nonsingular rotation fibers, with the group identity element mapped onto the point where the fiber intersects the section.

The metric tensor determines much of the geometry of the reduction by rotations. Since the metric on the TRCS is SO(3)-invariant, horizontal subspaces in the SO(3) fiber bundle (the TRCS minus the singular orbits) can be defined as the spaces orthogonal to the fibers (hence orthogonal to the vertical subspaces). This is a standard construction in Kaluza–Klein theories, which reappears here. Thus, the bundle has a connection, induced by the metric.

The moment-of-inertia tensor is the metric tensor restricted to a fiber, evaluated in a basis of left- (body frame) or right-invariant (space frame) vector fields on SO(3), which are transported to the fibers to create a basis of vertical vector fields.

The coordinate description of the connection is the gauge potential $\boldsymbol{A}_\mu$, in which the $\mu$ index refers to shape coordinates $q^\mu$, and the components of the 3-vector $\boldsymbol{A}$ refer to the standard set of left- or right-invariant vector fields on SO(3). The coordinate representative of the curvature 2-form is conveniently denoted by $\boldsymbol{B}_{\mu\nu}$, defined by

$$\boldsymbol{B}_{\mu\nu} = \frac{\partial \boldsymbol{A}_\nu}{\partial q^\mu} - \frac{\partial \boldsymbol{A}_\mu}{\partial q^\nu} - \boldsymbol{A}_\mu \times \boldsymbol{A}_\nu \qquad [18]$$

where it is understood that body frame components are used. Direct calculation shows that it is nonzero, hence the fiber bundle is not flat, for any value of $n \geq 3$. The curvature form $\boldsymbol{B}_{\mu\nu}$ appears in the classical equation of motion and in the quantum commutation relations.

The field $\boldsymbol{B}_{\mu\nu}$ satisfies differential equations on shape space that have the form of Yang–Mills field equations. It is interesting that the sources of this field are singularities of the monopole type, located on the singular shapes. In the case $n = 3$, the source is a single monopole located at the three-body collision, which is similar to a Dirac monopole in electromagnetic theory.

The $(3n - 6)$-dimensional horizontal subspaces of the TRCS are annihilated by three differential forms, whose values on a velocity vector of the system are the components of the classical angular momentum $\boldsymbol{L}$ (body or space components, depending on the basis of forms). Thus, horizontal motions are those for which $\boldsymbol{L} = 0$, and horizontal lifts of curves in shape space are motions of the system with vanishing angular momentum. Since angular momentum is conserved, such motions are generated by the classical equations of motion and are physically allowed. For loops in shape space, the holonomy generated by the horizontal lift is physically the rotation that a flexible body experiences when it is carried under conditions of vanishing angular momentum from an initial shape, through intermediate shapes and back to the initial shape. An example is the rotation generated by the "falling cat."

Since the metric on the TRCS is SO(3)-invariant, it may be projected onto shape space, which therefore is a Riemannian manifold in its own right. The projected metric is $ds^2 = g_{\mu\nu}\, dq^\mu\, dq^\nu$. This metric is not flat (the Riemann curvature tensor is nonzero for all values $n \geq 3$). Geodesics in shape space have horizontal lifts that are free particle motions ($V = 0$) of zero angular momentum. Conversely, such motions project onto geodesics on shape space.

A popular choice of body frame in molecular physics is the Eckart frame, which has advantages for the description of small vibrations and other purposes. The section defining the Eckart frame is a flat vector subspace of the TRCS of dimension $3n - 6$ that is orthogonal (horizontal) to a particular fiber (over an equilibrium shape) at a particular orientation.

The geometrical meaning of eqn [17] is that rotations act on a set of wave functions $\phi$ that span an irrep of SO(3) by multiplication by the representative element of the group. In standard physics notation, $l$ indexes the irrep, and $m$ indexes the basis vectors spanning the irrep. Thus, the values of these wave functions at any point on the fiber are known once their values are given at a reference point. A convenient choice for the reference point is the point on the section, and the wave functions $\chi_{lk}$ are simply the values of the $\phi_{lm}$ on this reference point (with a change of notation, $m \to k$). Thus, the wave functions $\chi_{lk}$ are properly not "wave functions on shape space," but rather wave functions on the section.

Shape space in the case $n = 3$ is homeomorphic to the region $x_3 \geq 0$ of $\mathbb{R}^3$, and in the case $n = 4$ to $\mathbb{R}^6$. A convenient tool for understanding the structure of shape space is by its foliation under the action of the kinematic rotations, eqn [5]. The kinematic rotations commute with ordinary rotations, and hence have an action on shape space. This action preserves the eigenvalues of the moment-of-inertia tensor.

## Concluding Remarks

The quantum $n$-body problem provides an interesting example in which nonabelian gauge theories find application in nonrelativistic quantum mechanics. The fields $\mathsf{E}$, $A_\mu$, and $g_{\mu\nu}$, and fields derived from them such as the curvature tensor $B_{\mu\nu}$ and the Riemann curvature tensor derived from $g_{\mu\nu}$, satisfy a complex set of differential equations on shape space that can be derived by considering the vanishing of the Riemann tensor on the TRCS. The resulting field equations are useful in perturbation theory, for example, in the study of small vibrations of a molecule. This means of constructing field equations on the base space of a bundle is standard in Kaluza–Klein theories, which are an important line of thinking in modern attempts to understand gauge field theories in particle physics.

The rotations generated by flexible bodies of vanishing angular momentum (the "falling cat") are an example of a "geometric phase," that is, a nonabelian generalization of "Berry's phase." It is interesting how the associated gauge potential $A_\mu$ in this problem plays a role in the dynamics of the $n$-particle system.

The Hamiltonian [15] is the starting point for numerous practical calculations, for example, the numerical evaluation of energy levels, cross-sections and reaction rates in molecular physics. One can compute, for example, chemical reaction rates for molecular processes in atmospheric or astrophysical contexts, where experiments would be difficult or expensive. The numerical analysis of the Hamiltonian [15] usually requires the introduction of a basis set and the processing of large matrices. Current techniques for basis set selection are not very satisfactory, and this is an area where research into wavelets and numerical analysis could have an impact.

# Quantum Phase Transitions

**S Sachdev**, Yale University, New Haven, CT, USA

## Introduction

The study of second-order phase transitions at nonzero temperatures has a long and distinguished history in statistical mechanics. Many key physical phenomena, such as the loss of ferromagnetism in iron at the Curie temperature or the critical endpoint of $CO_2$, are now understood in precise quantitative detail. This understanding began in the work of Onsager, and is based upon what may now be called the Landau–Ginzburg–Wilson theory. The content of this sophisticated theory may be summarized in a few basic principles: (1) The collective thermal fluctuations near second-order transitions can be accurately described by simple classical models, that is, quantum-mechanical effects can be entirely neglected. (2) The classical models identify an "order parameter," a collective variable which has to be treated on par with other thermodynamic variables, and whose correlations exhibit distinct behavior in the phases on either side of the transition. (3) The thermal fluctuations of the order parameter near the transition are controlled by a continuum field theory whose structure is usually completly dictated by simple symmetry considerations.

This article will not consider such nonzero temperature phase transitions, but will instead describe second-order phase transitions at the absolute zero of temperature. Such transitions are driven by quantum fluctuations mandated by the Heisenberg uncertainty principle: one can imagine moving across the quantum critical point by effectively "tuning the value of Planck's constant, $\hbar$." Clearly, quantum mechanics plays a central role at such transitions, unlike the situation at nonzero temperatures. The reader may object that absolute zero is an idealization not realized by any experimental system; hence, the study of quantum phase transitions is a subject only of academic interest. As we will illustrate below, knowledge of the zero-temperature quantum critical points of a system is often the key to understanding its finite-temperature properties, and in some cases the influence of a zero-temperature critical point can be detected at temperatures as high as ambient room temperature.

We will begin in the following section by introducing some simple lattice models which exhibit quantum phase transitions. Next the theory of the critical point in these models is based upon a natural extension of the Landau–Ginzburg–Wilson (LGW) method, and this will be presented. This section will also describe the consequences of a zero-temperature critical point on the nonzero temperature properties. Finally, we will consider more complex models in which quantum interference effects play a more subtle role, and which cannot be described in the LGW framework: such quantum critical points are likely to play a central role in understanding many of the correlated electron systems of current interest.

## Simple Models

### Quantum Ising Chain

This is a simple model of $N$ qubits, labeled by the index $j = 1, \ldots, N$. On each "site" $j$ there are two qubit quantum states $|\uparrow\rangle_j$ and $|\downarrow\rangle_j$ (in practice, these could be two magnetic states of an ion at site $j$ in a crystal). The Hilbert space therefore consists of $2^N$ states, each consisting of a tensor product of the states on each site. We introduce the Pauli spin operators, $\hat{\sigma}_j^\alpha$, on each site $j$, with $\alpha = x, y, z$:

$$\hat{\sigma}^x = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \qquad \hat{\sigma}^y = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix}$$
$$\hat{\sigma}^z = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} \qquad [1]$$

These operators clearly act on the two states of the qubit on site $j$, and the Pauli operators on different sites commute.

The quantum Ising chain is defined by the simple Hamiltonian

$$H_\mathrm{I} = -J \sum_{j=1}^{N-1} \hat{\sigma}_j^z \hat{\sigma}_{j+1}^z - gJ \sum_{j=1}^{N} \hat{\sigma}_j^x \qquad [2]$$

where $J > 0$ sets the energy scale, and $g \geq 0$ is a dimensionless coupling constant. In the thermodynamic limit ($N \to \infty$), the ground state of $H_\mathrm{I}$ exhibits a second-order quantum phase transition as $g$ is tuned across a critical value $g = g_\mathrm{c}$ (for the specific case of $H_\mathrm{I}$ it is known that $g_\mathrm{c} = 1$), as we will now illustrate.

First, consider the ground state of $H_\mathrm{I}$ for $g \ll 1$. At $g = 0$, there are two degenerate "ferromagnetically ordered" ground states

$$|\Uparrow\rangle = \prod_{j=1}^{N} |\uparrow\rangle_j, \qquad |\Downarrow\rangle = \prod_{j=1}^{N} |\downarrow\rangle_j \qquad [3]$$

Each of these states breaks a discrete "Ising" symmetry of the Hamiltonian rotations of all spins by 180° about the $x$-axis. These states are more succinctly characterized by defining the ferromagnetic moment, $N_0$, by

$$N_0 = \langle \Uparrow | \hat{\sigma}_j^z | \Uparrow \rangle = -\langle \Downarrow | \hat{\sigma}_j^z | \Downarrow \rangle \qquad [4]$$

At $g = 0$ we clearly have $N_0 = 1$. A key point is that in the thermodynamic limit, this simple picture of the ground state survives for a finite range of small $g$ (indeed, for all $g < g_\mathrm{c}$), but with $0 < N_0 < 1$. The quantum tunneling between the two ferromagnetic ground states is exponentially small in $N$ (and so can be neglected in the thermodynamic limit), and so the ground state remains 2-fold degenerate and the discrete Ising symmetry remains broken. The change in the wave functions of these states from eqn [3] can be easily determined by perturbation theory in $g$: these small $g$ quantum fluctuations reduce the value of $N_0$ from unity but do not cause the ferromagnetism to disappear.

Now consider the ground state of $H_\mathrm{I}$ for $g \gg 1$. At $g = \infty$ there is a single nondegenerate ground state which fully preserves all symmetries of $H_\mathrm{I}$:

$$\Rightarrow\rangle = 2^{-N/2} \prod_{j=1}^{N} \left( |\uparrow\rangle_j + |\downarrow\rangle_j \right) \qquad [5]$$

It is easy to verify that this state has no ferromagnetic moment $N_0 = \langle \Rightarrow | \hat{\sigma}_j^z | \Rightarrow \rangle = 0$. Further, perturbation theory in $1/g$ shows that these features of the ground state are preserved for a finite range of large $g$ values

(indeed, for all $g > g_c$). One can visualize this ground state as one in which strong quantum fluctuations have destroyed the ferromagnetism, with the local magnetic moments quantum tunneling between "up" and "down" on a timescale of order $\hbar/J$.

Given the very distinct signatures of the small $g$ and large $g$ ground states, it is clear that the ground state cannot evolve smoothly as a function of $g$. These must be at least one point of nonanalyticity as a function of $g$: for $H_I$ it is known that there is only a single nonanalytic point, and this is at the location of a second-order quantum phase transition at $g = g_c = 1$.

The character of the excitations above the ground state also undergoes a qualitative change across the quantum critical point. In both the $g < g_c$ and $g > g_c$ phases, these excitations can be described in the Landau quasiparticle scheme, that is, as superpositions of nearly independent particle-like excitations; a single well-isolated quasiparticle has an infinite lifetime at low excitation energies. However, the physical nature of the quasiparticles is very different in the two phases. In the ferromagnetic phase, with $g < g_c$, the quasiparticles are domain walls between regions of opposite magnetization:

$$|j, j+1\rangle = \prod_{k=1}^{j} |\uparrow\rangle_k \prod_{\ell=j+1}^{N} |\downarrow\rangle_\ell \qquad [6]$$

This is the exact wave function of a stationary quasiparticle excitation between sites $j$ and $j+1$ at $g = 0$; for small nonzero $g$ the quasiparticle acquires a "cloud" of further spin-flips and also becomes mobile. However its qualitative interpretation as a domain wall between the two degenerate ground states remains valid for all $g < g_c$. In contrast, for $g > g_c$, there is no ferromagnetism, and the nondegenerate paramagnetic state has a distinct quasiparticle excitation:

$$|j\rangle = 2^{-N/2}\left(|\uparrow\rangle_j - |\downarrow\rangle_j\right) \prod_{k \neq j} \left(|\uparrow\rangle_k + |\downarrow\rangle_k\right) \qquad [7]$$

This is a stationary "flipped spin" quasiparticle at site $j$, with its wave function exact at $g = \infty$. Again, this quasiparticle is mobile and applicable for all $g > g_c$, but there is no smooth connection between eqns [7] and [6].

## Coupled Dimer Antiferromagnet

This model also involves qubits, but they are now placed on the sites, $j$, of a two-dimensional square lattice. Models in this class describe the magnetic

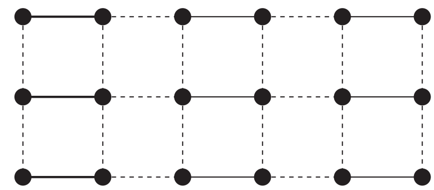

**Figure 1** The coupled dimer antiferromagnet. Qubits (i.e., $S = 1/2$ spins) are placed on the sites, the $\mathcal{A}$ links are shown as full lines, and the $\mathcal{B}$ links as dashed lines.

excitations of many experimentally important spin gap compounds.

The Hamiltonian of the dimer antiferromagnet is illustrated in Figure 1 and is given by

$$H_d = J \sum_{\langle jk \rangle \in A} \left( \hat{\sigma}_j^x \hat{\sigma}_k^x + \hat{\sigma}_j^y \hat{\sigma}_k^y + \hat{\sigma}_j^z \hat{\sigma}_k^z \right) + \frac{J}{g} \sum_{\langle jk \rangle \in B} \left( \hat{\sigma}_j^x \hat{\sigma}_k^x + \hat{\sigma}_j^y \hat{\sigma}_k^y + \hat{\sigma}_j^z \hat{\sigma}_k^z \right) \qquad [8]$$

where $J > 0$ is the exchange constant, $g \geq 1$ is the dimensionless coupling, and the set of nearest-neighbor links $\mathcal{A}$ and $\mathcal{B}$ are defined in Figure 1. An important property of $H_d$ is that it is now invariant under the full O(3) group of spin rotations under which the $\hat{\sigma}^\alpha$ transform as ordinary vectors (in contrast to the $Z_2$ symmetry group of $H_I$). In analogy with $H_I$, we will find that $H_d$ undergoes a quantum phase transition from a paramagnetic phase which preserves all symmetries of the Hamiltonian at large $g$, to an antiferromagnetic phase which breaks the O(3) symmetry at small $g$. This transition occurs at a critical value $g = g_c$, and the best current numerical estimate is $1/g_c = 0.52337(3)$.

As in the previous section, we can establish the existence of such a quantum phase transition by contrasting the disparate physical properties at large $g$ with those at $g \approx 1$. At $g = \infty$ the exact ground state of $H_d$ is

$$|\text{spin gap}\rangle = \prod_{\langle jk \rangle \in A} \frac{1}{\sqrt{2}} \left( |\uparrow\rangle_j |\downarrow\rangle_k - |\downarrow\rangle_j |\uparrow\rangle_k \right) \qquad [9]$$

and is illustrated in Figure 2. This state is nondegenerate and invariant under spin rotations, and so is a paramagnet: the qubits are paired into spin singlet valence bonds across all the $\mathcal{A}$ links.

The excitations above the ground state are created by breaking a valence bond, so that the pair of spins form a spin triplet with total spin $S = 1$ – this is illustrated in Figure 3. It costs a large energy to create this excitation, and at finite $g$ the

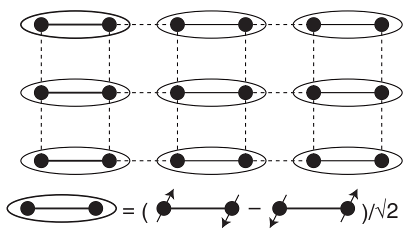

**Figure 2** The paramagnetic state of $H_d$ for $g > g_c$. The state illustrated is the exact ground state for $g = \infty$, and it is adiabatically connected to the ground state for all $g > g_c$.

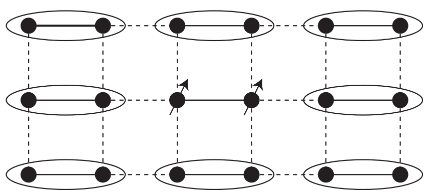

**Figure 3** The triplon excitation of the $g > g_c$ paramagnet. The stationary triplon is an eigenstate only for $g = \infty$ but it becomes mobile for finite $g$.

triplet can hop from link to link, creating a gapped "triplon" quasiparticle excitation. This is similar to the large $g$ paramagnet for $H_I$, with the important difference that each quasiparticle is now 3-fold degenerate.

At $g = 1$, the ground state of $H_d$ is not known exactly. However, at this point $H_d$ becomes equivalent to the nearest-neighbor square lattice antiferromagnet, and this is known to have antiferromagnetic order in the ground state, as illustrated in Figure 4. This state is similar to the ferromagnetic ground state of $H_I$, with the difference that the magnetic moment now acquires a staggered pattern on the two sublattices, rather than the uniform moment of the ferromagnet. Thus, in this ground state

$$\langle \mathrm{AF}|\hat{\sigma}_j^\alpha|\mathrm{AF}\rangle = N_0 \eta_j n_\alpha \qquad [10]$$

where $0 < N_0 < 1$ is the antiferromagnetic moment, $\eta_j = \pm 1$ identifies the two sublattices in Figure 4, and $n_\alpha$ is an arbitrary unit vector specifying the orientation of the spontaneous magnetic moment which breaks the O(3) spin rotation invariance of $H_d$. The excitations above this antiferromagnet are also distinct from those of the paramagnet: they are a doublet of spin waves consisting of a spatial variation in the local orientation, $n_\alpha$, of the antiferromagnetic order: the energy of this excitation vanishes in the limit of long wavelengths, in contrast to the finite energy gap of the triplon excitation of the paramagnet.

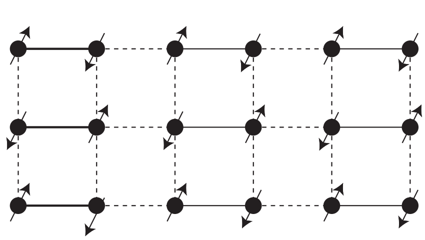

**Figure 4** Schematic of the ground state with antiferromagnetic order with $g < g_c$.

As with $H_I$, we can conclude from the distinct characters of the ground states and excitations for $g \gg 1$ and $g \approx 1$ that there must be a quantum critical point at some intermediate $g = g_c$.

## Quantum Criticality

The simple considerations of the previous section have given a rather complete description (based on the quasiparticle picture) of the physics for $g \ll g_c$ and $g \gg g_c$. We turn, finally, to the region $g \approx g_c$. For the specific models discussed in the previous section, a useful description is obtained by a method that is a generalization of the LGW method developed earlier for thermal phase transitions. However, some aspects of the critical behavior (e.g., the general forms of eqns [13]–[15]) will apply also to the quantum critical point of the section "Beyond LGW theory."

Following the canonical LGW strategy, we need to identify a collective order parameter which distinguishes the two phases. This is clearly given by the ferromagnetic moment in eqn [4] for the quantum Ising chain, and the antiferromagnetic moment in eqn [10] for the coupled dimer antiferromagnet. We coarse-grain these moments over some finite averaging region, and at long wavelengths this yields a real order parameter field $\phi_a$, with the index $a = 1, \ldots, n$. For the Ising case we have $n = 1$ and $\phi_a$ is a measure of the local average of $N_0$ as defined in eqn [4]. For the antiferromagnet, $a$ extends over the three values $x, y, z$ (so $n = 3$), and three components of $\phi_a$ specify the magnitude and orientation of the local antiferromagnetic order in eqn [10]; note the average orientation of a specific spin at site $j$ is $\eta_j$ times the local value of $\phi_a$.

The second step in the LGW approach is to write down a general field theory for the order parameter, consistent with all symmetries of the underlying model. As we are dealing with a quantum transition, the field theory has to extend over spacetime, with the temporal fluctuations representing the sum over histories in the Feynman path-integral approach. With this reasoning, the proposed partition function

for the vicinity of the critical point takes the following form:

$$\mathcal{Z}_\phi = \int \mathcal{D}\phi_a(x,\tau) \times \exp\left[-\int d^d x\, d\tau \left(\frac{1}{2}\left((\partial_\tau \phi_a)^2 + c^2(\nabla_x \phi_a)^2 + s\phi_a^2\right) + \frac{u}{4!}\left(\phi_a^2\right)^2\right)\right] \quad [11]$$

Here $\tau$ is imaginary time; there is an implied summation over the $n$ values of the index $a$, $c$ is a velocity, and $s$ and $u > 0$ are coupling constants. This is a field theory in $d+1$ spacetime dimensions, in which the Ising chain corresponds to $d=1$ and the dimer antiferromagnet to $d=2$. The quantum phase transition is accessed by tuning the "mass" $s$: there is a quantum critical point at $s=s_c$ and the $s<s_c(s>s_c)$ regions correspond to the $g<g_c(g>g_c)$ regions of the lattice models. The $s<s_c$ phase has $\langle\phi_a\rangle \neq 0$ and this corresponds to the spontaneous breaking of spin rotation symmetry noted in eqns [4] and [10] for the lattice models. The $s>s_c$ phase is the paramagnet with $\langle\phi_a\rangle=0$. The excitations in this phase can be understood as small harmonic oscillations of $\phi_a$ about the point (in field space) $\phi_a=0$. A glance at eqn [11] shows that there are $n$ such oscillators for each wave vector. These oscillators clearly constitute the $g>g_c$ quasiparticles found earlier in eqn [7] for the Ising chain (with $n=1$) and the triplon quasiparticle (with $n=3$) illustrated in **Figure 3** for the dimer antiferromagnet.

We have now seen that there is a perfect correspondence between the phases of the quantum field theory $\mathcal{Z}_\phi$ and those of the lattice models $H_I$ and $H_d$. The power of the representation in eqn [11] is that it also allows us to get a simple description of the quantum critical point. In particular, readers may already have noticed that if we interpret the temporal direction $\tau$ in eqn [11] as another spatial direction, then $\mathcal{Z}_\phi$ is simply the classical partition function for a thermal phase transition in a ferromagnet in $d+1$ dimensions: this is the canonical model for which the LGW theory was originally developed. We can now take over standard results for this classical critical point, and obtain some useful predictions for the quantum critical point of $\mathcal{Z}_\phi$. It is useful to express these in terms of the dynamic susceptibility defined by

$$\chi(k,\omega) = \frac{i}{\hbar}\int d^d x \times \int_0^\infty dt \left\langle \left[\hat{\phi}(x,t), \hat{\phi}(0,0)\right]\right\rangle_T e^{-ikx+i\omega t} \quad [12]$$

Here $\hat{\phi}$ is the Heisenberg field operator corresponding to the path integral in eqn [11], the square brackets represent a commutator, and the angular brackets an average over the partition function at a temperature $T$. The structure of $\chi$ can be deduced from the knowledge that the quantum correlators of $\mathcal{Z}_\phi$ are related by analytic continuation in time to the corresponding correlators of the classical statistical mechanics problem in $d+1$ dimensions. The latter are known to diverge at the critical point as $\sim 1/p^{2-\eta}$ where $p$ is the $(d+1)$-dimensional momentum, $\eta$ is defined to be the anomalous dimension of the order parameter ($\eta=1/4$ for the quantum Ising chain). Knowing this, we can deduce the form of the quantum correlator in eqn [12] at the zero-temperature quantum critical point

$$\chi(k,\omega) \sim \frac{1}{(c^2k^2-\omega^2)^{1-\eta/2}}, \quad T=0, \quad g=g_c \quad [13]$$

The most important property of eqn [13] is the absence of a quasiparticle pole in the spectral density. Instead, $\mathrm{Im}(\chi(k,\omega))$ is nonzero for all $\omega > ck$, reflecting the presence of a continuum of critical excitations. Thus the stable quasiparticles found at low enough energies for all $g \neq g_c$ are absent at the quantum critical point.

We now briefly discuss the nature of the phase diagram for $T>0$ with $g$ near $g_c$. In general, the interplay between quantum and thermal fluctuations near a quantum critical point can be quite complicated, and we cannot discuss it in any detail here. However, the physics of the quantum Ising chain is relatively simple, and also captures many key features found in more complex situations, and is summarized in **Figure 5**. For all $g \neq g_c$ there is a range of low temperatures ($T \lesssim |g-g_c|$) where the long time dynamics can be described using a dilute gas of thermally excited quasiparticles. Further, the

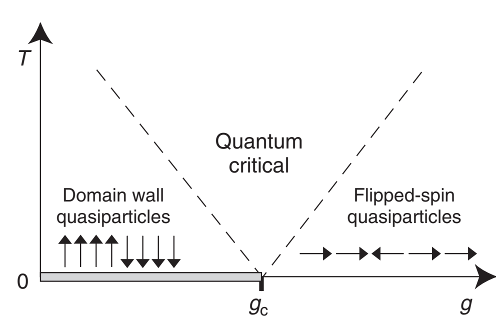

**Figure 5** Nonzero temperature phase diagram of $H_I$. The ferromagnetic order is present only at $T=0$ on the shaded line with $g<g_c$. The dashed lines at finite $T$ are crossovers out of the low-$T$ quasiparticle regimes where a quasiclassical description applies. The state sketched on the paramagnetic side used the notation $|\rightarrow\rangle_j = 2^{-1/2}(|\uparrow\rangle_j + |\downarrow\rangle_j)$ and $|\leftarrow\rangle_j = 2^{-1/2}(|\uparrow\rangle_j - |\downarrow\rangle_j)$.

dynamics of these quasiparticles is quasiclassical, although we reiterate that the nature of the quasiparticles is entirely distinct on opposite sides of the quantum critical point. Most interesting, however, is the novel quantum critical region, $T \gtrsim |g - g_c|$, where neither quasiparticle picture nor a quasiclassical description are appropriate. Instead, we have to understand the influence of temperature on the critical continuum associated with eqn [13]. This is aided by scaling arguments which show that the only important frequency scale which characterizes the spectrum is $k_B T/\hbar$, and the crossovers near this scale are universal, that is, independent of specific microscopic details of the lattice Hamiltonian. Consequently, the zero-momentum dynamic susceptibility in the quantum critical region takes the following form at small frequencies:

$$\chi(k = 0, \omega) \sim \frac{1}{T^{2-\eta}} \frac{1}{(1 - i\omega/\Gamma_R)} \quad [14]$$

This has the structure of the response of an overdamped oscillator, and the damping frequency, $\Gamma_R$, is given by the universal expression

$$\Gamma_R = \left(2 \tan \frac{\pi}{16}\right) \frac{k_B T}{\hbar} \quad [15]$$

The numerical proportionality constant in eqn. [15] is specific to the quantum Ising chain; other models also obey eqn [15] but with a different numerical value for this constant.

## Beyond LGW Theory

The quantum transitions discussed so far have turned to have a critical theory identical to that found for classical thermal transitions in $d+1$ dimensions. Over the last decade it has become clear that there are numerous models, of key physical importance, for which such a simple classical correspondence does not exist. In these models, quantum Berry phases are crucial in establishing the nature of the phases, and of the critical boundaries between them. In less technical terms, a signature of this subtlety is an important simplifying feature which was crucial in the analyses of the section "Simple models": both models had a straightforward $g \to \infty$ limit in which we were able to write down a simple, nondegenerate, ground-state wave function of the "disordered" paramagnet. In many other models, identification of the disordered phase is not as straightforward: specifying absence of a particular magnetic order is not enough to identify a quantum state, as we still need to write down a suitable wave function. Often, subtle quantum interference effects induce new types of order in the disordered state, and such effects are entirely absent in the LGW theory.

An important example of a system displaying such phenomena is the $S = 1/2$ square lattice antiferromagnet with additional frustrating interactions. The quantum degrees of freedom are identical to those of the coupled dimer antiferromagnet, but the Hamiltonian preserves the full point-group symmetry of the square lattice:

$$H_s = \sum_{j<k} J_{jk} \left( \hat{\sigma}_j^x \hat{\sigma}_k^x + \hat{\sigma}_j^y \hat{\sigma}_k^y + \hat{\sigma}_j^z \hat{\sigma}_k^z \right) + \cdots \quad [16]$$

Here the $J_{jk} > 0$ are short-range exchange interactions which preserve the square lattice symmetry, and the ellipses represent possible further multiple spin terms. Now imagine tuning all the non-nearest-neighbor terms as a function of some generic coupling constant $g$. For small $g$, when $H_s$ is nearly the square lattice antiferromagnet, the ground state has antiferromagnetic order as in **Figure 4** and eqn [10]. What is now the disordered ground state for large $g$? One natural candidate is the spin-singlet paramagnet in **Figure 2**. However, because all nearest neighbor bonds of the square lattice are now equivalent, the state in **Figure 2** is degenerate with three other states obtained by successive 90° rotations about a lattice site. In other words, the state in **Figure 2**, when transferred to the square lattice, breaks the symmetry of lattice rotations by 90°. Consequently it has a new type of order, often called valence-bond-solid (VBS) order. It is now believed that a large class of models like $H_s$ do indeed exhibit a second-order quantum phase transition between the antiferromagnetic state and a VBS state – see **Figure 6**. Both the existence of VBS order in the paramagnet, and of a second-order quantum transition, are features that are not predicted by LGW theory: these can only be

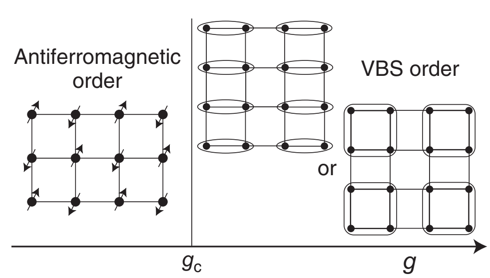

**Figure 6** Phase diagram of $H_s$. Two possible VBS states are shown: one which is the analog of **Figure 2**, and the other in which spins form singlets in a plaquette pattern. Both VBS states have a 4-fold degeneracy due to breaking of square lattice symmetry. So the novel critical point at $g = g_c$ (described by $\mathcal{Z}_z$) has the antiferromagnetic and VBS orders vanishing as it is approached from either side: this coincident vanishing of orders is generically forbidden in LGW theories.

understood by a careful study of quantum interference effects associated with Berry phases of spin fluctuations about the antiferromagnetic state. We will not enter into details of this analysis here, but will conclude our discussion by writing down the theory so obtained for the quantum critical point in Figure 6:

$$\mathcal{Z}_z = \int \mathcal{D}z_\alpha(x,\tau)\mathcal{D}A_\mu(x,\tau) \times \exp\left(-\int \mathrm{d}^2x\,\mathrm{d}\tau\left[|(\partial_\mu - \mathrm{i}A_\mu)z_\alpha|^2 + s|z_\alpha|^2 + \frac{u}{2}(|z_\alpha|^2)^2 + \frac{1}{2e^2}(\epsilon_{\mu\nu\lambda}\partial_\nu A_\lambda)^2\right]\right) \qquad [17]$$

Here $\mu, \nu, \lambda$ are spacetime indices which extend over the two spatial directions and $\tau$, $\alpha$ is a spinor index which extends over $\uparrow$, $\downarrow$, and $z_\alpha$ is complex spinor field. In comparing $\mathcal{Z}_z$ to $\mathcal{Z}_\phi$, note that the vector order parameter $\phi_a$ has been replaced by a spinor $z_\alpha$, and these are related by $\phi_a = z_\alpha^* \sigma^a_{\alpha\beta} z_\beta$, where $\sigma^a$ are the Pauli matrices. So the order parameter has fractionalized into the $z_\alpha$. A second novel property of $\mathcal{Z}_z$ is the presence of a U(1) gauge field $A_\mu$: this gauge force emerges near the critical point, even though the underlying model in eqn [16] only has simple two spin interactions. Studies of fractionalized critical theories like $\mathcal{Z}_c$ in other models with spin and/or charge excitations is an exciting avenue for further theoretical research.

# Quantum Spin Systems

**B Nachtergaele**, University of California at Davis, Davis, CA, USA

## Introduction

The theory of quantum spin systems is concerned with the properties of quantum systems with an infinite number of degrees of freedom that each have a finite-dimensional state space. Occasionally, one is specifically interested in finite systems. Among the most common examples, one has an *n*-dimensional Hilbert space associated with each site of a *d*-dimensional lattice.

A model is normally defined by describing a Hamiltonian or a family of Hamiltonians, which are self-adjoint operators on the Hilbert space, and one studies their spectrum, the eigenstates, the equilibrium states, the system dynamics, and non-equilibrium stationary states, etc.

More particularly, the term "quantum spin system" often refers to such models where each degree of freedom is thought of as a spin variable, that is, there are three basic observables representing the components of the spin, $S^1$, $S^2$, and $S^3$, and these components transform according to a unitary representation of SU(2). The most commonly encountered situation is where the system consists of $N$ spins, each associated with a fixed irreducible representation of SU(2). One speaks of a spin-$J$ model if this representation is the $(2J+1)$-dimensional one. The possible values of $J$ are $1/2, 1, 3/2, \ldots$

The spins are usually thought of as each being associated with a site in a lattice, or more generally, a vertex in a graph. In a condensed-matter-physics model, each spin may be associated with an ion in a crystalline lattice. Quantum spin systems are also used in quantum information theory and quantum computation, and show up as abstract mathematical objects in representation theory and quantum probability.

In this article we give a brief introduction to the subject, starting with a very short review of its history. The mathematical framework is sketched and the most important definitions are given. Three sections, "Symmetries and symmetry breaking," "Phase transitions," and "Dynamics," together cover the most important aspects of quantum spin systems actively pursued today.

## A Very Brief History

The introduction of quantum spin systems was the result of the marriage of two developments during the 1920s. The first was the realization that angular momentum (hence, also the magnetic moment) is quantized (Pauli 1920, Stern and Gerlach 1922) and that particles such as the electron have an intrinsic

angular momentum called spin (Compton 1921, Goudsmit and Uhlenbeck 1925).

The second development was the attempt in statistical mechanics to explain ferromagnetism and the phase transition associated with it on the basis of a microscopic theory (Lenz and Ising 1925). The fundamental interaction between spins, the so-called exchange operator which is a subtle consequence of the Pauli exclusion principle, was introduced independently by Dirac and Heisenberg in 1926. With this discovery, it was realized that magnetism is a quantum effect and that a fundamental theory of magnetism requires the study of quantum-mechanical models. This realization and a large amount of subsequent work notwithstanding, some of the most fundamental questions, such as a derivation of ferromagnetism from first principles, remain open.

The first and most important quantum spin model is the Heisenberg model, so named after Heisenberg. It has been studied intensely ever since the early 1930s and its study has led to an impressive variety of new ideas in both mathematics and physics. Here, we limit ourselves to listing only some landmark developments.

Spin waves were discovered independently by Bloch and Slater in 1930 and they continue to play an essential role in our understanding of the excitation spectrum of quantum spin Hamiltonians. In two papers published in 1956, Dyson advanced the theory of spin waves by showing how interactions between spin waves can be taken into account.

In 1931, Bethe introduced the famous Bethe ansatz to show how the exact eigenvectors of the spin-1/2 Heisenberg model on the one-dimensional lattice can be found. This exact solution, directly and indirectly, led to many important developments in statistical mechanics, combinatorics, representation theory, quantum field theory and more. Hulthén used the Bethe ansatz to compute the ground-state energy of the antiferromagnetic spin-1/2 Heisenberg chain in 1938.

In their famous 1961 paper, Lieb, Schultz, and Mattis showed that some quantum spin models in one dimension can be solved exactly by mapping them into a problem of free fermions. This paper is still one of the most cited in the field.

Robinson, in 1967, laid the foundation for the mathematical framework, which we describe in the next section. Using this framework, Araki established the absence of phase transitions at positive temperatures in a large class of one-dimensional quantum spin models in 1969.

During the more recent decades, the mathematical and computational techniques used to study quantum spin models have fanned out in many directions.

When it was realized in the 1980s that the magnetic properties of complex materials play an important role in high-$T_c$ superductivity, a variety of quantum spin models studied in the literature proliferated. This motivated a large number of theoretical and experimental studies of materials with exotic properties that are often based on quantum effects that do not have a classical analog. An example of unexpected behavior is the prediction by Haldane of the spin liquid ground state of the spin-1 Heisenberg antiferromagnetic chain in 1983. In the quest for a mathematical proof of this prediction (a quest still ongoing today), Affleck, Kennedy, Lieb, and Tasaki introduced the AKLT model in 1987. They were able to prove that the ground state of this model has all the characteristic properties predicted by Haldane for the Heisenberg chain: a unique ground state with exponential decay of correlations and a spectral gap above the ground state.

There are also particle models that are defined on a lattice, or more generally, a graph. Unlike spins, particles can hop from one site to another. These models are closely related to quantum spin systems and, in some cases, are mathematically equivalent. The best-known example of a model of lattice fermions is the Hubbard model. Such systems are not discussed further in this article.

## Mathematical Framework

Quantum spin systems present an area of mathematical physics where the demands of mathematical rigor can be fully met and, in many cases, this can be done without sacrificing the ability to include all physically relevant models and phenomena. This does not mean, however, that there are few open problems remaining. But it does mean that, in general, these open problems are precisely formulated mathematical questions.

In this section we review the standard mathematical framework for quantum spin systems, in which the topics discussed in the subsequent section can be given a precise mathematical formulation. It is possible, however, to skip this section and read the rest with only a physical or intuitive understanding of the notions of observable, Hamiltonian, dynamics, symmetry, ground state, etc.

The most common mathematical setup is as follows. Let $d \geq 1$, and let $\mathcal{L}$ denote the family of finite subsets of the $d$-dimensional integer lattice $\mathbb{Z}^d$. For simplicity we will assume that the Hilbert space of the "spin" associated with each $x \in \mathbb{Z}^d$ has the same dimension $n \geq 2$: $\mathcal{H}_{\{x\}} \cong \mathbb{C}^n$. The Hilbert space associated with the finite volume $\Lambda \in \mathcal{L}$ is then $\mathcal{H}_\Lambda = \bigotimes_{x \in \Lambda} \mathcal{H}_x$. The algebra of observables for the spin of site $x$ consists of the $n \times n$ complex matrices: $\mathcal{A}_{\{x\}} \cong M_n(\mathbb{C})$. For any

$\Lambda \in \mathcal{L}$, the algebra of observables for the system in $\Lambda$ is given by $\mathcal{A}_\Lambda = \bigotimes_{x\in\Lambda} \mathcal{A}_{\{x\}}$. The primary observables for a quantum spin model are the spin-$S$ matrices $S^1$, $S^2$, and $S^3$, where $S$ is the half-integer such that $n = 2S + 1$. They are defined as Hermitian matrices satisfying the SU(2) commutation relations. Instead of $S^1$ and $S^2$, one often works with the spin-raising and -lowering operators, $S^+$ and $S^-$, defined by the relations $S^1 = (S^+ + S^-)/2$, and $S^2 = (S^+ - S^-)/(2\mathrm{i})$. In terms of these, the SU(2) commutation relations are

$$[S^+, S^-] = 2S^3, \quad [S^3, S^\pm] = \pm S^\pm \qquad [1]$$

where we have used the standard notation for the commutator for two elements $A$ and $B$ in an algebra: $[A, B] = AB - BA$. In the standard basis $S^3$, $S^+$, and $S^-$ are given by the following matrices:

$$S^3 = \begin{pmatrix} S & & & \\ & S-1 & & \\ & & \ddots & \\ & & & -S \end{pmatrix}$$

$S^- = (S^+)^*$, and

$$S^+ = \begin{pmatrix} 0 & c_S & & & \\ & 0 & c_{S-1} & & \\ & & \ddots & \ddots & \\ & & & 0 & c_{-S+1} \\ & & & & 0 \end{pmatrix}$$

where, for $m = -S, -S+1, \ldots, S$,

$$c_m = \sqrt{S(S+1) - m(m-1)}$$

In the case $n = 2$, one often works with the Pauli matrices, $\sigma^1, \sigma^2, \sigma^3$, simply related to the spin matrices by $\sigma^j = 2S^j$, $j = 1, 2, 3$.

Most physical observables are expressed as finite sums and products of the spin matrices $S_x^j$, $j = 1, 2, 3$, associated with the site $x \in \Lambda$:

$$S_x^j = \bigotimes_{y\in\Lambda} A_y$$

with $A_x = S^j$, and $A_y = \mathbb{1}$ if $y \neq x$.

The $\mathcal{A}_\Lambda$ are finite-dimensional C*-algebras for the usual operations of sum, product, and Hermitian conjugation of matrices and with identity $\mathbb{1}_\Lambda$.

If $\Lambda_0 \subset \Lambda_1$, there is a natural embedding of $\mathcal{A}_{\Lambda_0}$ into $\mathcal{A}_{\Lambda_1}$, given by

$$\mathcal{A}_{\Lambda_0} \cong \mathcal{A}_{\Lambda_0} \otimes \mathbb{1}_{\Lambda_1\setminus\Lambda_0} \subset \mathcal{A}_{\Lambda_1}$$

The algebra of local observables is then defined by

$$\mathcal{A}_{\mathrm{loc}} = \bigcup_{\Lambda\in\mathcal{L}} \mathcal{A}_\Lambda$$

Its completion is the $C^*$-algebra of quasilocal observables, which we will simply denote by $\mathcal{A}$.

The dynamics and symmetries of a quantum spin model are described by (groups of) automorphisms of the $C^*$-algebra $\mathcal{A}$, that is, bijective linear transformations $\alpha$ on $\mathcal{A}$ that preserve the product and $^*$ operations. Translation invariance, for example, is expressed by the translation automorphisms $\tau_x$, $x \in \mathbb{Z}^d$, which map any subalgebra $\mathcal{A}_\Lambda$ to $\mathcal{A}_{\Lambda+x}$, in the natural way. They form a representation of the additive group $\mathbb{Z}^d$ on $\mathcal{A}$.

A translation-invariant interaction, or potential, defining a quantum spin model, is a map $\phi : \mathcal{L} \to \mathcal{A}$ with the following properties: for all $X \in \mathcal{L}$, we have $\phi(X) \in \mathcal{A}_X$, $\phi(X) = \phi(X)^*$, and for $x \in \mathbb{Z}^d$, $\phi(X + x) = \tau_x(\phi(X))$. An interaction is called finite range if there exists $R > 0$ such that $\phi(X) = 0$ whenever $\mathrm{diam}(X) > R$. The Hamiltonian in $\Lambda$ is the self-adjoint element of $\mathcal{A}_\Lambda$ defined by

$$H_\Lambda = \sum_{X\subset\Lambda} \phi(X)$$

For the standard Heisenberg model the interaction is given by

$$\phi(\{x, y\}) = -J\mathbf{S}_x \cdot \mathbf{S}_y, \text{ if } |x - y| = 1 \qquad [2]$$

and $\phi(X) = 0$ in all other cases. Here, $\mathbf{S}_x \cdot \mathbf{S}_y$ is the conventional notation for $S_x^1 S_y^1 + S_x^2 S_y^2 + S_x^3 S_y^3$. The magnitude of the coupling constant $J$ sets a natural unit of energy and is irrelevant from the mathematical point of view. Its sign, however, determines whether the model is ferromagnetic ($J > 0$), or antiferromagnetic ($J < 0$). For the classical Heisenberg model, where the role of $\mathbf{S}_x$ is played by a unit vector in $\mathbb{R}^3$, and which can be regarded, after rescaling by a factor $S^{-2}$, as the limit $S \to \infty$ of the quantum Heisenberg model, there is a simple transformation relating the ferro- and antiferromagnetic models (just map $\mathbf{S}_x$ to $-\mathbf{S}_x$ for all $x$ in the even sublattice of $\mathbb{Z}^d$). It is easy to see that there does not exist an automorphism of $\mathcal{A}$ mapping $\mathbf{S}_x$ to $-\mathbf{S}_x$, since that would be inconsistent with the commutation relations [1]. Not only is there no exact mapping between the ferro- and the antiferromagnetic models, their ground states and equilibrium states have radically different properties. See below for the definitions and further discussion.

The dynamics (or time evolution), of the system in finite volume $\Lambda$ is the one-parameter group of automorphisms of $\mathcal{A}_\Lambda$ given by

$$\alpha_t^{(\Lambda)}(A) = \mathrm{e}^{\mathrm{i}tH_\Lambda} A \mathrm{e}^{-\mathrm{i}tH_\Lambda}, \quad t \in \mathbb{R}$$

For each $t \in \mathbb{R}$, $\alpha_t^{(\Lambda)}$ is an automorphism of $\mathcal{A}$ and the family $\{\alpha_t^{(\Lambda)} \mid t \in \mathbb{R}\}$ forms a representation of the additive group $\mathbb{R}$.

Each $\alpha_t^{(\Lambda)}$ can trivially be extended to an automorphism on $\mathcal{A}$, by tensoring with the identity map. Under quite general conditions, $\alpha_t^{(\Lambda)}$ converges strongly as $\Lambda \to \mathbb{Z}^d$ in a suitable sense, that is, for every $A \in \mathcal{A}$, the limit

$$\lim_{\Lambda \uparrow \mathbb{Z}^d} \alpha_t^{(\Lambda)}(A) = \alpha_t(A)$$

exists in the norm in $\mathcal{A}$, and it can be shown that it defines a strongly continuous one-parameter group of automorphisms of $\mathcal{A}$. $\Lambda \uparrow \mathbb{Z}^d$ stands for any sequence of $\Lambda \in \mathcal{L}$ such that $\Lambda$ eventually contains any given element of $\mathcal{L}$. A sufficient condition on the potential $\phi$ is that there exists $\lambda > 0$ such that $\|\Phi\|_\lambda$ is finite, with

$$\|\Phi\|_\lambda = \sum_{X \ni 0} e^{\lambda |X|} \|\phi(X)\| \qquad [3]$$

Here $|\cdot|$ denotes the number of elements in $X$. One can show that, under the same conditions, $\delta$ defined on $\mathcal{A}_{\text{loc}}$ by

$$\delta(A) = \lim_{\Lambda \uparrow \mathbb{Z}^d} [H_\Lambda, A]$$

is a norm-closable (unbounded) derivation on $\mathcal{A}$ and that its closure is, up to a factor i, the generator of $\{\alpha_t \mid t \in \mathbb{R}\}$, that is, formally

$$\alpha_t = e^{it\delta}$$

For the class of $\phi$ with finite $\|\Phi\|_\lambda$ for some $\lambda > 0$, $\mathcal{A}_{\text{loc}}$ is a core of analytic vectors for $\delta$. This means that, for each $A \in \mathcal{A}_{\text{loc}}$, the function $t \mapsto \alpha_t(A)$ can be extended to a function $\alpha_z(A)$ analytic in a strip $|\text{Im } z| < a$ for some $a > 0$.

A state of the quantum spin system is a linear functional on $\mathcal{A}$ such that $\omega(A^*A) \geq 0$, for all $A \in \mathcal{A}$ (positivity), and $\omega(\mathbb{1}) = 1$ (normalization). The restriction of $\omega$ to $\mathcal{A}_\Lambda$, for each $\Lambda \in \mathcal{L}$, is uniquely determined by a density matrix, that is, $\rho_\Lambda \in \mathcal{A}_\Lambda$, such that

$$\omega(A) = \text{tr}\, \rho_\Lambda A, \quad \text{for all } A \in \mathcal{A}_\Lambda$$

where tr denotes the usual trace of matrices. $\rho_\Lambda$ is non-negative definite and of unit trace. If the density matrix is a one-dimensional projection, the state is called a vector state, and can be identified with a vector $\psi \in \mathcal{H}_\Lambda$, such that $\mathbb{C}\psi = \text{ran}\, \rho_\Lambda$.

A ground state of the quantum spin system is a state $\omega$ satisfying the local stability inequalties:

$$\omega(A^*\delta(A)) \geq 0, \quad \text{for all } A \in A_{\text{loc}} \qquad [4]$$

The states describing thermal equilibrium are characterized by the Kubo–Martin–Schwinger (KMS) condition: for any $\beta \geq 0$ (related to absolute temperature by $\beta = 1/(k_B T)$, where $k_B$ is the Boltzmann constant), $\omega$ is called $\beta$-KMS if

$$\omega(A\alpha_{i\beta}(B)) = \omega(BA), \quad \text{for all } A, B \in \mathcal{A}_{\text{loc}} \qquad [5]$$

The most common way to construct ground states and equilibrium states, namely solutions of [4] and [5], respectively, is by taking thermodynamic limits of finite-volume states with suitable boundary conditions. A ground state of the finite-volume Hamiltonian $H_\Lambda$ is a convex combination of vector states that are eigenstates of $H_\Lambda$ belonging to its smallest eigenvalue. The finite-volume equilibrium state at inverse temperature $\beta$ has density matrix $\rho_\beta$ defined by

$$\rho_\beta = Z(\Lambda, \beta)^{-1} e^{-\beta H_\Lambda}$$

where $Z(\Lambda, \beta) = \text{tr } e^{-\beta H_\Lambda}$ is called the partition function. By considering limit points as $\Lambda \to \mathbb{Z}^d$, one can show that a quantum spin model always has at least one ground state and at least one equilibrium state for all $\beta$.

In this section, the basic concepts have so far been discussed in the most standard setup. Clearly, many generalizations are possible: one can consider non-translation-invariant models; models with random potentials; the state spaces at each site may have different dimensions; instead of $\mathbb{Z}^d$ one can consider other lattices or define models on arbitrary graphs; one can allow interactions of infinite range that satisfy weaker conditions than those imposed by the finiteness of the norm [3], or restrict to subspaces of the Hilbert space by imposing symmetries or suitable hardcore conditions; and one can study models with infinite-dimensional spins. Examples of all these types of generalizations have been considered in the literature and have interesting applications.

## Symmetries and Symmetry Breaking

Many interesting properties of quantum spin systems are related to symmetries and symmetry breaking. Symmetries of a quantum spin model are realized as representations of groups, Lie algebras, or quantum (group) algebras on the Hilbert space and/or the observable algebra. The symmetry property of the model is expressed by the fact that the Hamiltonian (or the dynamics) commutes with this representation. We briefly discuss the most common symmetries.

*Translation invariance*. The translation automorphisms $\tau_x$ have already been defined on the

observable algebra of infinite quantum spin systems on $\mathbb{Z}^d$. One can also define translation automorphisms for finite systems with periodic boundary conditions, which are defined on the torus $\mathbb{Z}^d/T\mathbb{Z}^d$, where $T = (T_1, \ldots, T_d)$ is a positive integer vector representing the periods.

*Other graph automorphisms*. In general, if $G$ is a group of automorphisms of the graph $\Gamma$, and $\mathcal{H}_\Gamma = \bigotimes_{x\in\Gamma} \mathbb{C}^n$ is the Hilbert space of a system of identical spins defined on $\Gamma$, then, for each $g \in G$, one can define a unitary $U_g$ on $\mathcal{H}_\Gamma$ by linear extension of $U_g \bigotimes \varphi_x = \bigotimes \varphi_{g^{-1}(x)}$, where $\varphi_x \in \mathbb{C}^n$, for all $x \in \Gamma$. These unitaries form a representation of $G$. With the unitaries one can immediately define automorphisms of the algebra of observables: for $A \in \mathcal{A}_\Lambda$, and $U \in \mathcal{A}_\Lambda$ unitary, $\tau(A) = U^*AU$ defines an automorphism, and if $U_g$ is a group representation, the corresponding $\tau_g$ will be, too. Common examples of graph automorphisms are the lattice symmetries of rotation and reflection. Translation symmetry and other graph automorphisms are often referred to collectively as spatial symmetries.

*Local symmetries* (also called gauge symmetries). Let $G$ be a group and $u_g$, $g \in G$, a unitary representation of $G$ on $\mathbb{C}^n$. Then, $U_g = \bigotimes_{x\in\Lambda} u_g$ is a representation on $\mathcal{H}_\Lambda$. The Heisenberg model [2], for example, commutes with such a representation of SU(2). It is often convenient, and generally equivalent, to work with a representation of the Lie algebra. In that case the SU(2) invariance of the Heisenberg model is expressed by the fact that $H_\Lambda$ commutes with the following three operators:

$$S^i = \sum_{x\in\Lambda} S^i_x, \quad i = 1, 2, 3$$

Note: sometimes the Hamiltonian is only symmetric under certain combinations of spatial and local symmetries. CP symmetry is an example.

For an automorphism $\tau$, we say that a state $\omega$ is $\tau$-invariant if $\omega \circ \tau = \tau$. If $\omega$ is $\tau_g$-invariant for all $g \in G$, we say that $\omega$ is $G$-invariant.

It is easy to see that if a quantum spin model has a symmetry $G$, then the set of all ground states or all $\beta$-KMS states will be $G$-invariant, meaning that if $\omega$ is in the set, then so is $\omega \circ \tau_g$, for all $g \in G$. By a suitable averaging procedure, it is usually easy to establish that the sets of ground states or equilibrium states contain at least one $G$-invariant element.

An interesting situation occurs if the model is $G$-invariant, but there are ground states or KMS states that are not. This means that, for some $g \in G$, and some $\omega$ in the set (of ground states or KMS states), $\omega \circ \tau \neq \omega$. When this happens, one says that there is spontaneous symmetry breaking, a phenomenon that also plays an important role in quantum field theory.

The famous Hohenberg–Mermin–Wagner theorem, applied to quantum spin models, states that, as long as the interactions do not have very long range and the dimension of the lattice is 2 or less, continuous symmetries cannot be spontaneously broken in a $\beta$-KMS state for any finite $\beta$.

*Quantum group symmetries*. We restrict ourselves to one important example: the $\mathrm{SU}_q(2)$ invariance of the spin-1/2 XXZ Heisenberg chain with $q \in [0, 1]$, and with special boundary terms. The Hamiltonian of the $\mathrm{SU}_q(2)$-invariant XXZ chain of length $L$ is given by

$$H_L = \sum_{x=1}^{L-1} -\frac{1}{\Delta}\left(S^1_x S^1_{x+1} + S^2_x S^2_{x+1}\right) - \left(S^3_x S^3_{x+1} - 1/4\right) + \frac{1}{2}\sqrt{1-\Delta^{-2}}\left(S^3_{x+1} - S^3_x\right)$$

where $q \in (0, 1]$ is related to the parameter $\Delta \geq 1$ by the relation $\Delta = (q + q^{-1})/2$. When $q = 0$, $H_L$ is equivalent to the Ising chain. Thus, the XXZ model interpolates between the Ising model (the primordial classical spin system) and the isotropic Heisenberg model (the most widely studied quantum spin model). In the limit of infinite spin ($S \to \infty$), the model converges to the classical Heisenberg model (XXZ or isotropic). An interesting feature of the XXZ model are its non-translation-invariant ground states, called kink states.

In this family of models, one can see how aspects of discreteness (quantized spins) and continuous symmetry (SU(2), or quantum symmetry $\mathrm{SU}_q(2)$) are present at the same time in the quantum Heisenberg models, and the two classical limits ($q \to 0$ and $S \to \infty$) can be used as a starting point to study its properties.

Quantum group symmetry is not a special case of invariance under the action of a group. There is no group, but there is an algebra represented on the Hilbert space of each spin, for which there is a good definition of tensor product of representations, and "many" irreducible representations. In this example, the representation of $\mathrm{SU}_q(2)$ on $\mathcal{H}_{[1,L]}$ commuting with $H_L$ is generated by

$$S^3 = \sum_{x=1}^{L} \mathbb{1}_1 \otimes \cdots \otimes S^3_x \otimes \mathbb{1}_{x+1} \otimes \cdots \mathbb{1}_L$$

$$S^+ = \sum_{x=1}^{L} t_1 \otimes \cdots \otimes t_{x-1} \otimes S^+_x \otimes \mathbb{1}_{x+1} \otimes \cdots \mathbb{1}_L$$

$$S^- = \sum_{x=1}^{L} \mathbb{1}_1 \otimes \cdots \otimes S^-_x \otimes t^{-1}_{x+1} \otimes \cdots t^{-1}_L$$

where

$$t = \begin{pmatrix} q^{-1} & 0 \\ 0 & q \end{pmatrix}$$

Quantum group symmetries were discovered in exactly solvable models, starting with the spin-1/2 XXZ chain. One can exploit their representation theory to study the spectrum of the Hamiltonian in very much the same way as ordinary symmetries. The main restriction to its applicability is that the tensor product structure of the representations is inherently one-dimensional, that is, relying on an ordering from left to right. For the infinite XXZ chain the left-to-right and right-to-left orderings can be combined to generate an infinite-dimensional algebra, the quantum affine algebra $U_q(\widehat{sl_2})$.

## Phase Transitions

Quantum spin models of condensed matter physics often have interesting ground states. Not only are the ground states often a good approximation of the low-temperature behavior of the real systems that are modeled by it, and studying them is therefore useful, it is in many cases also a challenging mathematical problem. This is in contrast with classical lattice models for which the ground states are usually simple and easy to find. In more than one way, ground states of quantum spin systems display behavior similar to equilibrium states of classical spin systems at positive temperature.

The spin-1/2 Heisenberg antiferromagnet on $\Lambda \subset \mathbb{Z}^d$, with Hamiltonian

$$H_\Lambda = \sum_{x,y;\in\Lambda|x-y|=1} S_x \cdot S_y \qquad [6]$$

is a case in point. Even in the one-dimensional case ($d = 1$), and even though the model in that case is exactly solvable by the Bethe ansatz, its ground state is highly nontrivial. Analysis of the Bethe ansatz solution (which is not fully rigorous) shows that spin–spin correlation function decays to zero at infinity, but slower than exponentially (roughly as inverse distance squared). For $d = 2$, it is believed, but not mathematically proved, that the ground state has Néel order, that is, long-range antiferromagnetic order, accompanied by a spontaneous breaking of the SU(2) symmetry. Using reflection positivity, Dyson, Lieb, and Simon were able to prove the Néel order at sufficiently low temperature (large $\beta$), for $d \geq 3$ and all $S \geq 1/2$. This was later extended to the ground state for $d = 2$ and $S \geq 1$, and $d \geq 3$ and $S \geq 1/2$, that is, all the cases where Néel order is expected except $d = 2$, $S = 1/2$.

In contrast, no proof of long-range order in the Heisenberg ferromagnet at low temperature exists. This is rather remarkable since proving long-range order in the ground states of the ferromagnet is a trivial problem.

Of particular interest are the so-called quantum phase transitions. These are phase transitions that occur as a parameter in the Hamiltonian is varied and which are driven by the competing effects of energy and quantum fluctuations, rather than the balance between energy and entropy which drives usual equilibrium phase transitions. Since entropy does not play a role, quantum phase transitions can be oberved at zero temperature, that is, in the ground states.

An important example of a quantum phase transition occurs in the two-or higher-dimensional $XY$ model with a magnetic field in the $Z$-direction. It was proved by Kennedy, Lieb, and Shastry that, at zero field, this model has off-diagonal long-range order (ODLRO), and can be interpreted as a hard-core Bose gas at half-filling. It is also clear that if the magnetic field exceeds a critical value, $h_c$, the model has a simple ferromagnetically ordered ground state. There are indications that there is ODLRO for all $|h| < h_c$. However, so far there is no proof that ODLRO exists for any $h \neq 0$.

What makes the ground-state problem of quantum spin systems interesting and difficult at the same time is that ground states, in general, do not minimize the expectation value of the interaction terms in the Hamiltonian individually although, loosely speaking, the expectation value of their sum (the Hamiltonian) is minimized. However, there are interesting exceptions to this rule. Two examples are the AKLT model and the ferromagnetic XXZ model.

The wide-ranging behavior of quantum spin models has required an equally wide range of mathematical approaches to study them. There is one group of methods, however, that can make a claim of substantial generality: those that start from a representation of the partition function based on the Feynman–Kac formula. Such representations turn a $d$-dimensional quantum spin model into a $(d + 1)$-dimensional classical problem, albeit one with some special features. This technique was pioneered by Ginibre in 1968 and was quickly adopted by a number of authors to solve a variety of problems. Techniques borrowed from classical statistical mechanics have been adapted with great success to study ground states, the low-temperature phase diagram, or the high-temperature regime of quantum spin models that can be regarded as perturbations of a classical system. More recently, it was used to develop a quantum version of Pirogov–Sinai theory which is applicable to a large class of problems, including some with low-temperature phases not related by symmetry.

## Dynamics

Another feature of quantum spin systems that makes them mathematically richer than their classical couterpart is the existence of a Hamiltonian dynamics. Quite generally, the dynamics is well defined in the thermodynamic limit as a strongly continuous one-parameter group of automorphisms of the $C^*$-algebra of quasilocal observables. Strictly speaking, a quantum spin model is actually defined by its dynamics $\alpha_t$, or by its generator $\delta$, and not by the potential $\phi$. Indeed, $\phi$ is not uniquely determined by $\alpha_t$. In particular, it is possible to incorporate various types of boundary conditions into the definition of $\phi$. This approach has proved very useful in obtaining important structural results, such as the proof by Araki of the uniqueness the KMS state at any finite $\beta$ in one dimension. Another example is a characterization of equilibrium states by the energy–entropy balance inequalities, which is both physically appealing and mathematically useful: $\omega$ is a $\beta$-KMS state for a quantum spin model in the setting of the section on the mathematical framework in this article (and in fact also for more general quantum systems), if and only if the inequality

$$\beta\omega(X^*\delta(X)) \geq \omega(X^*X)\log\frac{\omega(X^*X)}{\omega(XX^*)}$$

is satisfied for all $X \in \mathcal{A}_{\text{loc}}$. This characterization and several related results were proved in a series of works by various authors (mainly Roepstorff, Araki, Fannes, Verbeure, and Sewell).

Detailed properties of the dynamics for specific models are generally lacking. One could point to the "immediate nonlocality" of the dynamics as the main difficulty. By this, we mean that, except in trivial cases, most local observables $A \in \mathcal{A}_{\text{loc}}$, become nonlocal after an arbitrarily short time, that is, $\alpha_t(A) \notin \mathcal{A}_{\text{loc}}$, for any $t \neq 0$. This nonlocality is not totally uncontrolled however. A result by Lieb and Robinson establishes that, for models with interactions that are sufficiently short range (e.g., finite range), the nonlocality propagates at a bounded speed. More precisely, under quite general conditions, there exist constants $c, v > 0$ such that, for any two local observables $A, B \in \mathcal{A}_{\{0\}}$,

$$\|[\alpha_t(A), \tau_x(B)]\| \leq 2\|A\|\|B\|\mathrm{e}^{-c(|x|-v|t|)}$$

Attempts to understand the dynamics have generally been aimed at one of the two issues: return to equilibrium from a perturbed state, and convergence to a nonequilibrium steady state in the presence of currents. Some interesting results have been obtained although much remains to be done.

# Quantum Statistical Mechanics: Overview

**L Triolo**, Università di Roma "Tor Vergata", Rome, Italy

## Introduction

Quantum theory actually started at the beginning of the twentieth century as a many-body theory, attempting to solve problems to which classical physics gave unsatisfactory answers.

This article aims to follow the developments of quantum statistical mechanics, hereafter called QSM, staying close to the underlying physics and sketching its methods and perspectives. The next section outlines the historical path, and the first achievements by Planck (1900) and Debye (1913); the subsequent free quantum gas theory will be recalled in the first original insights due to Fermi, Dirac (1926) and Bose, Einstein (1924–25), when many open problems began to find a coherent treatment.

In this framework, an interesting new idea appeared: the elementary units of the systems could be "particles", in the usual or in a broad meaning, a notion which includes photons, phonons, and quasiparticles of current use in condensed matter physics. The description of a classical harmonic system through independent normal modes is an example of a very fruitful use of collective variables.

The subsequent section will deal with more recent achievements, related to the properties of quantum $N$-body systems, which are fundamental for the derivation of their macroscopic behavior. In particular, the works by Dyson–Lenard and Lieb–Lebowitz on the stability of matter have to be recalled: a system made of electrons and ions has a thermodynamic behavior, thanks to the quantum nature of its constituents, where the Pauli exclusion principle plays an essential role.

We will then present relations that arise in quantum field theory, that is, from the second quantization methods; related technical and conceptual problems will also be presented briefly.

This is necessary for taking into account the recent works and perspectives, which will be considered in the last section. Here the new inputs and challenges from outstanding achievements in physics laboratories will be taken into account, referring to some exactly solvable models which help in understanding and in fixing the boundaries of approximate methods.

## The Crisis of Classical Physics: The Quantum Free Gas

Let us briefly recall some of what Lord Kelvin called the "nineteenth century clouds" over the physics of that time (1884), and the subsequent new ideas, (Gallavotti 1999).

It is well known that the classical Dulong–Petit law of specific heat of solid crystals may be derived from the model of point particles interacting through harmonic forces; the equipartition of the mean energy among the degrees of freedom implies, for $N$ particles, the linear dependence of the internal energy $U_N$ on absolute temperature $T$, hence a constant heat capacity $C_N$ ($k_B$ is the Boltzmann's constant)

$$U_N = 6 \cdot \frac{1}{2} N k_B T, \qquad C_N := \frac{\partial U_N}{\partial T} = 3 N k_B \qquad [1]$$

Experimentally this is relatively well satisfied at high temperatures but it is violated for low $T$: one observes that $U_N$ vanishes faster than linearly as $T$ goes to zero, so that $C_N$ vanishes. Moreover, the contributions to the heat capacity from the internal degrees of freedom of the molecular gases or from the free electrons in conducting solids are negligible, at room temperature: these degrees of freedom, in spite of the equipartition principle, seem frozen.

The analysis of the blackbody radiation problem from the classical point of view, that is, using equipartition among the normal modes of the electromagnetic field in the "black" cavity at temperature $T$, gives the following dependence, Rayleigh–Jeans law (1900), of the spectral energy density $u(\nu, T)$, on frequency $\nu$ and temperature $T$ ($c$ is the speed of light in vacuum):

$$u(\nu, T) = \frac{8\pi\nu^2}{c^3} k_B T \qquad [2]$$

The experimental curves for any positive $T$ show a maximum for a frequency $\nu_{\max}(T)$ which increases linearly with $T$ according to Wien's displacement law (1893). The spectral energy density decreases fast enough to zero as $\nu \to \infty$ in such a way that the overall (integrated) energy is (finite and) proportional to $T^4$, according to Stefan's law (1879); the agreement with the classical form holds for low frequencies. The analytic form of the classical $u(\nu, T)$ in [2] does not present maxima and the overall radiated energy is clearly divergent (this bad behavior for large $\nu$, present in many formulas for other models, sometimes in the corresponding "short-distance" form, is called an "ultraviolet catastrophe").

The effort by M Planck (1900) to understand the right dependence of $u$ from $\nu$ and $T$ was based on a thermodynamic argument about the possible energy–entropy relation, and on an assumption similar to the discretization rules on which the "old quantum theory" for the atomic structure is based. The electromagnetic field is represented, via Fourier analysis, as a set of infinitely many independent harmonic oscillators, two for every wave vector $\boldsymbol{k}$, to take into account the polarization. The frequency depends linearly on the wave number $k = |\boldsymbol{k}|$ (linear dispersion law), and the spacing becomes negligible for macroscopic dimensions of the cavity. The key idea for computing the partition function is the discretization of the phase space of each oscillator (of frequency $\nu = \omega/2\pi$). Putting there the adimensionalized Lebesgue measure $\mathrm{d}p\,\mathrm{d}q/h$, where $h$ is a constant with physical dimensions of an action, we consider the regions $R_E$ bounded by the constant-energy ellipses and their areas $|R_E|$, and find

$$|R_E| = \int_{R_E} \frac{\mathrm{d}p\mathrm{d}q}{h} = \frac{2\pi E}{h\omega} = \frac{E}{h\nu}$$

If these adimensional areas have integer values, that is, $E = nh\nu, n = 0, 1, 2, \ldots$, the annular region ("cell" $C_n$) between $R_{E_n}$ and $R_{E_{n+1}}$ has unit area and so we approximate the partition function with the series ($\beta = 1/(k_\mathrm{B}T)$, the ubiquitous parameter in statistical mechanics, often called "inverse temperature")

$$Z_{\mathrm{discr}} = \sum_n \exp(-\beta nh\nu) = \frac{1}{1 - \exp(-\beta h\nu)}$$

In this way, the probabilistic weight given to this cell is

$$\begin{aligned} p(C_n) &= \frac{\exp(-\beta nh\nu)}{\sum_j \exp(-\beta jh\nu)} \\ &= \exp(-\beta nh\nu)(1 - \exp(-\beta h\nu)) \end{aligned} \qquad [3]$$

A well-defined value for the constant $h$ (i.e., $h = 6.626\ldots \times 10^{-27}$ erg s, the Planck constant), combined with the usual computation for the density of states, gives a formula which quantitatively agrees with experimental data (see Figure 1)

$$u(\nu, T) = \frac{8\pi\nu^2}{c^3}\frac{h\nu}{\exp(h\nu/k_\mathrm{B}T) - 1} \qquad [4]$$

Moreover, for a certain range of parameters, that is, such that $\beta h\nu \ll 1$, there is agreement with the classical law.

The "quantum of light," introduced by Einstein in 1905 in his work on photoelectric effect, was later (1926) called photon by G N Lewis. The picture for representing the radiating system was one of a gas of noninteracting photons, carrying energy and momentum, and being continuously created and absorbed.

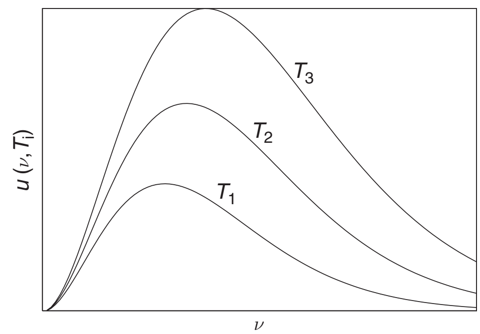

**Figure 1** Dependence of the electromagnetic energy density on $\nu$, for $T_1 < T_2 < T_3$.

A slightly different approach was used about the same time, for the problem of specific heat of crystalline solids.

The simpler model considers $N$ points on the nodes of the lattice $\mathbb{Z}^3$, in a cubic box of side $L$, and interacting through harmonic forces; similarly to the radiation problem, the system is represented by a collection of independent harmonic oscillators (normal modes), which are "quantized" as before: the corresponding quanta were called phonons (by Fraenkel, in 1932) for the role of the acoustic band of frequencies. In this simplified approach (by Debye, in 1913) the different phonons are determined by a finite set of wave vectors

$$\boldsymbol{k} = \frac{2\pi}{L}\boldsymbol{n}, \quad n_i \text{ integer}, \ i = 1, 2, 3; \ |\boldsymbol{k}| \le k_\mathrm{M}$$

where the maximal modulus $k_\mathrm{M}$ is such that the total number of different $\boldsymbol{k}$'s is $3N$ (degrees of freedom).

Moreover, the frequency–wave number relation is simplified too, extrapolating the low-frequency (acoustic) linear relation $\nu = |\boldsymbol{k}|v_0$ ($v_0$ is the sound speed). In this way, the density of states which is quadratic in the frequency, has a cutoff to zero at the maximal frequency, $\nu_\mathrm{D}$, corresponding to $|k_\mathrm{M}|$, with an associate temperature $\Theta_\mathrm{D} = h\nu_\mathrm{D}/k_\mathrm{B}$ (Debye's temperature). The expected energy $U_N$ in the canonical ensemble, after the computation of the canonical partition function, is given in term of the Debye function $D(\cdot)$:

$$\begin{aligned} U_N &= 3Nk_\mathrm{B}TD\left(\frac{\Theta}{T}\right) \\ D(y) &:= \frac{3}{y^3}\int_0^y \frac{x^3\mathrm{d}x}{\exp x - 1} \end{aligned} \qquad [5]$$

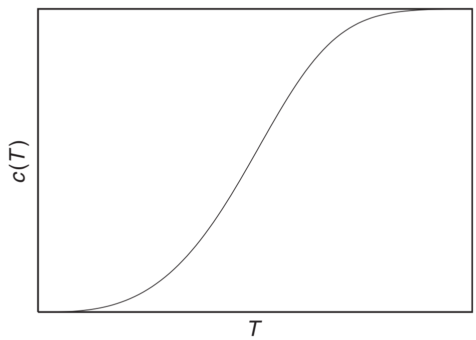

**Figure 2** The specific heat of crystal solids according to Debye.

The agreement with experimental data, for the specific heat of different materials (i.e., different $\Theta_D$), at low and high temperatures, is rather good. At low temperatures, one recovers the empirical $T^3$ behavior (see Figure 2). More careful measurements at low $T$ put into evidence, for metallic solids, the role of the conduction electrons: their contribution to the heat capacity turns out to be linear in $T$, with a coefficient such that at room temperature it is much smaller than the lattice contribution, so that a satisfactory agreement with the classical law is found.

Soon after the beginning of quantum mechanics in its modern form (1925–26), physicists considered many-particle systems, dealing initially with the simplest situations, with a relatively easy formal apparatus, yet sufficient enough to understand in the main lines the "anomalous," that is, nonclassical, behavior.

For a system of $N$ free particles in a cubic box of side $L$, quantum theory brings the labeling of the one-particle states with the wave vectors $\boldsymbol{k}$, recalling the de Broglie relation for the momentum $\boldsymbol{p} = \hbar \boldsymbol{k}$, with a possible additional spin (intrinsic angular moment) label $\sigma$

$$\boldsymbol{k} = \frac{2\pi}{L}\boldsymbol{n}, \quad \boldsymbol{n} \in \mathbb{Z}^3 \backslash \{0\}$$

and the statistics of the particles: because of indistinguishability, the wave function of several identical particles has to be symmetric (B–E, Bose–Einstein statistics) or antisymmetric (F–D, Fermi–Dirac statistics) in the exchange of the particles. This has the deep implication that no more than one fermion shares the same quantum state.

We may here recall the spin–statistics connection, which, in the framework of a local relativistic theory, states that integer spin particles are bosons, while particles with half-odd-integer spin are fermions.

As the state is completely defined by the knowledge of occupation numbers $n_{\boldsymbol{k},\sigma}$, we have the simple and relevant statement on the ground states for the $N$ spinless bosons and $N$ spin-1/2 fermion systems are described by the statement:

$$\begin{aligned} &\text{B–E system}: \quad && n_{\boldsymbol{k}} = N\delta_{\boldsymbol{k},\boldsymbol{k}_0} \\ &\text{F–D system}: \quad && n_{\boldsymbol{k},\sigma} = \mathbf{1}(|\boldsymbol{k}| \le k_F)\forall\sigma \end{aligned} \qquad [6]$$

The constant $k_F$ (Fermi wave number), or the equivalent $p_F = \hbar k_F$ and $\varepsilon_F = {p_F}^2/2m$ (Fermi momentum and energy, respectively) denotes the higher occupied level. In the continuum approximation, this implies the following relation between Fermi energy $\varepsilon_F$ and density $\rho = N/L^3$:

$$\varepsilon_F = \frac{\hbar^2}{2m}(3\pi^2\rho)^{2/3} \qquad [7]$$

Going to the positive-temperature case, the grand canonical partition function is computed by considering that occupation numbers are non-negative integers for the B–E case and just 0 or 1 for the F–D case. This implies the simple formulas, with obvious meaning of symbols and leaving more details to the vast literature (see Figure 3):

$$\langle n_{\boldsymbol{k},\sigma}\rangle_{\beta,\mu} = \frac{1}{\exp(\beta(\varepsilon_{\boldsymbol{k}} - \mu)) \pm 1}, \quad + \text{for F–D}, \ - \text{for B–E} \qquad [8]$$

It is useful to introduce the Fermi temperature $T_F = \varepsilon_F / k_B$; using some realistic data, that is, for common metals like copper, $T_F$ ranges roughly between $10^4$–$10^5$ K, that is, well above the "normal," room temperatures: the quantum nature (i.e., quantum degeneracy) of the conduction electrons, modeled as free electrons, is macroscopically visible in normal conditions.

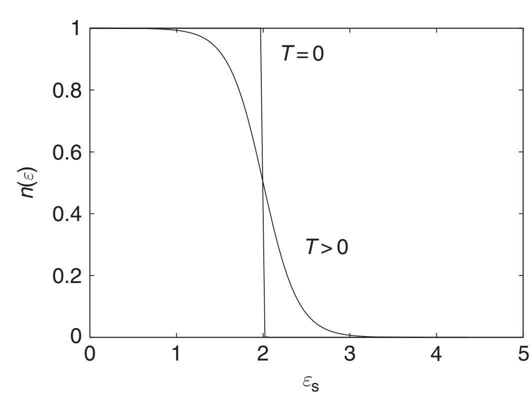

**Figure 3** Expected fermionic occupation number, for $T = 0$, $T > 0$, and $\mu = 2$.

The presence of an external field, like the periodic one given by the ionic lattice of a crystal, changes the situation in a relevant way, as the one-particle spectrum generally gets a band structure, and the allowed momenta are described in the reciprocal lattice: the Fermi sphere becomes a surface, and its structure is central for further developments.

For massive bosons, the strange superfluid features of liquid $^4$He at low temperature, that is, below the critical value 2.17 $K$, led F London, just after Kapitza's discovery in 1937, to speculate that these were related to a macroscopic occupation of the ground state (B–E condensation). A more realistic model has to take into account interaction between bosons (see last section) as the microscopic interactions in superfluid liquid $^4$He are not negligible.

## Quantum *N*-Body Properties: Second Quantization

The main step in analyzing a quantum $N$-body system is its energy spectrum, and in particular its ground state, as it may represent a good approximation of the low-temperature states: its structure, the relations with possible symmetries of the Hamiltonian, its degeneracy, the dependence of its energy on the number of particles, are further relevant questions. The last one is related to the possibility of defining a thermodynamics for the system (Ruelle 1969). As a physically very interesting example, consider a system of electrically charged particles, $N$ electrons with negative unit charge, and $K$ atoms with positive charge $z$, say, interacting through electrostatic forces; the classical Coulomb potential as a function of distance behaves badly, as it diverges at zero and decreases slowly at infinity. The first question is about the stability: thanks to the exclusion principle, for the ground-state energy $E^0_{N,K}$ an extensive estimate from below is valid:

$$E^0_{N,K} \geq -c_0(N + Kz)$$

so that a finite-volume grand partition function exists, while for the thermodynamic limit, which involves large distances, we need more, that is, charge neutrality, which allows for screening, and a fast-decreasing effective interaction.

Let us see an example (quantum spin, Heisenberg model) belonging to the class of lattice models, where the identical microscopic elements are distinguishable by their fixed positions, that is, the nodes of a lattice like $\mathbb{Z}^d$. To any site $x \in \mathbb{Z}^d$ is associated a copy $\mathcal{H}_x$ of a $(2s+1)$-dimensional Hilbert space $\mathcal{H}$, where an irreducible unitary representation of SU(2) is given, so that the nonzero values for $s$ are $1/2, 1, 3/2, \ldots$. For any $x$, the generators $S_\alpha(x), (\alpha = 1, 2, 3)$ satisfy the well-known commutation relations of the angular momentum; moreover, $\sum_\alpha {S_\alpha}^2(x) = s(s+1)\mathbf{1}$, and operators related to different sites commute. The ferromagnetic, isotropic, next-neighbors, magnetic field Hamiltonian for the finite system is

$$H_\Lambda = -J \sum_{<x,y>} \boldsymbol{S}(x) \cdot \boldsymbol{S}(y) - h \sum_x S_3(x) \qquad [9]$$

where $J$ is the positive strength of the next-neighbors coupling ($<x, y>$ means that $x$ and $y$ are next neighbors); $h$ is the intensity of the magnetic field oriented along the third axis. This model is considerably studied even now with several variants regarding possible anisotropies of the interaction, the possibly infinite range of the interaction, and the sign of $J$, for other (e.g., antiferromagnetic) couplings. Among the relevant results, the Mermin–Wagner theorem, at variance with the analogous classical spin model, states the absence of spontaneous magnetization in this zero-field model for $d = 2$ for any positive temperature; this can also be formulated as absence of symmetry breaking for this model (Fröhlich and Pfister in 1981 shed more light on this point).

As mentioned earlier, a useful mathematical tool for dealing with quantum systems of many particles or quasiparticles, is the occupation-number representation for the state of the system. The vector space for a system with an indefinite number of particles is the Fock space: it is the direct sum of all spaces with any number of particles, starting with the zero-particle, vacuum state. The operators which connect these subspaces are the creation and annihilation operators, very similar to the raising and lowering operators introduced by Dirac for the spectral analysis of the harmonic-oscillator Hamiltonian and the angular momentum, in the context of one-particle quantum theory.

It is perhaps worth sketching the action of these operators on the Fock space.

We consider spinless bosons first, as spin might easily be taken into account, if necessary. We suppose that a one-particle Hamiltonian has eigenfunctions labeled by a set of quantum numbers $\boldsymbol{k}$, say, as the wave vector for the purely kinetic one-particle Hamiltonian. Let $|n_{k_1}, n_{k_2}, \ldots, n_{k_p} >$ denote a vector state with $\sum_{i=1,\ldots,p} n_{k_i}$ particles, where $n_{k_i}$ denotes the number of particles with wave vector $\boldsymbol{k}_i, i = 1, \ldots, p; |0>$ denotes the no-particle, vacuum state. We define the creation operators $a^*_{\boldsymbol{k}}$ as follows:

$$a^*_{\boldsymbol{k}} | \ldots n_{\boldsymbol{k}}, \ldots \rangle = \sqrt{n_{\boldsymbol{k}} + 1} | \ldots, n_{\boldsymbol{k}} + 1, \ldots \rangle \qquad [10]$$

Its adjoint $a_k$ is called the annihilation operator, for its action on the vectors

$$a_k|\ldots n_k,\ldots\rangle = \sqrt{n_k}|\ldots,n_k-1,\ldots\rangle \quad [11]$$

The operator $a_k^*$ creates a new particle with that momentum: for any $\boldsymbol{k}$

$$a_k^* a_k|\ldots n_k,\ldots\rangle = n_k|\ldots n_k,\ldots\rangle$$

$$a_k^* a_k := \hat{n}_k \text{ (the occupation-number operator)}$$

The vacuum state belongs to $\mathrm{Ker}\, a_k$ for any $\boldsymbol{k}$, and the whole space is generated by application of creation operators on the vacuum state.

The following basic commutation relations, for any $\boldsymbol{k}, \boldsymbol{k}'$, are valid:

$$[a_k, a_{k'}^*] = \delta(\boldsymbol{k}, \boldsymbol{k}'), \quad [a_k, a_{k'}] = [a_k^*, a_{k'}^*] = 0 \quad [12]$$

For fermions, multiple occupancy is forbidden, so that the analogous annihilation ($\alpha_k$) and creation ($\alpha_k^*$) operators satisfy anticommutation relations:

$$[\alpha_k, \alpha_{k'}^*]_+ = \delta(\boldsymbol{k}, \boldsymbol{k}'), \quad [\alpha_k, \alpha_{k'}]_+ = [\alpha_k^*, \alpha_{k'}^*]_+ = 0 \quad [13]$$

The presence of spin is dealt by an additional spin label $\sigma$ to these symbols, and a $\delta(\sigma, \sigma')$, where necessary.

The Hamiltonian for a system of particles, say spinless bosons, in a box $\Lambda$, made of its kinetic part together with a two-body ($\lambda v(x-y)$) interaction, is written in terms of the "field operators"; if $\{\phi_k(x)\}$ are the one-particle eigenfunctions of the single-particle purely kinetic Hamiltonian for the spinless case, and their complex conjugates are $\{\phi_k^*(x)\}$, we define the fields

$$\Phi(x) = \sum_k \phi_k(x) a_k, \quad \Phi^*(x) = \sum_k \phi_k^*(x) a_k^* \quad [14]$$

So that the full Hamiltonian is given by

$$H_\Lambda = \int_\Lambda \mathrm{d}x\, \Phi^*(x) \left(\frac{-\hbar^2}{2m}\right) \Delta\Phi(x) + \lambda \int_\Lambda \mathrm{d}x \int_\Lambda \mathrm{d}y\, v(x-y) \Phi^*(x)\Phi(x)\Phi^*(y)\Phi(y) \quad [15]$$

We mention that a theoretical breakthrough in the analysis of superfluidity was made by Bogoliubov (1946), who, starting from the Hamiltonian in [15], introduced the following Hamiltonian in the momentum representation:

$$H_\Lambda = \sum_k \varepsilon_k a_k^* a_k + \frac{1}{2} \sum_{k,k',q} \hat{v}_q a_{k-q}^* a_{k'+q}^* a_k a_{k'} \quad [16]$$

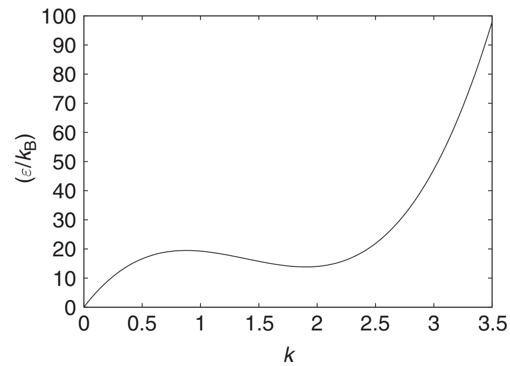

**Figure 4** Excitation spectrum for superfluids.

where $\varepsilon_k$ is the one-particle kinetic energy and $\hat{v}_q$ is the Fourier transform of the two-body potential. To study the excitation spectrum above the ground state, he introduced an approximation about the persistency of a macroscopic occupation of the ground state and a diagonalization procedure leading to new quasiparticles with a characteristic energy spectrum, linearly increasing near $|\boldsymbol{k}| = 0$, then presenting a positive minimum before the subsequent increase (see Figure 4).

## Some Mathematical Tools for Macroscopic Quantum Systems

The formal apparatus of second quantization, born in the context of the quantum field theory, brought to statistical mechanics new ideas and techniques and related difficulties. For instance, the renormalization group was conceived in the 1970s to deal both with critical phenomena (i.e., power singularities of thermodynamic quantities around the critical point) and with divergences in quantum field theory. This subject is currently being developed and applied in models of quantum statistical mechanics (QSM) (Benfatto and Gallavotti, 1995).

Another issue, which has again strong relations with quantum field theory, is the algebraic formulation of QSM. This point of view, which is well suited for the analysis of infinitely extended quantum systems, uses a unified, synthetic, and rigorous language. The procedure for passing from a finite quantum system to its infinitely extended version deserves some attention.

It is well known that, for finite quantum systems, say $N$ particles in a box $\Lambda$, an observable is represented by a self-adjoint operator $A$ on a Hilbert space $\mathcal{H}_\Lambda$, and the normalized elements $\{|\psi\rangle\}$ of this space are the pure states $\rho_\psi$ which define the expectations

$$\rho_\psi(A) := \langle\psi|A\psi\rangle$$

The mixed states (mixtures) are defined by convex combinations of pure states, the coefficients having an obvious statistical meaning.

Among the observables, the Hamiltonian plays a special role, as it generates the dynamics of the system, which evolves the pure states through the unitary group (Schrödinger picture)

$$\left|\psi(t) \geq \exp\left(-\frac{\mathrm{i}tH_\Lambda}{\hbar}\right)\right|\psi>$$

To the notion of equilibrium probability measure on the phase space of a classical system, corresponds the mixed state $\rho_{H_\Lambda,\beta}$ such that

$$\rho_{H_\Lambda,\beta}(A) := Z_{\Lambda,\beta}{}^{-1}\,\mathrm{tr}(\exp(-\beta H_\Lambda)A) \qquad [17]$$

The normalization factor $Z_{\Lambda,\beta} = \mathrm{tr}(\exp(-H_{\Lambda\beta}))$ is the canonical partition function.

Consider now the algebra $\mathcal{A}(\Lambda)$ of local observables; sending $\Lambda$ to infinity, by induction, it is possible to define the algebra $\mathcal{A}$ of quasilocal observables. The main point is a set of algebraic relations like the canonical commutation relations (CCRs) and the canonical anticommutation relations (CARs) for the creation/annihilation operators: the observables of $\mathcal{A}$, through the GNS (Gel'fand, Naimark, and Segal) construction may be represented as operators on the appropriate Hilbert spaces, depending on the chosen state; the representations, at variance with the finite case, might be inequivalent. It is possible to define the equilibrium state for the infinite system and how to insert in a natural way the possible group invariance of the system ($\mathbb{R}^d$ or $\mathbb{Z}^d$, typically), ending with characterization of the pure phases of the system as the ergodic components in the decomposition of an equilibrium state. These states have the property that coarse-grained observables have sharp values (Ruelle 1969, Sewell 2002): if $\mathrm{Av}_l(A)$ is the space average on scale $l$, that is, over boxes of side $l$, for an ergodic state $\rho$,

$$\lim_{l\to\infty} \rho([\mathrm{Av}_l(A) - \rho(A)]^2) = 0$$

Another issue which is worth mentioning is the characterization of equilibrium states through the KMS (Kubo–Martin–Schwinger) condition. The strong formal similarity between the finite-volume quantum evolution operator $\alpha_t := \exp(-\mathrm{i}tH_\Lambda/\hbar)$ and the statistical equilibrium density operator $\exp(-\beta H_\Lambda)$, leads to the identity, valid for any couple of bounded observables $A$ and $B$, using the short symbol $< \cdot >_{\beta,\Lambda}$ for the expectations with respect to the statistical operator:

$$<A_t B>_{\beta,\Lambda} = <BA_{t+\mathrm{i}\hbar\beta}>_{\beta,\Lambda} \qquad [18]$$

This relation is suitably extended for infinite size, and therefore defines a KMS state; it implies some physically relevant properties like stability with respect to local disturbances and dissipativity (Sewell 2002).

A final issue in this section concerns another formalism stemming from the Feynman path-integral formulation of quantum mechanics: here a functional integral represents the statistical equilibrium density operator $W_\beta = \exp(-\beta H)$. For a $d$-dimensional system of $N$ particles in a potential field ($X \in \mathbb{R}^{dN}$) $V = V(X) = \sum_{i<j}\phi(x_i - x_j)$ and Hamiltonian $H = -(1/2)\,\Delta + V$ the Feynman–Kac formula which, for a test function $\chi$, may be written as follows:

$$(W_\beta\chi)(X) = \int P^\beta_{X,Y}(\mathrm{d}\omega)\exp\left(-\int_0^\beta \mathrm{d}s V(\omega(s))\chi(Y)\mathrm{d}Y\right)$$

where $P^\beta_{X,Y}(\mathrm{d}\omega)$ is the Wiener measure on the space of paths $\{\omega(s), s \in [0,\beta]\}$. For details on the construction and several other related features on the treatment of the different statistics, see Glimm and Jaffe (1981).

## New Problems and Challenges

In this final section, we recall some phenomena which have been observed recently in physics laboratories, and which presumably deserve considerable efforts to overcome the heuristic level of explanation. About this last point, it is worth quoting a method that has been used to get results even without clear justifications of the underlying hypotheses, that is, the mean-field procedure. It started with the Curie–Weiss theory of magnetism and is based on the following drastic simplification: the microscopic element of the system feels an average interaction field due to other elements, indipendently of the positions of the latter. This method might provide relatively good results if the range of the interaction is very large, and in fact, a clear version with due limiting procedure was introduced by Kac, and applied by Lebowitz and Penrose in the 1960s for a microscopic derivation of van der Waals equation, and soon extended by Lieb to quantum systems.

We will briefly outline some aspects of three recent achievements of condensed matter physics for which modeling is still on the way of further progress: the B–E condensation, the high-$T_c$ superconductivity, and the fractional quantum Hall effect. The first consists in trapping an ultracold (at less than 50 μK) dilute bosonic gas, for example, $10^4$–$10^7$ atoms of $^{87}$Rb, finding experimental evidence for Bose condensation. To understand the

properties of this system, an important tool is the Gross–Pitaevskii energy functional for the condensate wave function $\Phi$,

$$E[\Phi] = \int \mathrm{d}x \left[ \frac{\hbar^2}{2m} |\nabla\Phi|^2 + V_{\mathrm{ext}}(x)|\Phi|^2 + \frac{g}{2}|\Phi|^4 \right]$$

where the quartic term represents the reduced (mean-field) interaction among particles.

The second issue, that is, the high-temperature superconductivity, certainly deserves much attention. It has been observed recently in some ceramic materials well above 100 K, and a clear model which takes into account the formation of pairs and the peculiar isotropy–anisotropy aspects of the normal conductivity and superconductivity is still lacking (Mattis 2003).

Finally, let us consider the fractional quantum Hall effect; recall that the integer version, that is, a discretization of the Hall resistivity $R_{\mathrm{H}}$ by multiples of $h/(e^2)$, finds an explanation in terms of band spectra, formation of magnetic Landau levels, and localization from surface impurities, that is, without taking into account direct interactions among electrons.

The fractional discretization of $R_{\mathrm{H}}$ (Störmer 1999) has a theoretical interpretation, in terms of subtle collective behavior of the two-dimensional semiconductor electron system: the quasiparticles which represent the excitations may behave as composite fermions or bosons, or exhibit a fractional statistics (*see* Fractional Quantum Hall Effect).

This brief excursion through these new fascinating phenomena shows the rich interplay between theory and experiments: these phenomena are a source of new ideas and suggest new models for further progress.

# Quasiperiodic Systems

**P Kramer**, Universität Tübingen, Tübingen, Germany

## Introduction: From Periodic to Quasiperiodic Systems

Periodic systems occur in many branches of physics. Their mathematical analysis was stimulated in particular by the analysis of the periodic translational symmetry of crystals. The systematic study of the compatibility between translational and crystallographic point or reflection symmetry leads to the concept of space group symmetry. Mathematical crystallography in three dimensions (3D) culminated in 1892 in the complete classification of the 230 space groups due to Fedorov and Schoenflies (see Schwarzenberger (1980, pp. 132–135). One characteristic property of periodic systems is that their Fourier transform has a pure point spectrum. Since the Fourier spectrum is experimentally accessible through diffraction experiments, it provides a main tool for the structure determination of crystals.

With quantum mechanics in the twentieth century, it became possible to describe crystal structures quantitatively as ordered systems of atomic nuclei and electrons with electromagnetic interactions. The representation theory of crystallographic space groups now opened the way to verify the

space group symmetry of atomic systems for example from the band structure of crystals. It was then believed that in physics atomic long-range order is linked to periodicity and hence to the paradigm of the 230 space groups in 3D.

Mathematical analysis beyond this paradigm started independently in various directions. Bohr (1925) studied quasiperiodic functions and their Fourier transform. He interpreted them as restrictions of periodic functions in $n$D to their values on a linear subspace of orientation irrational with respect to a lattice. Mathematical crystallography in general dimension $n > 3$, including point group symmetry, was started around 1949 in work by Hermann and by Zassenhaus (see Schwarzenberger (1980)), and completed in 1978 for $n = 4$ in Brown *et al.* (1978). A different route was taken by Penrose (1974). He constructed an aperiodic tiling (covering without gaps or overlaps) of the plane. Its tiles in two rhombus shapes provide global 5-fold point symmetry and make the tiling incompatible with any periodic lattice in 2D. The connection between Penrose's aperiodic tiling and irrational subspaces in periodic structures was made by de Bruijn (1981). He interpreted the Penrose rhombus tiling as the intersection of geometric objects from cells of a hypercubic lattice in 5D with a 2D subspace, irrational and invariant under 5-fold noncrystallographic point symmetry. Kramer and Neri (1984) embedded the icosahedral group as a point group into the hypercubic lattice in 6D and constructed a 3D irrational subspace invariant under the noncrystallographic icosahedral point group. From intersections of boundaries of the hypercubic lattice cells with this subspace, they constructed a 3D tiling of global icosahedral point symmetry with two rhombohedral tiles.

Shechtman *et al.* (1984) discovered in the system *AlMn* diffraction patterns of icosahedral point symmetry. Since icosahedral symmetry is incompatible with a lattice in 3D, they concluded that there exists atomic long-range order without a lattice. The new paradigm of quasiperiodic long-range order in quasicrystals was established and since then stimulated a broad range of theoretical and experimental research.

The interplay between the notions – (1) of crystallographic symmetry in $n$D, $n > 3$, (2) of subspaces invariant under a point group but irrational and hence incompatible with a lattice, and (3) of discrete geometric periodic objects in $n$D providing quasiperiodic tilings on these subspaces – forms the mathematical basis for a new quasiperiodic long-range order found in quasicrystals. The present-day theory of quasicrystals offers the most elaborate study of quasiperiodic systems. Therefore, we shall focus in what follows on the concepts developed in this theory.

In the following section, we briefly review basic concepts of periodic systems and lattices in $n$D, their classification in terms of point symmetry and space groups, and their cell structure. In a section on quasiperiodic point sets and functions, a quasiperiodic system is taken as a geometric object on an irrational $m$D subspace in an $n$-dimensional space and lattice. Noncrystallographic point symmetry is shown to select the irrational subspace. Next, scaling symmetry in quasiperiodic systems is demonstrated. Then, examples of quasiperiodic systems with point and scaling symmetry are given. The penultimate section discusses quasiperiodic tilings and their windows. Finally, the notion of a fundamental domain for quasiperiodic functions compatible with a tiling is illustrated.

## Concepts from Periodic Systems

A distribution $f^p(x)$ of geometric objects on Euclidean space $E^n$ (a real linear space equipped with standard Euclidean scalar product $\langle\,,\rangle$ and metric) with coordinates $x \in E^n$ is called "periodic" if it is invariant under translations $b^i$ in $n$ linearly independent directions,

$$(p) : f^p : f^p(x + b^i) = f^p(x), \quad i = 1, \ldots, n \qquad [1]$$

The set of all translations on $E^n$ forms the discrete additive abelian translation group

$$T = \left\{ b \in E^n : b = \sum_i^n m_i b^i, (m_1, \ldots, m_n) \in \mathbf{Z}^n \right\} \qquad [2]$$

Any orbit (set of all images of an initial point) under the action $T \times E^n \to E^n$ yields a lattice $\Lambda$ on $E^n$. Since $T$ acts fixpoint-free, there is a one-to-one correspondence $\Lambda \leftrightarrow T$. A fundamental domain on $E^n$ is defined as a subset of points $x \in E^n$ which contains a representative point from any orbit under $T$. Such a fundamental domain can be chosen, for example, as the unit cell of the lattice $\Lambda$ or as the Voronoi cell (eqn [5]). By eqn [1], the functional values on $E^n$ of a periodic function $f^p(x)$ are completely determined from its values on a fundamental domain of $E^n$.

Given the lattice basis $(b^1, \ldots, b^n)$ of eqn [2] in $E^n$, the vector components of the basis form the $n \times n$ basis matrix $B$ of $\Lambda$. The most general change of the basis preserving the lattice is given by acting with any element $h$ of the general linear group

$\mathrm{Gl}(n, \boldsymbol{Z})$, with integral matrix entries and determinant $\pm 1$, on the lattice basis,

$$\mathrm{Gl}(n, \boldsymbol{Z}) \ni h : B \to B' = Bh \qquad [3]$$

The crystallographic classification of inequivalent lattices in $E^n$ starts from $\mathrm{Gl}(n, \boldsymbol{Z})$. In addition to translations, it employs crystallographic point symmetry operations, (Brown *et al.* 1978, p. 9). A crystallographic point group operation of a lattice $\Lambda$ is a Euclidean isometry $g$ which belongs to a group $G \ni g$ with representations $D : G \to O(n, R)$ and $\mathcal{D} : G \to \mathrm{Gl}(n, \boldsymbol{Z})$ such that

$$G = \{g : D(g)B = B\mathcal{D}(g)\} \qquad [4]$$

The maximal crystallographic point group for given lattice $\Lambda$ is the holohedry of $\Lambda$. The group generated by $T, G$ is a space group which classifies the lattice. For finer details in the classification of space groups, we refer to Brown *et al.* (1978). For crystallography in $E^3$, this classification yields 230 space groups. Crystallography in $E^n$ is described in Schwarzenberger (1980) and in Brown *et al.* (1978) where it is elaborated for $E^4$.

From a lattice $\Lambda \in E^n$ and from the Euclidean metric, one constructs a cell structure as follows: the Voronoi cell $V(b)$, centered at a lattice point $b \in \Lambda$, known in physics as the Wigner–Seitz cell, is the set of points

$$V(b) = \{x \in E^n : |x - b| \leq |x - b'|,\ b' \in \Lambda\} \qquad [5]$$

Any Voronoi cell has a hierarchy of boundaries $X_p$ of dimension $p, 0 \leq p \leq n$ which we denote as $p$-boundaries.

The set of Voronoi cells at all lattice points form the $\Lambda$-periodic Voronoi complex of $\Lambda \in E^n$. The Voronoi cells and complexes associated with a lattice admit a notion of geometric duality. We denote dual objects by a star, $^*$. They are built from convex hulls of sets of lattice points (Kramer and Schlottmann 1989) as follows. A Voronoi $p$-boundary $X_p$ is shared by several Voronoi cells $V(b)$ and determines a set of lattice points

$$S(X_p) : \{b \in \Lambda : X_p \in V(b)\} \qquad [6]$$

The boundary dual to $X_p$ is defined as the convex hull $X^*_{(n-p)} := \mathrm{conv}\{b : b \in S(X_p)\}$. $X^*_{(n-p)}$ can be shown to be an $(n-p)$-boundary of a dual Delone cell. A Delone cell $D$ is defined as the convex hull of all lattice points whose Voronoi cells share a single vertex, called a hole of the lattice. Since these vertices fall into classes of orbits under translations, they determine translationally inequivalent classes of Delone cells $D^\alpha, D^\beta, \ldots$.

Fourier analysis applied to a periodic function $f^p(x)$ on $E^n$ reduces to an $n$-fold Fourier series. The Fourier spectrum is a pure point spectrum and the Fourier coefficients can be referred to the points of a reciprocal lattice $\Lambda^\circ$ (eqn [7]) in Fourier space $E^{\circ n}$. We denote objects belonging to this Fourier space by the index $^\circ$. The basis matrix $B^\circ$ of the reciprocal lattice $\Lambda^\circ \in E^{\circ n}$ is obtained from $B$ as the inverse transpose,

$$\langle b^{\circ i}, b^j \rangle = \delta^{ij} \leftrightarrow B^\circ = (B^{-1})^{\mathrm{T}} \qquad [7]$$

The values of the Fourier coefficients of $f^p(x)$ reduce to integrals over the fundamental domain of the lattice $\Lambda$. From eqns [4] and [7] it follows that the orthogonal representation of a point group $G$ in coordinate and in Fourier space coincides. The Fourier spectrum and its point symmetry in crystals are observed in diffraction experiments.

## Quasiperiodic Point Sets and Functions

Quasiperiodic functions are characterized from their Fourier spectrum (Bohr 1925) by

(**qp**$^\circ$) The Fourier point spectrum of a quasiperiodic function forms a $\boldsymbol{Z}$-module $M^\circ$ of rank $n, n > m$ on Fourier space $E^{\circ m}$.

A $\boldsymbol{Z}$-module of rank $n, n > m$ on $E^{\circ m}$ is defined as a set

$$M^\circ = \left\{ b^\circ : b^\circ = \sum_j^n m_j b^{\circ i},\ (m_1, \ldots, m_n) \in \boldsymbol{Z}^n \right\} \qquad [8]$$

with the $\boldsymbol{Z}$-module basis $(b^{\circ 1}, \ldots, b^{\circ n})$ linearly independent with respect to integral linear combinations. The step from a lattice $\Lambda^\circ$ to a module $M^\circ$ is nontrivial since the set of all module points becomes dense on $E^{\circ m}$. The Fourier coefficients of a quasiperiodic function are assigned to the discrete set of module points (eqn [8]).

Bohr in his analysis of quasiperiodic functions (Bohr 1925, II, pp. 111–125) shows that a general $\boldsymbol{Z}$-module $M^\circ$ of rank $n$ can be taken as the projection to a subspace $E^{\circ m}$ of dimension $m$ of a (nonunique) lattice $\Lambda^\circ \in E^{\circ n}, n > m$. It is convenient to consider in Fourier space $E^{\circ n}$ an orthogonal splitting which we denote as

$$E^{\circ n} = E^{\circ m}_{\parallel} + E^{\circ (n-m)}_{\perp},\ E^{\circ m}_{\parallel} \perp E^{\circ (n-m)}_{\perp} \qquad [9]$$

A characterization of a quasiperiodic function $f^{qp}(x)$ on coordinate space is obtained as follows. From $\Lambda^\circ$ one can construct with the help of eqn [7] the lattice $\Lambda := (\Lambda^\circ)^\circ$ reciprocal to $\Lambda^\circ$ on a coordinate space $E^n$ and associate to it via the Fourier series a quasiperiodic function on a coordinate subspace $E^m_{\parallel}$ of $E^n = E^m_{\parallel} + E^{(n-m)}_{\perp}$, equipped with a $\boldsymbol{Z}$-module $M$ (eqn [11]). As a result one finds a

characterization of a quasiperiodic function in coordinate space:

(**qp**) A quasiperiodic function $f^{qp}(x_\parallel), x_\parallel \in E^m_\parallel$ can always be interpreted as the restriction to a subspace $E^m_\parallel$ of a $\Lambda$-periodic function $f^p(x)$ on $E^n$,

$$E^n = E^m_\parallel + E^{(n-m)}_\perp, x = x_\parallel + x_\perp \\ f^p(x_\parallel + c_\perp) =: f^{qp}(x_\parallel) \qquad [10]$$

In the interpretation (**qp**) (eqn [10]), the $\boldsymbol{Z}$-modules in Fourier space (eqn [8]) and in coordinate space $E^m_\parallel$ become projections of reciprocal lattices,

$$M^\circ = \pi_\parallel(\Lambda^\circ), M = \pi_\parallel(\Lambda) \qquad [11]$$

The linear independence of the module basis enforces a splitting (eqn [9]), irrational with respect to the lattice $\Lambda^\circ \in E^{\circ n}$.

As in the classification of crystal lattices, point symmetry plays a crucial role in the classification of $\boldsymbol{Z}$-modules for quasiperiodic systems like quasicrystals. Noncrystallographic point groups $G$ (with a representation incompatible with any lattice) give rise to quasiperiodic systems as follows:

(**qp**) Given a point group $G$ with orthogonal representations $D_\parallel : G \to O(m, R), D_\perp : G \to O(n-m, R)$ such that $D_\parallel$ is incompatible with any lattice in $E^m_\parallel$, we now require in $E^n$ instead of eqn [10] a lattice $\Lambda$ with basis $B$ and a representation $\mathcal{D} : G \to \mathrm{Gl}(n, \boldsymbol{Z})$ such that

$$\begin{bmatrix} D_\parallel(G) & 0 \\ 0 & D_\perp(G) \end{bmatrix} B = B\,\mathcal{D}(G) \qquad [12]$$

Equation [12] requires that the matrix $B$ provides an irrational reduction of the representation $\mathcal{D}(G)$ into the two representations $D_\parallel(G), D_\perp(G)$. Periodic functions restricted as in the second line of eqn [10] are quasiperiodic.

For any finite group $G$, a representation $\mathcal{D}(G)$ allowing for lattice embedding can always be constructed by the technique of induced representations. Its reduction into representations $D_\parallel(G)$, $D_\perp(G)$ contained in this induced representation is obtained by standard techniques. If $D_\parallel(G)$ is noncrystallographic and inequivalent to $D_\perp(G)$, the subspace decomposition (eqn [12]) is unique.

Quasiperiodic functions compatible with tilings and their windows can be constructed from the dual cell structure (eqns [5] and [6]) of the embedding lattice (Kramer and Schlottmann 1989). Examples are given in the sections "Point symmetry in quasiperiodic systems" and "Quasiperiodic tilings and their windows".

## Scaling and Quasiperiodicity

Quasiperiodic systems lack periodicity but can have scaling symmetries originating from a non-Euclidean extension of eqn [12].

### Example 1: Scaling in the Square Lattice $Z^2$

We begin with the Fibonacci scaling on the square lattice $\boldsymbol{Z}^2$ of $E^2$. The symmetric matrix

$$h = \begin{bmatrix} 1 & 1 \\ 1 & 0 \end{bmatrix} \in \mathrm{Gl}(2, \boldsymbol{Z}) \qquad [13]$$

has eigenvalues

$$\lambda_1 = -\tau^{-1} = -\tau + 1, \qquad \lambda_2 = \tau := (1 + \sqrt{5})/2 \qquad [14]$$

Evaluation of the orthogonal eigenvectors allows us to define a lattice basis $B = (b^1, b^2)$ and rewrite the eigenvalue equation similar to eqn [12] as

$$\begin{bmatrix} -\tau^{-1} & 0 \\ 0 & \tau \end{bmatrix} B = B \begin{bmatrix} 1 & 1 \\ 1 & 0 \end{bmatrix} \\ B = \begin{bmatrix} -\sqrt{\frac{-\tau+3}{5}} & \sqrt{\frac{\tau+2}{5}} \\ \sqrt{\frac{\tau+2}{5}} & \sqrt{\frac{-\tau+3}{5}} \end{bmatrix} \qquad [15]$$

This relation shows that $h$ with respect to the basis $B$ acts as a non-Euclidean point symmetry of the square lattice and generates an infinite discrete group. Equation [15] provides an orthogonal splitting $E^2 = E_\parallel + E_\perp$. The element $h$ acts on the two subspaces as a discrete linear scaling by $-\tau^{-1}, \tau$, respectively. It maps points of $\boldsymbol{Z}^2$ in $E^2$, hence also their projections to $E_\parallel$, into one another.

**Figure 1** shows the lattice basis from eqn [15]. We choose as fundamental domain of $\boldsymbol{Z}^2$ two squares $A, B$ whose boundaries are parallel or perpendicular to $E_\parallel$. A horizontal line $E_\parallel$ intersects these two squares at vertical distances varying with respect to their horizontal boundaries. The quasiperiodic restriction $f^{qp}(x_\parallel) = f^p(x_\parallel + c_\perp)$ of a $\boldsymbol{Z}^2$-periodic function $f^p(x)$ to a line $x = x_\parallel + c_\perp$ picks up varying functional values on these sections. Clearly, one needs all the values of $f^p$ on its fundamental domain in $E^2$ to obtain all the values taken by $f^{qp}$.

Scaling symmetry appears in conjunction with noncrystallographic point symmetry (cf. the following section). Combined with quasiperiodic tilings, it gives rise to a hierarchy of self-similar tilings whose tiles scale with $\tau$.

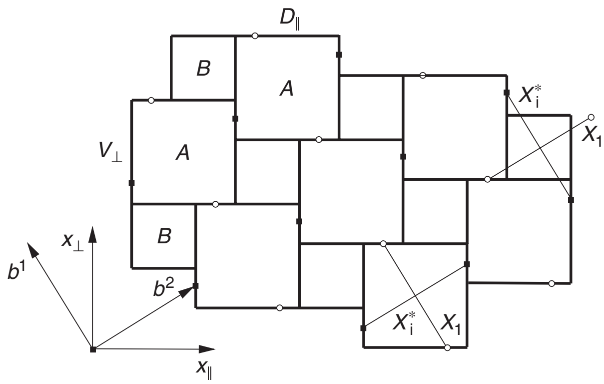

**Figure 1** The square lattice with Fibonacci scaling. Lattice points are black squares, holes white circles. The vectors $(b^1, b^2)$ indicate the lattice basis. The directions $x_\|, x_\perp$ of scalings by $-\tau^{-1}, \tau$ run horizontally and vertically, respectively. Perpendicular and parallel projections $V_\perp$ of Voronoi and $D_\|$ of Delone cells are attached to the lattice and hole points, respectively. Two different pairs of dual 1-boundaries $X_1, X_1^*$ of Voronoi and Delone squares are marked on the right. The product polytopes $X^*_{1,\|} \times X_{1,\perp}$ of their projections form two squares $A, B$ and yield a periodic tiling of $E^2$. A single pair $A, B$ forms a fundamental domain of the lattice. The characteristic functions on $A, B$ are windows for the tiles. A general quasiperiodic function $f^{qp}(x_\|)$ is the restriction of a periodic function $f^p(x)$, defined on $A, B$, to its values on a horizontal line $x = x_\| + c_\perp$. If the periodic function $f^p(x)$ on $A, B$ takes only values independent of $x_\perp$, its quasiperiodic restriction $f^{qp}(x_\|) := f^p(x_\| + c_\perp)$ to this line repeats its values on the long and short tiles $A_\|, B_\|$, respectively, of the standard Fibonacci tiling. Then $A_\|, B_\|$ form a fundamental domain for quasiperiodic functions compatible with the tiling.

## Point Symmetry in Quasiperiodic Systems

Quasiperiodic systems with noncrystallographic point symmetry provide the structure theory and physics of quasicrystals. We illustrate the general scheme (**qp**) of eqn [12] by examples of 5-fold and icosahedral point symmetry. For generalizations, see Janssen (1986).

### Example 2: 5-Fold Point Symmetry from the Root Lattice $A_4$

The $A_4$ root lattice basis in $E^4$ may be derived (Baake *et al.* 1990) from five orthonormal unit vectors $(e^1, e^2, e^3, e^4, e^5)$ in $E^5$ as

$$B = (b^1, b^2, b^3, b^4) := (e^1 - e^2, e^2 - e^3, e^3 - e^4, e^4 - e^5) \qquad [16]$$

As the generator of the cyclic group $C_5$ of 5-fold rotations, we take the cyclic permutation (12345) in cycle notation acting on the vectors $(e^1, e^2, e^3, e^4, e^5)$.

A possible choice of the basis for eqn [12] is the irrational matrix

$$B = (b^1, b^2, b^3, b^4) = \begin{bmatrix} 1 & c & c' & c' & c \\ 0 & s & s' & -s' & -s \\ 1 & c' & c & c & c' \\ 0 & s' & -s & s & -s' \end{bmatrix} \begin{bmatrix} 1 & 0 & 0 & 0 \\ -1 & 1 & 0 & 0 \\ 0 & -1 & 1 & 0 \\ 0 & 0 & -1 & 1 \\ 0 & 0 & 0 & -1 \end{bmatrix}$$

$$c = \cos\left(\frac{2\pi}{5}\right) = \frac{\tau - 1}{2}, \quad s = \sin\left(\frac{2\pi}{5}\right) = \frac{\sqrt{\tau + 2}}{2}$$
$$c' = \cos\left(\frac{4\pi}{5}\right) = -\frac{\tau}{2}, \quad s' = \sin\left(\frac{4\pi}{5}\right) = -\frac{\sqrt{3 - \tau}}{2} \qquad [17]$$

Equation [12] for the representation of the generator (12345) of the cyclic group $C_5$ becomes

$$\begin{bmatrix} c & -s & 0 & 0 \\ s & c & 0 & 0 \\ 0 & 0 & c' & -s' \\ 0 & 0 & s' & c' \end{bmatrix} (b^1, b^2, b^3, b^4) = (b^1, b^2, b^3, b^4) \begin{bmatrix} 0 & 0 & 0 & -1 \\ 1 & 0 & 0 & -1 \\ 0 & 1 & 0 & -1 \\ 0 & 0 & 1 & -1 \end{bmatrix} \qquad [18]$$

The left of eqn [18] generates two 2D inequivalent representations of 5-fold planar rotations which are incompatible with any 2D lattice.

The lattice $A_4$ in addition has a scaling symmetry with a factor $\tau$. The scaling transformation may be expressed in terms of the basis (eqn [16]) and an element $h \in Gl(4, \mathbf{Z})$ as

$$\begin{bmatrix} -\tau & 0 & 0 & 0 \\ 0 & -\tau & 0 & 0 \\ 0 & 0 & \tau^{-1} & 0 \\ 0 & 0 & 0 & \tau^{-1} \end{bmatrix} (b^1, b^2, b^3, b^4) = (b^1, b^2, b^3, b^4) \begin{bmatrix} 0 & -1 & 0 & 1 \\ 0 & -1 & -1 & 1 \\ 1 & -1 & -1 & 0 \\ 1 & 0 & -1 & 0 \end{bmatrix} \qquad [19]$$

It is easily verified that the operations of scaling and of 5-fold rotation (eqns [19] and [18]) commute with one another.

**Example 3: Icosahedral Point Symmetry from Lattices $\Lambda = \boldsymbol{Z}^6, D_6$**

The icosahedral group $G = H_3$ has two inequivalent 3D noncrystallographic representations. $H_3$ allows for an induced embedding representation $\mathcal{D}: H_3 \to \mathrm{Gl}(6, \boldsymbol{Z})$, (Kramer and Neri 1984, Kramer *et al.* 1992, Kramer and Papadopolos 1997) into a hypercubic lattice $\Lambda = \boldsymbol{Z}^6$. This representation reduces into two 3D orthogonal inequivalent irreducible noncrystallographic representations $D_\parallel : H_3 \to O(3, R), D_\perp : H_3 \to O(3, R)$. The irrational basis matrix of eqn [12] for $\Lambda = \boldsymbol{Z}^6$ becomes (Kramer *et al.* 1992, p. 185, eqn (7))

$$B = (b^1, b^2, b^3, b^4, b^5, b^6)$$

$$= \sqrt{\frac{1}{2(\tau+2)}} \begin{bmatrix} 0 & 1 & \bar{1} & \bar{\tau} & 0 & \tau \\ 1 & \tau & \tau & 0 & \bar{1} & 0 \\ \tau & 0 & 0 & 1 & \tau & 1 \\ 0 & \tau & \bar{\tau} & 1 & 0 & \bar{1} \\ \tau & \bar{1} & \bar{1} & 0 & \bar{\tau} & 0 \\ \bar{1} & 0 & 0 & \tau & \bar{1} & \tau \end{bmatrix} \qquad [20]$$

with $\bar{\tau} = -\tau, \bar{1} = -1$. The six basis vectors with components in the upper three rows span the so-called primitive icosahedral $\boldsymbol{Z}$-module associated with $D_\parallel$ in $E^3_\parallel$ in the sense of eqn [11]. In this space they point along the directions of six 5-fold axes of the icosahedron.

A second lattice in $E^6$ which admits icosahedral point symmetry is the root lattice $D_6$. The basis of this root lattice, often denoted as the $P$-lattice, is obtained from eqn [20] by a centering matrix given in Kramer *et al.* (1992, p. 185, eqn (8)). The corresponding $\boldsymbol{Z}$-module is inequivalent to the module projected from eqn [20]. The third lattice of icosahedral point symmetry in $E^6$ is $\Lambda = I := P^\circ$ reciprocal to the root lattice $D_6$. All three icosahedral modules admit (powers of) $\tau$-scaling.

## Quasiperiodic Tilings and Their Windows

Quasiperiodic sets of points arise from the general scheme (**qp**) (eqn [12]) by choosing particular periodic functions in the embedding space $E^n$, called the "windows," whose intersections with $E_\parallel$ are the quasiperiodic sets of points.

The window for the construction of a discrete quasiperiodic point set based on eqn [12] is given by the characteristic function $\chi(x_\perp)$ on the projection $V_\perp(x_\perp) := \pi_\perp(V(b))$ of the Voronoi cell (eqn [5]), attached to any lattice point $b \in \Lambda$.

**Example 4: The Quasiperiodic Fibonacci Point Set**

If in the Fibonacci system (Figure 1), one attaches to any point $b$ of the square lattice as a window the characteristic function $\chi$ of the perpendicular projection $V_\perp(b)$ of the unit square attached to $b$, the function $f^{qp}(x_\parallel)$ becomes the standard quasiperiodic Fibonacci sequence of points.

The dual cell geometry of Voronoi and Delone cells and their dual boundaries (eqns [5] and [6]) allows us to construct dual canonical quasiperiodic tilings $(\mathcal{T}, \Lambda), (\mathcal{T}^*, \Lambda)$ (Kramer and Schlottmann 1989). To this end one constructs from local projections of pairs of dual boundaries $X_{m,\parallel}, X^*_{(n-m),\perp}$ or $X^*_{m,\parallel}, X_{(n-m),\perp}$ the direct product polytopes $X_{m,\parallel} \times X^*_{(n-m),\perp}$ or $X^*_\parallel \times X_\perp$ called "klotz polytopes." The characteristic functions on these polytopes form the windows for the tiles $X_{m,\parallel}, X^*_{(n-m),\parallel}$, respectively.

**Example 5: The Quasiperiodic Fibonacci Tiling**

The Voronoi cells $V$ of the square lattice are squares centered at lattice points, the Delone cells $D$ are squares centered at the vertices of Voronoi squares. The product polytopes $X^*_{1,\perp} \times X_{1,\parallel}$ from projections of dual 1-boundaries $X^*_1, X_1$ of Delone and Voronoi squares (cf. Figure 1) become the two types of square windows $A, B$. If a parallel line section $x = x_\parallel + c_\perp$ crosses one of these squares, the tile $A_\parallel$ or $B_\parallel$ is formed. The standard Fibonacci tiling results.

**Example 6: Canonical Tilings from the Root Lattices $A_4, D_6$**

The two rhombus tiles of the planar quasiperiodic Penrose pattern (Penrose 1974) $(\mathcal{T}, A_4)$ are the projections of 2-boundaries of the Voronoi complex of the root lattice $A_4 \in E^4$ (Baake *et al.* 1990). The triangle tiles of the dual tiling $(\mathcal{T}^*, A_4)$ are shown in **Figure 2**.

They are projections of 2-boundaries from the Delone complex of the same lattice. A full analysis of dual Voronoi and Delone boundaries of the root lattice $D_6$ is given in Kramer *et al.* (1992). It leads to icosahedral tilings $(\mathcal{T}, D_6)$ and $(\mathcal{T}^*, D_6)$ of $E^3$, (Kramer *et al.* 1992, Kramer and Papadopolos 1997, Kramer and Schlottmann 1989) and to models of icosahedral quasicrystals.

## Fundamental Domains for Quasiperiodic Tilings

Canonical tilings allow us to construct quasiperiodic functions equipped with a quasiperiodic counterpart of fundamental domains or cells in crystals: assume that the tiles of a tiling $(\mathcal{T}, \Lambda)$ all are translates in $E^m$ of a finite minimal set of prototiles $(X^1, \ldots, X^r)$. Consider the class of quasiperiodic functions which

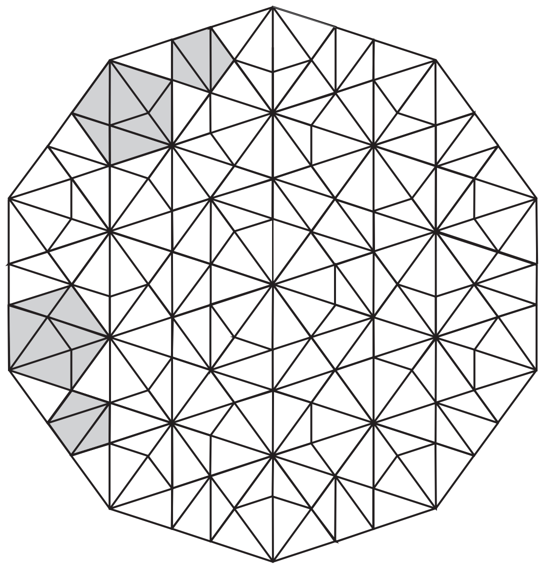

**Figure 2** A patch of the planar quasiperiodic triangle tiling $(\mathcal{T}^*, A_4)$ obtained from the root lattice $A_4 \in E^4$. The tiles are two triangles, projections of 2-boundaries from the Delone cells of $A_4$. The vertices are projections of lattice points. The 20 shaded triangles form a set of prototiles such that any other tile is a translate of one of them. The shaded set forms a fundamental domain for the tiling.

take identical values on any translate of a prototile. These values are prescribed on the finite set of prototiles in $E^m$ which define a fundamental domain for this class of quasiperiodic functions. Only this class of quasiperiodic functions is compatible with the tiling. It can be characterized in the scheme (**qp**) (eqn [12]) by $\Lambda$-periodic functions on $E^n$ whose values on the tile windows of the previous section are independent of the perpendicular coordinate. A fundamental domain for the triangle tiling $(\mathcal{T}^*, A_4)$ is given by the shaded parts in **Figure 2**. The fundamental domain property appears in relation with the theory of covering of quasiperiodic sets (see Kramer and Papadopolos (2000)).

### Example 7: Fundamental Domain for the Fibonacci Tiling

Attach to the squares $A, B$ in **Figure 1** a periodic function $f^p(x)$ with functional values independent of the perpendicular coordinate $x_\perp$ within the two squares. Consider the functional values $f^{qp}(x_\parallel) = f^p(x_\parallel + c_\perp)$ picked up on a parallel line. Clearly, these values become independent of the perpendicular coordinate of any intersection with a square $A, B$. The general prescription of values on a fundamental domain of $\Lambda \in E^2$ needed for a quasiperiodic function reduces to a prescription of its functional values in $E_\parallel$ on the fundamental domain formed by the two prototiles $A_\parallel, B_\parallel$.

## Conclusion

For quasiperiodic systems, the general construction was introduced in the section “Quasiperiodic point sets and functions”, and illustrations were given in four subsequent sections. Further reading resources are provided by the references given at the end. Here, we mention some of the many possible generalizations.

Bohr (1925) considers quasiperiodic as special cases of almost periodic systems. The module of an almost periodic function has a countable basis.

Moody (1997) discusses the notion of Meyer sets. These describe discrete sets on locally compact abelian groups and as particular cases encompass quasiperiodic systems.

Lagarias (2000) studies aperiodic sets characterized by the following properties, shared with periodic and quasiperiodic sets:

(**ap1**): inequivalent patches of points are volume bounded,
(**ap2**): pure point Fourier spectrum,
(**ap3**): linear repetitivity of patches, and
(**ap4**): self-similarity.

# Quillen Determinant

**S Scott**, King's College London, London, UK

## Determinants in Finite Dimensions

The determinant of a linear transformation $A: V \longrightarrow W$ acting between finite-dimensional complex vector spaces is an element det $A$ of a complex line $L_A$. The abstract element $\det A$ is called the *Quillen determinant* of $A$, and the complex line $L_A$ is called the determinant line of $A$. A choice of (linear) isomorphism

$$\phi : L_A \longrightarrow \mathbb{C} \qquad [1]$$

associates to det $A$ the complex number

$$\det{}_{\phi} A := \phi(\det A) \in \mathbb{C} \qquad [2]$$

which can equivalently be written as the ratio

$$\det{}_{\phi} A = \frac{\det A}{\phi^{-1}(1)} \qquad [3]$$

taken in the one-dimensional complex vector space $L_A$ relative to the canonical generator $\phi^{-1}(1)$. It is not necessarily the case that det $A$ determines a generator for $L_A$; specifically, if $\dim V = m$ and $\dim W = n$, then $\det A = 0$ if $m \neq n$ (by "fiat"), while if $m = n$, then $\det A = 0$ precisely when $A$ is not invertible. For the moment, set $m = n$.

For $k \in \{0, 1, \ldots, n\}$ the $k$th exterior power operator is defined by

$$\wedge^k A : \wedge^k V \longrightarrow \wedge^k W$$
$$\wedge^k A(v_1 \wedge v_2 \wedge \cdots \wedge v_k) := Av_1 \wedge Av_2 \wedge \cdots \wedge Av_k \qquad [4]$$

where $v_1, \ldots, v_k \in V$ and $\wedge^0 V := \mathbb{C}$ and $\wedge^0 A := 1$. When $k = n$, $\operatorname{Det} V := \wedge^n V$ and $\operatorname{Det} W := \wedge^n W$ are complex lines and the determinant line of $A$ is

$$L_A := \operatorname{Det} V^* \otimes \operatorname{Det} W \qquad [5]$$

while for any basis $\{e_1, \ldots, e_n\}$ for $V$, with dual basis $\{e_1^*, \ldots, e_n^*\}$ for $V^*$,

$$\det A := e_1^* \wedge \cdots \wedge e_n^* \otimes (\wedge^n A)(e_1 \wedge \cdots \wedge e_n) \in L_A \qquad [6]$$

There is a canonical isomorphism for $A \in \operatorname{Hom}(V, W)$, $B \in \operatorname{Hom}(U, V)$

$$L_{AB} \cong L_A \otimes L_B \qquad [7]$$

coming from the isomorphism

$$\operatorname{Det} V^* \otimes \operatorname{Det} V \longrightarrow \mathbb{C} \qquad [8]$$

defined by the canonical pairing $\operatorname{Det} V^* \times \operatorname{Det} V \to \mathbb{C}$, and this preserves the determinant elements

$$\det\,(AB) \longleftrightarrow \det A \otimes \det B \qquad [9]$$

### The Classical Determinant

When $V = W$ these constructions take on a more familiar form. Then $\phi$ can be chosen to be the canonical isomorphism [8] and evaluation on $\det A \in L_A$ outputs the classical determinant

$$\det{}_{\mathbb{C}} A = \sum_{\sigma} (-1)^{\sigma} a_{1,\sigma(1)} \cdots a_{n,\sigma(n)} \qquad [10]$$

where the sum is over permutations of $\{1, \ldots, n\}$ and $(a_{i,j})$ is the matrix of $A$ with respect to any basis of $V$ – changing the basis may change the summands on the right-hand side of [10], but not their sum. It is fundamental that when $V = W$ the classical determinant is an intrinsic invariant of the operator $A$, independent of the choice of basis for $V$; when $V \neq W$ that is no longer so since there is then no *canonical* bilinear pairing $\operatorname{Det} V^* \times \operatorname{Det} W \longrightarrow \mathbb{C}$; the choice of a nondegenerate pairing is equivalent to a choice of $\phi$ in [1].

The identification of [10] from [6] and [8] amounts to the identity in Det $V$

$$(\wedge^n A)(e_1 \wedge \cdots \wedge e_n) = \det{}_{\mathbb{C}} A \,.\, e_1 \wedge \cdots \wedge e_n \qquad [11]$$

Since $\wedge^n(AB) = \wedge^n A \circ \wedge^n B$, [11] in turn implies the characterizing multiplicativity property of the classical determinant

$$\det{}_{\mathbb{C}}(AB) = \det{}_{\mathbb{C}}A \, . \det{}_{\mathbb{C}}B \qquad [12]$$

for $A, B \in \mathrm{End}(V)$, specializing the general fact in [7]. Similarly, the group $\mathrm{Gl}(V, \mathbb{C})$ of invertible elements of $\mathrm{End}(V)$ is identified with those $A$ with $\det_{\mathbb{C}} A \neq 0$.

The classical determinant can also be thought of in the following ways. First, the direct sum of the operators defined in [4] yields the total exterior power operator $\wedge A : \wedge V \longrightarrow \wedge V$ on the exterior algebra $\wedge V = \oplus_{k=0}^{n} \wedge^k V$ and this has trace

$$\mathrm{tr}\,(\wedge A) = \det{}_{\mathbb{C}}(I + A) \qquad [13]$$

where $I$ is the identity. Alternatively, one can do something a little more sophisticated and use the holomorphic functional calculus to define the logarithm $\log_\theta B$ of $B \in \mathrm{End}(V)$ by

$$\log_\theta B = \frac{\mathrm{i}}{2\pi} \int_{\Gamma_\theta} \log_\theta \lambda \, (B - \lambda I)^{-1} \, \mathrm{d}\lambda \qquad [14]$$

Here $\log_\theta \lambda$ is the branch of the complex logarithm defined by $\theta - 2\pi < \arg(\lambda) \leq \theta$ and $\Gamma_\theta$ is a positively oriented contour enclosing $\mathrm{spec}(B)$ but not any point of the spectral cut $R_\theta = \{r\mathrm{e}^{\mathrm{i}\theta} \mid r \geq 0\}$. Then, if $B$ is invertible,

$$\mathrm{tr}\,(\log_\theta B) = \log_\theta \det{}_{\mathbb{C}}B \qquad [15]$$

## The Fredholm Determinant

The advantage of the constructions [13] and [15] is that they extend to a restricted class of bounded linear operators on infinite-dimensional Hilbert spaces. This is consequent on the fact that both of the formulas [13] and [15] are computed as operator traces.

(Recall that a trace on a Banach algebra $\mathcal{B}$ is a linear functional $\tau : \mathcal{B} \to \mathbb{C}$ which has the property $\tau([a, b]) = 0$ for all $a$, $b$ in $\mathcal{B}$, where $[a, b] := ab - ba$ is defined by the product structure on $\mathcal{B}$. Since one can define the logarithm $\log_\theta b$ of an element $b$ of $\mathcal{B}$ with spectral cut $R_\theta$ by the formula [14], one in this case obtains a determinant $\det_{\tau,\theta}(b)$ on such elements by setting

$$\log_\theta \det{}_{\tau,\theta}(b) = \tau(\log_\theta b) \qquad [16]$$

If $a, b, ab \in \mathcal{B}$ have common spectral cuts $\theta$, the trace property of $\tau$ translates into the multiplicativity property $\det_{\tau,\theta}(ab) = \det_{\tau,\theta}(a)\det_{\tau,\theta}(b)$ via a version of the Campbell–Hausdorff formula.)

The operator trace arises as follows. Let $H$ be a complex separable Hilbert space with inner product $<,>$, let $\mathcal{C}(H)$ be the algebra of compact operators on $H$, and let

$$L_1 = \left\{ A \in \mathcal{C}(H) \mid \|A\|_1^2 := \sum_{i=1}^{\infty} \mu_i(A^*A) < \infty \right\} \qquad [17]$$

be the ideal of trace-class operators, where the sum is over the real discrete eigenvalues $\mu_i(A^*A) \searrow +0$ of the compact self-adjoint operator $A^*A$. For any orthonormal basis $\{\eta_j\}$ of $H$ the map

$$\mathrm{tr} : L_1 \longrightarrow \mathbb{C}, \qquad A \mapsto \mathrm{tr}\,(A) := \sum_j < \eta_j, A\eta_j >$$

is a trace functional on $L_1(H)$, independent of the choice of basis. Lidskii's theorem states that

$$\mathrm{tr}\,(A) = \sum_{\lambda \in \mathrm{spec}(A)} \lambda \qquad [18]$$

with the sum over the eigenvalues of $A$ counted up to algebraic multiplicity; for general trace-class operators this equality is highly nontrivial.

If $A$ is trace class, then for each non-negative integer $k$ so is each of the exterior power operators $\wedge^k A : \wedge^k H \longrightarrow \wedge^k H$, defined as in [4]. Following [13], a determinant can therefore be defined on the semigroup $I + L_1 := \{I + A \mid A \in L_1\}$ of determinant-class operators by the absolutely convergent sum

$$\det{}_{\mathrm{F}}(I + A) := \mathrm{tr}\,(\wedge A) = 1 + \sum_{k=1}^{\infty} \mathrm{tr}\,(\wedge^k A) \qquad [19]$$

On the other hand, since tr is tracial and $\log_\pi (I + A)$ defined by [14] is trace class, then according to [16], there is a determinant given on invertible determinant-class operators by

$$\log_\pi \det{}_{\mathrm{F}}(I + A) = \mathrm{tr}\,(\log_\pi (I + A)) \qquad [20]$$

which, as the left-hand side already suggests, coincides with the Fredholm determinant.

The Fredholm determinant retains the characterizing properties of the classical determinant in finite dimensions, that $\det_{\mathrm{F}} : I + L_1 \longrightarrow \mathbb{C}$ is multiplicative,

$$\det{}_{\mathrm{F}}((I + A)(I + B)) = \det{}_{\mathrm{F}}(I + A) \det{}_{\mathrm{F}}(I + B), \quad A, B \in L_1 \qquad [21]$$

and $\det_{\mathrm{F}}(I + A) \neq 0$ if and only if $I + A$ is invertible. It is, moreover, essentially unique; any other multiplicative functional on $I + L_1$ is equal to some power of the Fredholm determinant, or, equivalently, any trace on $L_1$ is a constant multiple of the operator trace. The trace property, the operator trace, and the multiplicativity of the Fredholm determinant do not, however, persist to any functional extension of the operator trace (resp. Fredholm determinant) on the

space of pseudodifferential operators of any real order acting on function spaces (fields over space-time). In quantum physics, this is a primary cause of anomalies. More precisely, determinants of differential operators arise in quantum field theories (QFTs) and string theory through the formal evaluation of their defining Feynman path integrals and the calculation of certain stable quantum numbers, which are in some sense "topological."

From the latter perspective, it is instructive to be aware also of the following, third, construction of the Fredholm determinant, which equates the existence of a nontrivial determinant to the existence of nontrivial topology of the general linear group. First, in a surprising contrast to $\mathrm{Gl}(n, \mathbb{C})$, the general linear group $\mathrm{Gl}(H)$ of an infinite-dimensional Hilbert space $H$ with the norm topology is contractible, and hence topologically trivial. By transgression properties in cohomology, this implies any vector bundle with structure group $\mathrm{Gl}(H)$ is isomorphic to the trivial bundle. In order to recapture some topology (and hence, in applications, some physics), it is necessary to reduce to certain infinite-dimensional subgroups of $\mathrm{Gl}(H)$. The most obvious one is the group $\mathrm{Gl}(\infty)$ of of invertible operators differing from the identity by an operator of finite rank. As the inductive limit of the $\mathrm{Gl}(n, \mathbb{C})$, the cohomology and homotopy groups of $\mathrm{Gl}(\infty)$ are a stable version of those of $\mathrm{Gl}(n, \mathbb{C})$. Precisely, $\mathrm{Gl}(\infty)$ is torsion free and its cohomology ring is an exterior algebra with odd degree generators, while Bott (1959) periodicity identifies $\pi_k(\mathrm{Gl}(\infty))$ to be isomorphic to $\mathbb{Z}$ if $k$ is odd and trivial if $k$ is even. Topologically, it is preferable to consider the closure of $\mathrm{Gl}(\infty)$ in $\mathrm{Gl}(H)$, which yields the group $\mathrm{Gl}_{\mathrm{cpt}}(H)$ of operators differing from the identity by a compact operator, but this is now a little "too large" for analysis and differential geometry. Given our earlier comments, there is an intermediate natural choice of the Banach Lie group $\mathrm{Gl}_1(H)$ of operators differing from the identity by a trace-class operator (in fact, there is a tower of such Schatten class groups). Moreover, the inclusions $\mathrm{Gl}(\infty) \subset \mathrm{Gl}_1(H) \subset \mathrm{Gl}_{\mathrm{cpt}}(H)$ are homotopy equivalences, and so the cohomology of $\mathrm{Gl}_1(H)$ is just the exterior algebra mentioned above

$$H^*(\mathrm{Gl}_1(H)) = \wedge(\omega_1, \omega_3, \omega_5, \ldots), \quad \deg\omega_j = 2j - 1 \qquad [22]$$

The advantage of considering $\mathrm{Gl}_1(H)$ is that precise analytical representatives for the classes $\omega_j$ can be written down:

$$\omega_j = \left(\frac{\mathrm{i}}{2\pi}\right)^j \frac{(j-1)!}{(2j-1)!}\, \Theta^{2j-1}$$

where

$$\Theta = \mathrm{tr}\,(Z^{-1}\mathrm{d}Z) \qquad [23]$$

is the 1-form on $\mathrm{Gl}_1(H)$.

This equation makes sense because the derivative $\mathrm{d}Z$ is trace class, and hence so is $Z^{-1}\mathrm{d}Z$. Now, locally $\Theta = \mathrm{d}\log \det_{\mathrm{F}}(Z)$, so that the 1-form $\omega_1$ pulled back by a path $\sigma: S^1 \to \mathrm{Gl}_1(H)$ is precisely the winding number of the curve traced out in $\mathbb{C}^*$ by the function $\det_{\mathrm{F}}(\sigma)$. In fact, this is just a special case of the Bott periodicity theorem, which tells us that the stable homotopy group $\pi_{2j-1}(\mathrm{Gl}_1(H))$ is isomorphic to $\mathbb{Z}$ and an isomorphism is defined by assigning to a map $f: S^{2j-1} \to \mathrm{Gl}_1(H)$ the integer $\int_{S^{2j-1}} f^*\omega_j \in \mathbb{Z}$ (it is not obvious *a priori* that it is an integer).

Notice that it was not necessary to have mentioned the Fredholm determinant of $Z$ at this point. Indeed, the third definition of the Fredholm determinant is to see it as the integral of the 1-form $\Theta$, define

$$\log_\pi \det_{\mathrm{F}}(\mathrm{I} + \mathrm{A}) := \int_\gamma \Theta \qquad [24]$$

where $\gamma: [0,1] \to \mathrm{Gl}_1(H)$ is any path with $\gamma(0) = I$ and $\gamma(1) = I + A$; this uses the connectedness of $\mathrm{Gl}_1(H)$ and independence of the choice of $\gamma$, as guaranteed by Bott periodicity.

Interestingly, this is closely tied in with the Atiyah–Singer index theorem for elliptic pseudodifferential operators (which in full generality uses the Bott periodicity theorem). Here, there is the following simple but quintessential version of that theorem which links it to the winding number of the determinant of the symbol of a differential operator

$$D = \sum_{\alpha| \leq m} a_\alpha(x) D_x^\alpha \qquad [25]$$

on Euclidean space $\mathbb{R}^n$ with $\alpha = (\alpha_1, \ldots, \alpha_n)$ a multi-index of non-negative integers, $|\alpha| = \alpha_1 + \cdots + \alpha_n$, and $D_x = \mathrm{i}\partial/\partial x_i$. Here $D$ acts on $C^\infty(\mathbb{R}^n, V)$ with $V$ a finite-dimensional complex vector space and the coefficients of $D$ are matrices varying smoothly with $x$ which are required to decay suitably fast, $\left|D_x^\beta a_\alpha(x)\right| = O(|x|^{-|\beta|})$ as $|x| \to \infty$. If the symbol $\sigma_D$ of $D$, defined by

$$\sigma_D(x, \xi) = \sum_{\alpha| \leq m} a_\alpha(x) \xi^\alpha \qquad [26]$$

with $\xi = (\xi_1, \ldots, \xi_n) \in \mathbb{R}^n$, satisfies the ellipticity condition of being invertible on the $2n-1$ sphere $S^{2n-1}$ in $(x, \xi)$ space, then $D$ is a Fredholm operator. The index theorem then states

$$\mathrm{index}\,(D) = \int_{S^{2j-1}} \sigma_D^*(\omega_n)$$

the higher-dimensional analog of the winding number of the determinant.

## Fredholm Operators and Determinant Line Bundles

The operators whose determinants are considered in this article are all Fredholm operators. Recall that a linear operator $A : H_1 \to H_2$ between Hilbert spaces is Fredholm if it is invertible modulo compact operators; that is, there is a "parametrix" $Q : H_2 \to H_1$ such that $QA - I$ and $AQ - I$ are compact operators on $H_1$ and $H_2$, respectively. Equivalently, the range $A(H_1)$ of $A$ is closed in $H_2$, and the kernel $\mathrm{Ker}(A) = \{\eta \in H_1 \mid A\eta = 0\}$ and cokernel $\mathrm{Coker}(A) = H_2/A(H_1)$ of $A$ are finite dimensional. (This is equally true for Banach and Frechet spaces, we restrict our attention to Hilbert spaces for brevity.) The space $\mathsf{Fred}$ of all such Fredholm operators with the norm topology has the homotopy type of the classifying space $\mathbb{Z} \times B\mathrm{Gl}(\infty)$. The first factor parametrizes the connected components of $\mathsf{Fred}$, two Fredholm operators are in the same component if and only if they have the same index

$$\mathrm{index}\,(A) = \dim \mathrm{Ker}(A) - \dim \mathrm{Coker}(A)$$

Mostly we restrict our attention to the connected component $\mathsf{Fred}_0$ of operators of index zero. The cohomology of $\mathsf{Fred}_0 \sim B\mathrm{Gl}(\infty)$ is a polynomial ring

$$H^*(\mathsf{Fred}_0) = \mathbb{R}[\mathrm{ch}_1, \mathrm{ch}_2, \mathrm{ch}_3, \ldots]$$

whose generators may be formally realized as the even degree components of the Chern character of an infinite-dimensional bundle over $\mathsf{Fred}_0$. In fact, the generators $\omega_{2j-1}$ of $H^*(\mathrm{Gl}_1(H))$ are related to the $\mathrm{ch}_j$ through transgression, see Chern and Simons (1974). We shall be interested here in the first generator $\mathrm{ch}_1$, a transgression of the Fredholm determinant "winding number 1-form" $\omega_1$, which coincides with the real Chern class of a canonical complex line bundle $\mathrm{DET}_0 \to \mathsf{Fred}_0$. The fiber of $\mathrm{DET}_0$ at $A \in \mathsf{Fred}_0$ is the determinant line $\mathrm{Det}(A)$ of the Fredholm operator $A$, which is defined as follows (Segal 2004).

Just as for finite-rank operators (see the subsection "Determinants in finite dimensions"), the determinant of a Fredholm operator $A : H^1 \to H^2$ exists abstractly not as a number but as an element $\det A$ of a complex line $\mathrm{Det}(A)$. For simplicity, we suppose that $\mathrm{index}\,(A) = 0$. Elements of the determinant line $\mathrm{Det}(A)$ are equivalence classes $[E, \lambda]$ of pairs $(E, \lambda)$, where $E : H^1 \to H^2$ such that $A - E$ is trace class and relative to the equivalence relation $(Eq, \lambda) \sim (E, \det_{\mathrm{F}}(q)\lambda)$ for $q : H^1 \to H^1$ of determinant class and where $\det_{\mathrm{F}}(q)$ is the Fredholm determinant of $q$. Complex multiplication on $\mathrm{Det}(A)$ is defined by $\mu[A, \lambda] = [A, \mu\lambda]$. The abstract, or Quillen, determinant of $A$ is the preferred element $\det A := [A, 1]$ in $\mathrm{Det}(A)$.

Here are some essential properties of the determinant line. First, $\det A$ is nonzero if and only if $A$ is invertible. Next, quotients of abstract determinants in $\mathrm{Det}(A)$ are given by Fredholm determinants; for if $A_1 : H^1 \to H^2$, $A_2 : H^1 \to H^2$ are Fredholm operators such that $A_i - A$ are trace class, then if $A_2$ is invertible we see that $A_2^{-1}A_1$ is determinant class and hence from the definition that

$$\frac{\det(A_1)}{\det(A_2)} = \det{}_{\mathrm{F}}(A_2^{-1}A_1) \qquad [27]$$

where the quotient on the left-hand side is taken in $\mathrm{Det}(A)$. The principal functorial property of the determinant line is that given a commutative diagram with exact rows and Fredholm columns

$$\begin{array}{ccccccccc} 0 & \longrightarrow & H_1 & \longrightarrow & H_1' & \longrightarrow & H_1'' & \longrightarrow & 0 \\ & & \downarrow_A & & \downarrow_{A'} & & \downarrow_{A''} & & \\ 0 & \longrightarrow & H_2 & \longrightarrow & H_2' & \longrightarrow & H_2'' & \longrightarrow & 0 \end{array} \qquad [28]$$

then there is canonical isomorphism of complex lines

$$\mathrm{Det}(A') \cong \mathrm{Det}(A) \otimes \mathrm{Det}(A'') \qquad [29]$$

preserving the Quillen determinants $\det(A') \leftrightarrow \det(A) \otimes \det(A'')$. A consequence of this property is that given Fredholm operators $A : H_2 \to H_3$ and $B : H_1 \to H_2$, then

$$\mathrm{Det}(AB) \cong \mathrm{Det}(A) \otimes \mathrm{Det}(B)$$

with $\det(AB) \leftrightarrow \det(A) \otimes \det(B)$, generalizing the elementary property [9].

The principal context of interest for studying determinant lines is the case where one has a family $\mathcal{A} = \{A_x \mid x \in B\}$ of Fredholm operators parametrized by a manifold $B$, satisfying suitable continuity properties, and one aims to make sense of the determinant as a function $\mathcal{A} \to \mathbb{C}$. It is then of no difficulty to show that the corresponding family of determinant lines $\mathrm{DET}(\mathcal{A}) = \cup \mathrm{Det}(A_x)$ defines a complex line bundle over $B$ endowed with a canonical section $\det : B \longrightarrow \mathrm{DET}(\mathcal{A})$

assigning to $x \in B$ the Quillen determinant $\det(A_x) \in \mathrm{Det}(A_x)$ (Quillen 1985, Segal 2004). To identify the Quillen determinant section with a function on $\mathcal{A}$, we need to identify a trivialization of the line bundle $\mathrm{DET}(\mathcal{A})$, giving a global basis for the fibers. This is the same thing as giving a non(or never)vanishing section $\psi : B \to \mathrm{DET}(\mathcal{A})$, with respect to which we have the regularized determinant function (cf. [3]):

$$x \mapsto \det{}_{\psi}(A_x) := \frac{\det(A_x)}{\psi(x)} \qquad [30]$$

If $\mathcal{A}$ is trivializable, so a nonzero section exists, there will be many such sections and some extra data is needed to fix a natural choice of $\psi$.

Each of the properties mentioned above for determinant lines carries forward to determinant line bundles in a natural way. In particular, one easily deduces from [28], or from the exact sequence

$$0 \longrightarrow \mathrm{Ker}A_x \longrightarrow H_{1,x} \xrightarrow{A_x} H_{2,x} \longrightarrow \mathrm{Coker}A_x \longrightarrow 0$$

that if the kernels $\mathrm{Ker}A_x$ have constant dimension as $x$ varies, then there is a canonical isomorphism

$$\mathrm{Det}(\mathcal{A}) \cong \wedge^{\max}\mathrm{Ker}(\mathcal{A})^* \otimes \wedge^{\max}\mathrm{Coker}(\mathcal{A}) \qquad [31]$$

where $\mathrm{Ker}(\mathcal{A})$ is the finite-rank complex vector bundle over $B$ with fiber $\mathrm{Ker}A_x$, and $\mathrm{Coker}(\mathcal{A})$ similarly. The interesting feature here is that it shows the determinant bundle to be the top exterior power of the index bundle $\mathrm{Ind}(\mathcal{A}) = [\mathrm{Ker}(\mathcal{A})] - [\mathrm{Coker}(\mathcal{A})] \in K(B)$ in the even $K$-theory of $B$, and in this sense determinant theory may be seen as a particular aspect of index theory – understood is the very broadest sense; in fact, the computation of determinants is usually a considerably more complex and difficult task than computing an index.

## Determinant Bundles for Differential Operators over Manifolds

The Quillen determinant has been of particular interest in the case of families of Dirac operators. Such a family is associated to a $C^\infty$ fibration $\pi : M \longrightarrow B$ of closed boundaryless finite-dimensional Riemannian manifolds of even dimension. If there is a graded Hermitian vector bundle $\mathcal{E} = \mathcal{E}^+ \oplus \mathcal{E}^- \to M$ of Clifford modules, then from the Riemannian structure one can construct a Levi-Civita connection on the vertical tangent bundle $T(M/B)$ which can be lifted to a Clifford connection on $\mathcal{E}$; for example, the spinor connection if we have a family of spin manifolds. This data yields a smooth family of first-order elliptic differential operators $\boldsymbol{D} = \{D_x : C^\infty(M_x; \mathcal{E}_x^+) \longrightarrow C^\infty(M_x; \mathcal{E}_x^-) \mid x \in B\}$ of chiral Dirac-type, with $D_x$ a Dirac-type operator acting over the manifold $M_x = \pi^{-1}(x)$ parametrized by the fibration, along with a determinant line bundle $\mathrm{DET}(\boldsymbol{D}) \to B$ endowed with a canonical section $x \mapsto \det(D_x)$. There are various contexts in mathematics and physics in which one would like to assign to the determinant section a naturally associated smooth function (a regularized determinant) $\det_{\mathrm{reg}} : B \longrightarrow \mathbb{C}$, which can, for example, then be integrated. As discussed in the previous section, this depends on identifying a trivializing (nonzero) section of $\mathrm{DET}(\boldsymbol{D})$. For such a section to exist, the first Chern class $c_1(\mathrm{DET}(\boldsymbol{D}) \in H^2(B)$ must vanish, and this in turn can be computed as a term in the Atiyah–Singer (1984) index theorem for families. Indeed, this is clear from the formal identification [31] which here takes on a precise meaning.

The following simple example, which is the basic topological anomaly computation in string theory, may help to explain the type of computation. Let $M_x$ be a copy of $\Sigma$ a compact Riemann surface, so that $M$ is a family of surfaces parametrized by $B$. Let $T = \cup T_x$ be the vertical complex tangent line bundle on $M$, where $T_x$ is the complex tangent line bundle to $M_x$. Each fiber has an associated $\overline{\partial}$-operator $\overline{\partial}_x$ which we couple to the Hermitian bundle $\mathcal{E}_x := T_x^{\otimes m}$ for $m$ a non-negative integer. In this way, we get a family $\boldsymbol{D}_\Sigma$ of $\overline{\partial}$-operators coupled to $\mathcal{E} = T^{\otimes m}$ whose index bundle is the element $\mathrm{Ind}(\boldsymbol{D}_\Sigma) = f_!(T^{\otimes m}) \in K(B)$. The Atiyah–Singer index theorem for families in this situation coincides with the Grothendieck–Riemann–Roch theorem and this says that

$$\mathrm{ch}(f_!(T^{\otimes m})) = f_*(\mathrm{ch}(T^{\otimes m})\mathrm{Todd}(T))$$

where ch is the Chern character class and $\mathrm{Todd}(T)$ is the Todd class defined for a vector bundle $F$ whose first few terms are

$$\mathrm{Todd}(F) = 1 + \tfrac{1}{2}c_1(F) + \tfrac{1}{12}c_1(F)^2 + \cdots$$

and where $f_* : H^i(M) \to H^{i-1}(B)$ is integration over the fibers. That is, with $\xi = c_1(T)$,

$$\begin{aligned}\mathrm{ch}(f_!(T^{\otimes m})) &= f_*\big(\big(1 + m\xi + \tfrac{1}{2}m^2\xi^2 + \cdots\big) \\ &\qquad \times \big(1 + \tfrac{1}{2}\xi + \tfrac{1}{12}\xi^2 + \cdots\big)\big) \\ &= f_*\big(1 + \big(m + \tfrac{1}{2}\big)\xi + \tfrac{1}{12}\big(m^2 + m + \tfrac{1}{6}\big) \\ &\qquad \times \xi^2 + \cdots\big)\end{aligned}$$

So we have

$$c_1(f_!(T^{\otimes m})) = \tfrac{1}{12}(6m^2 + 6m + 1)f_*(\xi^2) \in H^2(B) \qquad [32]$$

But for any element of $K$-theory, $c_1(E) = c_1(\mathrm{DET}(E))$, and so the left-hand side of [32] is the first Chern class of the determinant line bundle $\mathrm{DET}(\boldsymbol{D}_\Sigma)$. If we take, in particular, $B = \mathrm{Conf}(\Sigma)$, the space of conformal classes of metrics on $\Sigma$ (or compact subsets of this space), and couple the family $\boldsymbol{D}_\Sigma$ to a background trivial real bundle of rank $d/2$, or its negative in $K$-theory, then taking $m = 1$ [32] is easily seen to be modified to

$$c_1(\boldsymbol{D}_{\Sigma,-d/2}) = \frac{(d-26)}{24} f_*(\xi^2)$$

It follows for this topological anomaly to vanish one must have background spacetime of dimension $d = 26$. The idea here is that $\mathrm{Conf}(\Sigma)$ is a configuration space for bosonic strings in $\mathbb{R}^d$ with the requirement that the determinant section of the determinant line bundle be conformally invariant, corresponding to the classical invariance of the string Lagrangian defining the string path integral from which the determinant arises. That is, in order to evaluate the path integral on the reduced configuration space, one requires a trivialization of the determinant line bundle which defines a conformally invariant regularized determinant function. The above calculation says that there is a topological obstruction to this occurring when the background space dimension differs from 26.

This is the most basic example of determinant anomaly computations, which have acquired considerably more sophisticated constructions in modern versions of string theory and QFT. One immediate deficiency in the approach explained so far is that not all anomalies are topological and so even though the first Chern class of the determinant line bundle may vanish, there may still be local and global obstructions to the existence of a determinant function with the correct symmetry properties. To be more precise, one needs to say not just that a trivialization of the determinant line bundle formally exists, but to actually be able to construct a specific preferred trivialization. For this more refined objective, one needs to know more about the differential geometry of the determinant line. One approach is to fix a canonical choice of connection and, if the determinant bundle is topologically trivial, to construct a determinant section (up to phase) using the parallel transport of the connection.

The principal contribution to such a theory was made in a remarkable four page paper by Quillen (1985) in which using zeta-function regularization he presented a construction of a metric and connection on the determinant line bundle for a family of $\bar{\partial}$-operators over a Riemann surface coupled to a holomorphic vector bundle. (This is the first paper one should read on determinant line bundles; Quillen's motivation, in fact, did not come from physics but from a problem in number theory.)

To outline this construction, which was extended to general families of Dirac-type operators in Bismut and Freed (1986), first we recall that if $\Delta$ is an invertible Laplacian-type second-order elliptic differential operator acting on the space of sections of a vector bundle over a compact manifold of dimension $n$, then it has a spectrum consisting of real discrete eigenvalues $\{\lambda\}$ forming an unbounded subset of the positive real line. The zeta function of $\Delta$ is defined in the complex half-plane $\mathrm{Re}(s) > n/2$ by

$$\zeta(\Delta, s) = \mathrm{tr}\,(\Delta^{-s}) = \sum_\lambda \lambda^{-s}, \quad \mathrm{Re}(s) > \frac{n}{2}$$

and extends to a meromorphic function of $s$ on the whole complex plane. It turns out that the extension has no pole at $s = 0$ and this means that we may define the zeta-function regularized determinant of $\Delta$ by

$$\det_\zeta(\Delta) := \exp\left(-\frac{\mathrm{d}}{\mathrm{d}s_{|s=0}} \zeta(\Delta, s)\right)$$

since $(\mathrm{d}/\mathrm{d}s)|_{s=0} \lambda^s = \log \lambda$ this formally represents a regularized product of the eigenvalues of $\Delta$. A metric is now defined on the determinant line bundle $\mathrm{DET}(\boldsymbol{D})$ by defining the norm square of the element $\det(D_x) \in \mathrm{Det}(D_x)$ by

$$\| \det(D_x) \|^2 := \det_\zeta(D_x^* D_x)$$

over the subset $B_0$ of $x \in B$ where $D_x$ is invertible. Elsewhere in $B$, one includes a factor defined by the induced $L^2$ metric in the kernel and cokernel. See Quillen (1985) and Bismut and Freed (1986) for full details.

A connection is defined by similarly constructing a regularized version of the connection we would define if we were working with finite-rank bundles. First, one includes in the data associated to the fibration $\pi : M \longrightarrow B$ defining the family of operators $\boldsymbol{D}$ a splitting of the tangent bundle $TM = T(M/B) \oplus \pi^*(TB)$. This assumption and the Riemannian geometry of the fibration yield a connection $\nabla^{(\pi)}$ defined along the fibers of the fibration. The connection form over $B_0$ is then defined by

$$\omega(x) = \mathrm{tr}_\zeta(D_x^{-1} \nabla^{(\pi)} D_x)$$

where the zeta-regularized trace $\mathrm{tr}_\zeta$ is defined on a vertical bundle endomorphism-valued 1 form $x \mapsto A_x$ on $M$ by

$$\mathrm{tr}_\zeta(A_x) := \mathrm{fp}_{s=0}\mathrm{tr}\,\left(A_x\left(D_x^* D_x\right)^{-s}\right)|^{\mathrm{mer}}$$

where the superscript indicates we are considering the meromorphically extended form, and $\mathrm{fp}_{s=0}(G(s))$ means the finite part of a meromorphic function $G$ on $\mathbb{C}$; that is, the constant term in the Laurent expansion of $G(s)$ near $s = 0$.

A theorem of Bismut and Freed, generalizing Quillen's original computation, computes the curvature $\Omega^{(\mathrm{DET}(\boldsymbol{D}))}$ of this connection to be the 2-form component in the local Atiyah–Singer families index density. This is a refined version of the topological version of that theorem which we utilized earlier; it expresses the characteristic classes on $B$ in terms of specific canonical differential forms constructed by integrating, along the fibers of the fibration, canonically defined vertical characteristic forms. More precisely, they prove the formula (Bismut and Freed 1986 and Berline *et al.* 1992)

$$\Omega^{(\mathrm{DET}(\boldsymbol{D}))} = (2\pi \mathrm{i})^{-n/2}\left(\int_{M/B} \widehat{A}(M/B)\mathrm{ch}(\mathcal{E})\right)_{[2]} \qquad [33]$$

where $(\sigma)_{[2]} \in \Omega^2(B)$ means the 2-form component of a differential form $\sigma$ on $B$. Here $\widehat{A}(M/B) = \det^{1/2}((R^{M/B}/2)/\sinh(R^{M/B}/2))$ is the vertical $\widehat{A}$-genus differential form, while $\mathrm{ch}(\mathcal{E})$ is the vertical Chern character form associated to the curvature form of the bundle $\mathcal{E}$.

This theory seems a long way from the classical theory of stable characteristic classes and the Fredholm determinant discussed in earlier sections. There are, however, interesting parallels which may guide the search for an understanding of the geometry of families of elliptic operators, of which determinants form a component. The prototypical situation where determinants arise in the quantization of gauge theory is the following. Consider the infinite-dimensional affine space $\mathcal{A}$ of connections on a complex vector bundle $E$ with structure group $G$ sitting over $S^n$ the $n$-sphere. The Lie group $G$ is assumed to be compact. For each connection $A \in \mathcal{A}$, we consider a Dirac operator $D_A : C^\infty(S^n, S^+ \otimes E) \longrightarrow C^\infty(S^n, S^- \otimes E)$, where $E$ is a Hermitian vector bundle coupled to the spinor bundles $S^\pm$. The group $\mathcal{G}$ of based gauge transformations acts on $\mathcal{A}$ and symmetry properties of conservation laws lead one to be interested in constructing a determinant function on the quotient space $\mathcal{A}/\mathcal{G}$. More precisely, $g \in \mathcal{G}$ transforms $D_A$ to $D_{g.A}$ and by equivariance the Quillen determinant section pushes down to a section of a reduced determinant line bundle over $\mathcal{A}/\mathcal{G}$. As seen earlier, the topological obstruction to realizing this determinant section as a function on $\mathcal{A}/\mathcal{G}$ can be computed from the Atiyah–Singer index theorem for families applied to the corresponding index bundle $\mathrm{Ind}(\boldsymbol{D}_{\mathcal{A}/\mathcal{G}})$ in the $K(\mathcal{A}/\mathcal{G})$ by picking out the degree-2 component in $H^2(\mathcal{A}/\mathcal{G})$ of the Chern character $\mathrm{ch}(\mathrm{Ind}(\boldsymbol{D}_{\mathcal{A}/\mathcal{G}}))$. On the other hand, it turns out that this characteristic class is the transgression of the element of $H^1(\mathcal{G}, \mathbb{Z})$ defined by the zeta-determinant trace

$$\begin{aligned}\Theta_\zeta &:= \mathrm{tr}_\zeta\left(\left(D_A^* D_{g.A}\right)^{-1} d_{\mathcal{G}}\left(D_A^* D_{g.A}\right)\right) \\ &:= \mathrm{fp}_{s=0}\mathrm{tr}\,\left(D_A^* D_{g.A}\right)^{-1} d_{\mathcal{G}}\left(D_A^* D_{g.A}\right)\left(D_A^* D_{g.A}\right)^{-s})|^{\mathrm{mer}}\end{aligned}$$

which counts the winding number of the zeta determinant $\mathcal{G} \longrightarrow \mathbb{C}^*$ defined by $\det_\zeta(D_A^* D_{g.A})$. This provides an interesting parallel of the classical theory described in the section "The Fredholm determinant." For more details of this and more advanced ideas take a look at Singer (1985). (A similar parallel holds between the topological derivation of the conformal anomaly outlined at the beginning of this section and what it called the Polyakov multiplicative anomaly formula for the zeta determinant of the Laplacian with respect to conformal changes in the metric on the surface.)

Aspects of more recent work in this direction have been the extension of the theory to manifolds with boundary, and how it encodes into the structures of topological and conformal field theories, see Segal (2004) and Mickelsson and Scott (2001), and more generally into $M$-theory (Freed and Moore 2004).

## Random Algebraic Geometry, Attractors and Flux Vacua

**M R Douglas**, Rutgers, The State University of New Jersey, Piscataway, NJ, USA

### Introduction

A classic question in probability theory, studied by M Kac, S O Rice, and many others, is to find the expected number and distribution of zeros or critical points of a random polynomial. The same question can be asked for random holomorphic functions or sections of bundles, and are the subject of "random algebraic geometry."

While this theory has many physical applications, in this article we focus on a variation on a standard question in the theory of disordered systems. This is to find the expected distribution of minima of a potential function randomly chosen from an ensemble, which might be chosen to model a crystal with impurities, a spin glass, or another disordered system. Now whereas standard potentials are real-valued functions, analogous functions in supersymmetric theories, such as the superpotential and the central charge, are holomorphic sections of a line bundle. Thus, one is interested in finding the distribution of critical points of a randomly chosen holomorphic section.

Two related and much-studied problems of this type are (1) the problem of finding attractor points in the sense of Ferrara, Kallosh, and Strominger, and (2) the problem of finding flux vacua as posed by Giddings, Kachru, and Polchinski. These problems involve a good deal of fascinating mathematics and are good illustrations of the general theory.

A note on general references for further reading on the subject of this article is in order. For background on random algebraic geometry and some of its other applications, as well as references in the text not listed here, consult Edelman and Kostlan (1995) and Zelditch (2001). The attractor problem is discussed in Ferrara *et al.* (1995) and Moore (2004), while IIb flux vacua were introduced in Giddings *et al.* (2002). Background on Calabi–Yau manifolds can be found in Cox and Katz (1999) and Gross *et al.* (2003).

### Elementary Random Algebraic Geometry

Let us introduce this subject with the problem of finding the expected distribution of zeros of a random polynomial,

$$f(z) = c_0 + c_1 z + \cdots + c_N z^N$$

We define a random polynomial to be a probability measure on a space of polynomials. A natural choice might be independent Gaussian measures on the coefficients,

$$d\mu\,[f] = d\mu[c_0, \ldots, c_N] = \prod_{i=0}^{N} d^2 c_i \frac{\sigma_i}{2\pi}\, e^{-|c_i|^2/2\sigma_i^2} \quad [1]$$

We still need to choose the variances. At first the most natural choice would seem to be equal variance for each coefficient, say $\sigma_i = 1/2$. We can characterize this ensemble by its two-point function,

$$\begin{aligned} G(z_1, \bar{z}_2) &\equiv \mathbb{E}[f(z_1) f^*(\bar{z}_2)] \\ &= \int d\mu[f]\, f(z_1) f^*(\bar{z}_2) \\ &= \sum_{n=0}^{N} (z_1 \bar{z}_2)^n \\ &= \frac{1 - z_1^{N+1} \bar{z}_2^{N+1}}{1 - z_1 \bar{z}_2} \end{aligned}$$

We now define $d\mu_0(z)$ to be a measure with unit weight at each solution of $f(z) = 0$, such that its integral over a region in $\mathbb{C}$ counts the expected number of zeros in that region. It can be written in terms of the standard Dirac delta function, by multiplication by a Jacobian factor,

$$d\mu_0(z) = \mathbb{E}[\delta^{(2)}(f(z)) \partial f(z) \bar{\partial} f^*(\bar{z})] \quad [2]$$

To compute this expectation value, we introduce a constrained two-point function,

$$G_{f(z)=0}(z_1, \bar{z}_2) = \frac{\mathbb{E}[\delta^{(2)}(f(z))\, f(z_1) f^*(\bar{z}_2)]}{\mathbb{E}[\delta^{(2)}(f(z))]}$$

It could be explicitly computed by using the constraint $f(z) = 0$ to solve for a coefficient $c_i$ in

the Gaussian integral, that is, projecting on the linear subspace $0 = \sum c_i z^i$. The result, in terms of $G(z_1, \bar{z}_2)$, is

$$\mathbb{E}[\delta^{(2)}(f(z))] = \frac{1}{\pi G(z, \bar{z})}$$
$$G_{f(z)=0}(z_1, \bar{z}_2) = G(z_1, \bar{z}_2) - \frac{G(z_1, \bar{z})G(z, \bar{z}_2)}{G(z, \bar{z})}$$

as can be verified by considering

$$\mathbb{E}[\delta^{(2)}(f(z))f(z)f^*(\bar{z}_2)] \propto G_{f(z)=0}(z, \bar{z}_2)$$
$$= G(z, \bar{z}_2) - \frac{G(z, \bar{z})G(z, \bar{z}_2)}{G(z, \bar{z})} = 0$$

Using this, eqn [2] can be evaluated by taking derivatives:

$$\mathrm{d}\mu_0(z) = \frac{1}{G(z, \bar{z})} \lim_{z_1, z_2 \to z} D_1 \bar{D}_2 G_z(z_1, \bar{z}_2)$$
$$= \frac{1}{\pi} \partial\bar{\partial} \log G(z, \bar{z})$$

For the constant variance ensemble eqn [2],

$$\mathrm{d}\mu_0(z) = \frac{\mathrm{d}^2 z}{\pi} \left( \frac{1}{(1 - z\bar{z})^2} - \frac{(N+1)^2 (z\bar{z})^N}{(1 - (z\bar{z})^{N+1})^2} \right) \qquad [3]$$

We see that as $N \to \infty$, the zeros concentrate on the unit circle $|z| = 1$ (Hammersley 1954).

A similar formula can be derived for the distribution of roots of a real polynomial on the real axis, using $\mathrm{d}\mu(t) = \mathbb{E}[\delta(f(t))|\mathrm{d}f/\mathrm{d}t|]$. One obtains (Kac 1943):

$$\mathrm{d}\mu_0^r(t) = \frac{\mathrm{d}t}{\pi} \sqrt{\frac{1}{(1 - t^2)^2} - \frac{(N+1)^2 t^{2N}}{(1 - t^{2N+2})^2}}$$

Integrating, one finds the expected number of real zeros of a degree $N$ random real polynomial is $E_N \sim (2/\pi) \log N$, and as $N \to \infty$ the zeros are concentrated at $t = \pm 1$.

While concentration of measure is a fairly generic property for random polynomials, it is by no means universal. Let us consider another Gaussian ensemble, with variance $\sigma_n = N!/n!(N-n)!$. This choice leads to a particularly simple two-point function,

$$G(z, \bar{z}) = (1 + z\bar{z})^N \qquad [4]$$

and the distribution of zeros

$$\mathrm{d}\mu_0 = \frac{1}{\pi} \partial\bar{\partial} \log G = \frac{N \, \mathrm{d}^2 z}{\pi (1 + z\bar{z})^2} \qquad [5]$$

Rather than concentrate the zeros, in this ensemble zeros are uniformly distributed according to the volume of the Fubini–Study (SU(2)-invariant) Kähler metric

$$\omega = \partial\bar{\partial} K, \quad K = \log(1 + z\bar{z})$$

on complex projective space $\mathbb{CP}^1$.

We can better understand the different behaviors in our two examples by focusing on a Hermitian inner product $(f, g)$ on function space, associated to the measure eqn [1] by the formal expression

$$\mathrm{d}\mu[f] = [Df] \, \mathrm{e}^{-(f, f)}$$

In making this precise, let us generalize a bit further and allow $f$ to be a holomorphic section of a line bundle $\mathcal{L}$, say $\mathcal{O}(N)$ over $\mathbb{CP}^1$ in our examples. We then choose an orthonormal basis of sections $(s_i, s_j) = \delta_{ij}$, and write

$$f \equiv \sum_i c_i s_i \qquad [6]$$

and

$$\mathrm{d}\mu[f] = \frac{1}{(2\pi)^N} \prod_{i=1}^{N} \mathrm{d}^2 c_i \, \mathrm{e}^{-|c_i|^2/2}$$

We can then compute the two-point function

$$G(z_1, \bar{z}_2) \equiv \mathbb{E}[s(z_1)s^*(\bar{z}_2)] = \sum_{i=1}^{N} s_i(z_1)s_i^*(\bar{z}_2) \qquad [7]$$

and proceed as before.

In these terms, the simplest way to describe the measure for our first example is that it follows from the inner product on the unit circle,

$$(f, g) = \oint_{|z|=1} \frac{\mathrm{d}z}{2\pi z} f^*(z) g(z)$$

Thus, we might suspect that this has something to do with the concentration of eqn [3] on the unit circle. Indeed, this idea is made precise and generalized in Shiffman and Zelditch (2003).

Our second example belongs to a class of problems in which $\mathcal{M}$ is compact and $\mathcal{L}$ positive. In this case, the space $H^0(\mathcal{M}, \mathcal{L})$ of holomorphic sections is finite dimensional, so we can take the basis to consist of all sections. Then, if $\mathcal{M}$ is in addition Kähler, we can derive all the other data from a choice of Hermitian metric $h(f, g)$ on $\mathcal{L}$. In particular, this determines a Kähler form $\omega$ as the curvature of the metric compatible connection, and thus a volume form $\mathrm{Vol}_\omega = \omega^n/n!$. We then define the inner product to be

$$(f, g) = \int_{\mathcal{M}} \mathrm{Vol}_\omega \, h(f, g)$$

Thus, the measure equation [1] and the final distribution equation [2] are entirely determined by $h$. In

these terms, the underlying reason for the simplicity of eqn [5] is that we started with the SU(2)-invariant metric $h$, so the final distribution must be invariant as well. More generally, eqn [7] is a Szegö kernel. Taking $\mathcal{L} = \mathcal{L}_1^{\otimes N}$ for $N$ large, this has a known asymptotic expansion, enabling a rather complete treatment (Zelditch 2001).

Our two examples also make the larger point that a wide variety of distributions are possible. Thus, to get convincing results, we must put in some information about the ensemble of random polynomials or sections which appear in the problem at hand.

The basic computation we just discussed can be vastly generalized to multiple variables, multipoint correlation functions, many different ensembles, and different counting problems. We will discuss the distribution of critical points of holomorphic sections below.

## The Attractor Problem

We now turn to our physical problems. Both are posed in the context of compactification of the type IIb superstring theory on a Calabi–Yau 3-fold $M$. This leads to a four-dimensional effective field theory with $N = 2$ supersymmetry, determined by the geometry of $M$.

Let us begin by stating the attractor problem mathematically, and afterwards give its physical background. We begin by reviewing a bit of the theory of Calabi–Yau manifolds. By Yau's proof of the Calabi conjecture, the moduli space of Ricci-flat metrics on $M$ is determined by a choice of complex structure on $M$, denote this $J$, and a choice of Kähler class. Using deformation theory, it can be shown that the moduli space of complex structures, denote this $\mathcal{M}_c(M)$, is locally a complex manifold of dimension $h^{2,1}(M)$. A point $J$ in $\mathcal{M}_c(M)$ picks out a holomorphic 3-form $\Omega_J \in H^{3,0}(M, \mathbb{C})$, unique up to an overall choice of normalization. The converse is also true; this can be made precise by defining the period map $\mathcal{M}_c(M) \to \mathbb{P}(H^3(M, \mathbb{Z}) \otimes \mathbb{C})$ to be the class of $\Omega$ in $H^3(M, \mathbb{Z}) \otimes \mathbb{C}$ up to projective equivalence. One can prove that the period map is injective (the Torelli theorem), locally in general and globally in certain cases such as the quintic in $\mathbb{CP}^4$.

Now, the data for the attractor problem is a charge, a class $\gamma \in H^3(M, \mathbb{Z})$. An attractor point for $\gamma$ is then a complex structure $J$ on $M$ such that

$$\gamma \in H_J^{3,0}(M, \mathbb{C}) \oplus H_J^{0,3}(M, \mathbb{C}) \qquad [8]$$

This amounts to $h^{2,1}$ complex conditions on the $h^{2,1}$ complex structure moduli, so picks out isolated points in $\mathcal{M}_c(M)$, the attractor points.

There are many mathematical and physical questions one can ask about attractor points, and it would be very interesting to have a general method to find them. As emphasized by G Moore, this is one of the simplest problems arising from string theory in which integrality (here due to charge quantization) plays a central role, and thus it provides a natural point of contact between string theory and number theory. For example, one might suspect that attractor Calabi–Yau's are arithmetic, that is, are projective varieties whose defining equations live in an algebraic number field. This can be shown to always be true for $K3 \times T^2$, and there are conjectures about when this is true more generally (Moore 2004).

A simpler problem is to characterize the distribution of attractor points in $\mathcal{M}_c(M)$. As these are infinite in number, one must introduce some control parameter. While the first idea which might come to mind is to bound the magnitude of $\gamma$, since the intersection form on $H^3(M, \mathbb{Z})$ is antisymmetric, there is no natural way to do this. A better way to get a finite set is to bound the period of $\gamma$, and consider the attractor points satisfying

$$Z_{\max}^2 \geq |Z(\gamma; z)|^2 \equiv \frac{|\int_M \gamma \wedge \Omega|^2}{\int_M \Omega \wedge \bar{\Omega}} \qquad [9]$$

As an example of the type of result we will discuss below, one can show that for large $Z_{\max}$, the density of such attractor points asymptotically approaches the Weil–Peterson volume form on $\mathcal{M}_c$.

We now briefly review the origins of this problem, in the physics of 1/2 BPS (Bogomoln'yi–Prasad–Sommerfield) black holes in $N = 2$ supergravity. We begin by introducing local complex coordinates $z^i$ on $\mathcal{M}_c(M)$. Physically, these can be thought of as massless complex scalar fields. These sit in vector multiplets of $N = 2$ supersymmetry, so there must be $h^{2,1}(M)$ vector potentials to serve as their bosonic partners under supersymmetry. These appear because the massless modes of the type IIb string include various higher rank-$p$ form gauge potentials, in particular a self-dual 4-form which we denote $C$. Self-duality means that $dC = * dC$ up to nonlinear terms, where $*$ is the Hodge star operator in ten dimensions. Now, Kaluza–Klein reduction of this 4-form potential produces $b^3(M)$ 1-form vector potentials $A_I$ in four dimensions. Given an explicit basis of 3-forms $\omega_I$ for $H^3(M, \mathbb{R}) \cap H^3(M, \mathbb{Z})$, this follows from the decomposition

$$C = \sum_{I=1}^{b_3} A_I \wedge \omega_I + \text{massive modes}$$

However, because of the self-duality relation, only half of these vector potentials are independent; the other half are determined in terms of them by four-dimensional electric–magnetic duality. Explicitly, given the intersection form $\eta_{ij}$ on $H^3 \otimes H^3$, we have

$$\mathrm{d}A_i = \eta_{ij} *_4 \mathrm{d}A_j \qquad [10]$$

where $*_4$ denotes the Hodge star in $d=4$. Thus we have $h^{2,1}+1$ independent vector potentials. One of these sits in the $N=2$ supergravity multiplet, and the rest are the correct number to pair with the complex structure moduli. We now consider 1/2 BPS black hole solutions of this four-dimensional $N=2$ theory. Choosing any $S^2$ which surrounds the horizon, we can define the charge $\gamma$ as the class in $H^3(M,\mathbb{Z})$ which reproduces the corresponding magnetic charges

$$Q_i = \frac{1}{2\pi}\int_{S^2} \mathrm{d}A_i \equiv \int_M \omega_i \wedge \gamma$$

Using eqn [10], this includes all charges.

One can show that the mass $M$ of any charged object in supergravity satisfies a BPS bound,

$$M^2 \geq |Z(\gamma;z)|^2 \qquad [11]$$

The quantity $|Z(\gamma;z)|^2$, defined in eqn [9], depends explicitly on $\gamma$, and implicitly on the complex structure moduli $z$ through $\Omega$. A 1/2 BPS solution by definition saturates this bound.

We now explain the "attractor paradox." According to Bekenstein and Hawking, the entropy of any black hole is proportional to the area of its event horizon. This area can be found by finding the black hole as an explicit solution of four-dimensional supergravity, which clearly depends on the charge $\gamma$. In fact, we must fix boundary conditions for all the fields at infinity, in particular the complex structure moduli, to get a particular black hole solution. Now, normally varying the boundary conditions varies all the data of a solution in a continuous way. On the other hand, if the entropy has any microscopic interpretation as the logarithm of the number of quantum states of the black hole, one would expect $e^S$ to be integrally quantized. Thus, it must remain fixed as the boundary conditions on complex structure moduli are varied, in contradiction with naive expectations for the area of the horizon, and seemingly contradicting Bekenstein and Hawking.

The resolution of this paradox is the attractor mechanism. Let us work in coordinates for which the four-dimensional metric takes the form

$$\mathrm{d}s^2 = -f(r)\,\mathrm{d}t^2 + \mathrm{d}r^2 + \frac{A(r)}{4\pi}\,\mathrm{d}\Omega^2_{S^2}$$

With some work, one can see that in the 1/2 BPS case, the equations of motion imply that as $r$ decreases, the complex structure moduli $z$ follow gradient flow with respect to $|Z(\gamma,z)|^2$ in eqn [11], and the area $A(r)$ of an $S^2$ at radius $r$ decreases. Finally, at the horizon, $z$ reaches a value $z_*$ at which $|Z(\gamma,z_*)|^2$ is a local minimum, and the area of the event horizon is $A=4\pi|Z(\gamma,z_*)|^2$. Since $z_*$ is determined by minimization, this area will not change under small variations of the initial $z$, resolving the paradox.

A little algebra shows that the problem of finding nonzero critical points of $|Z(\gamma,z)|^2$ is equivalent to that of finding critical points $D_iZ=0$ of the period associated to $\gamma$,

$$Z = \int_M \gamma \wedge \Omega \qquad [12]$$

usually called the central charge, with respect to the covariant derivative

$$D_i Z = \partial_i Z + (\partial_i K) Z \qquad [13]$$

Here

$$\mathrm{e}^{-K} \equiv \int \Omega \wedge \bar{\Omega} \qquad [14]$$

The mathematical significance of this rephrasing is that $K$ is a Kähler potential for the Weil–Peterson Kähler metric on $\mathcal{M}_c(M)$, with Kähler form $\omega = \partial\bar{\partial}K$, and eqn [13] is the unique connection on $H^{(3,0)}(M,\mathbb{C})$ regarded as a line bundle over $\mathcal{M}_c(M)$, whose curvature is $-\omega$. These facts can be used to show that $D_i\Omega$ provides a basis for $H^{(2,1)}(M,\mathbb{C})$, so that the critical point condition forces the projection of $\gamma$ on $H^{(2,1)}$ to vanish. This justifies our original definition eqn [8].

## Flux Vacua in IIb String Theory

We will not describe our second problem in as much detail, but just give the analogous final formulation. In this problem, a "choice of flux" is a pair of elements of $H^3(M,\mathbb{Z})$, or equivalently a single element

$$F \in H^3(M, \mathbb{Z} \oplus \tau\mathbb{Z}) \qquad [15]$$

where $\tau \in \mathcal{H} \equiv \{\tau \in \mathbb{C} | \mathrm{Im}\tau > 0\}$ is the so-called "dilaton-axion."

A flux vacuum is then a choice of complex structure $J$ and $\tau$ for which

$$F \in H^{3,0}_J(M,\mathbb{C}) \oplus H^{1,2}_J(M,\mathbb{C}) \qquad [16]$$

Now we have $h^{2,1}+h^{0,3}=h^{2,1}+1$ complex conditions on the joint choice of $h^{2,1}$ complex structure

moduli and $\tau$, so this condition also picks out special points, now in $\mathcal{M}_c \times \mathcal{H}$.

The critical point formulation of this problem is that of finding critical points of

$$W = \int \Omega \wedge F \qquad [17]$$

under the covariant derivatives eqn [13] and

$$D_\tau W = \partial_\tau W + (\partial_\tau W) Z$$

with $K$ the sum of eqn [14] and the Kähler potential $-\log \mathrm{Im}\tau$ for the metric on the upper half-plane of constant curvature –1.

This is a sort of complexified version of the previous problem and arises naturally in IIb compactification by postulating a nonzero value $F$ for a certain 3-form gauge field strength, the flux. The quantity eqn [17] is the superpotential of the resulting $N=1$ supergravity theory, and it is a standard fact in this context that supersymmetric vacua (critical points of the effective potential) are critical points of $W$ in the sense we just stated.

We can again pose the question of finding the distribution of flux vacua in $\mathcal{M}_c(M) \times \mathcal{H}$. Besides $|W|^2$, which physically is one of the contributions to the vacuum energy, we can also use the "length of the flux"

$$L = \frac{1}{\mathrm{Im}\tau} \int \mathrm{Re}\ F \wedge \mathrm{Im}\ F \qquad [18]$$

as a control parameter, and count flux vacua for which $L \leq L_{\max}$. In fact, this parameter arises naturally in the actual IIb problem, as the "orientifold three-plane charge."

What makes this problem particularly interesting physically is that it (and its analogs in other string theories) may bear on the solution of the cosmological constant problem. This begins with Einstein's famous observation that the equations of general relativity admit a one-parameter generalization,

$$R_{\mu\nu} - \tfrac{1}{2} g_{\mu\nu} R = 8\pi T_{\mu\nu} + \Lambda g_{\mu\nu}$$

Physically, the cosmological constant $\Lambda$ is the vacuum energy, which in our flux problem takes the form $\Lambda = \cdots - 3|W|^2$ (the other terms are inessential for us here).

Cosmological observations tell us that $\Lambda$ is very small, of the same order as the energy of matter in the present era, about $10^{-122} M^4_{\mathrm{Planck}}$ in Planck units. However, in a generic theory of quantum gravity, including string theory, quantum effects are expected to produce a large vacuum energy, *a priori* of order $M^4_{\mathrm{Planck}}$. Finding an explanation for why the theory of our universe is in this sense nongeneric is the cosmological constant problem.

One of the standard solutions of this problem is the "anthropic solution," initiated in work of Weinberg and others, and discussed in string theory in Bousso and Polchinski (2000). Suppose that we are discussing a theory with a large number of vacuum states, all of which are otherwise candidates to describe our universe, but which differ in $\Lambda$. If the number of these vacuum states were sufficiently large, the claim that a few of these states realize a small $\Lambda$ would not be surprising. But one might still feel a need to explain why our universe is a vacuum with small $\Lambda$, and not one of the multitude with large $\Lambda$.

The anthropic argument is that, according to accepted models for early cosmology, if the value of $|\Lambda|$ were even 100 times larger than what is observed, galaxies and stars could not form. Thus, the known laws of physics guarantee that we will observe a universe with $\Lambda$ within this bound; it is irrelevant whether other possible vacuum states "exist" in any sense.

While such anthropic arguments are controversial, one can avoid them in this case by simply asking whether or not any vacuum state fits the observed value of $\Lambda$. Given a precise definition of vacuum state, this is a question of mathematics. Still, answering it for any given vacuum state is extremely difficult, as it would require computing $\Lambda$ to $10^{-122}$ precision. But it is not out of reach to argue that out of a large number of vacua, some of them are expected to realize small $\Lambda$. For example, if we could show that the number of otherwise physically acceptable vacua was larger than $10^{122}$, and that the distribution of $\Lambda$ among these was approximately uniform over the range $(-M^4_{\mathrm{Planck}}, M^4_{\mathrm{Planck}})$, we would have made a good case for this expectation. This style of reasoning can be vastly generalized and, given favorable assumptions about the number of vacua in a theory, could lead to falsifiable predictions independent of any *a priori* assumptions about the choice of vacuum state (Douglas 2003).

## Asymptotic Counting Formulas

We have just defined two classes of physically preferred points in the complex structure moduli space of Calabi–Yau 3-folds, the attractor points and the flux vacua. Both have simple definitions in terms of Hodge structure, eqn [8] and eqn [16], and both are also critical points of integral periods of the holomorphic 3-form.

This second phrasing of the problem suggests the following language. We define a random period of the holomorphic 3-form to be the period for a randomly chosen cycle in $H_3(M, \mathbb{Z})$ of the types we

just discussed (real or complex, and with the appropriate control parameters). We are then interested in the expected distribution of critical points for a random period. This brings our problem into the framework of random algebraic geometry. Before proceeding to use this framework, let us first point out some differences with the toy problems we discussed. First, while eqn [12] and eqn [17] are sums of the form eqn [6], we take not an orthonormal basis but instead a basis $s_i$ of integral periods of $\Omega$. Second, the coefficients $c_i$ are not normally distributed but instead drawn from a discrete uniform distribution, that is, correspond to a choice of $\gamma$ in $H^3(M, \mathbb{Z})$ or $F$ as in eqn [15], satisfying the bounds on $|Z|$ or $L$. Finally, we do not normalize the distribution (which is thus not a probability measure) but instead take each choice with unit weight.

These choices can of course be modified, but are made in order to answer the question, "how many attractor points (or flux vacua) sit within a specified region of moduli space?" The answer we will get is a density $\mu(Z_{\max})$ or $\mu(L_{\max})$ on moduli space, such that as the control parameter becomes large, the number of critical points within a region $R$ asymptotes to

$$\mathcal{N}(R; Z_{\max}) \sim \int_R \mu(Z_{\max})$$

The key observation is that to get such asymptotics, we can start with a Gaussian random element $s$ of $H^3(M, \mathbb{R})$ or $H^3(M, \mathbb{C})$. In other words, we neglect the integral quantization of the charge or flux. Intuitively, this might be expected to make little difference in the limit that the charge or flux is large, and in fact one can prove that this simplification reproduces the leading large $L$ or $|Z|$ asymptotics for the density of critical points, using standard ideas in lattice point counting.

This justifies starting with a two-point function like eqn [7]. While the integral periods $s_i$ of $\Omega$ can be computed in principle (and have been in many examples) by solving a system of linear PDEs, the Picard–Fuchs equations, it turns out that one does not need such detailed results. Rather, one can use the following ansatz for the two-point function,

$$\begin{aligned} G(z_1, \bar{z}_2) &= \sum_{I=1}^{b_3} \eta^{IJ} s_I(z_1) s_J^*(\bar{z}_2) \\ &= \int_M \Omega(z_1) \wedge \bar{\Omega}(\bar{z}_2) \\ &= \exp -K(z_1, \bar{z}_2) \end{aligned}$$

In words, the two-point function is the formal continuation of the Kähler potential on $\mathcal{M}_c(M)$ to independent holomorphic and antiholomorphic variables. This incorporates the quadratic form appearing in eqn [18] and can be used to count sections with such a bound.

We can now follow the same strategy as before, by introducing an expected density of critical points,

$$d\mu(z) = \mathbb{E}[\delta^{(n)}(D_i s(z)) \delta^{(n)}(\bar{D}_{\bar{i}} \bar{s}(\bar{z})) \mid \det_{1 \le i,j \le 2n} H_{ij}|] \quad [19]$$

where the "complex Hessian" $H$ is the $2n \times 2n$ matrix of second derivatives

$$H \equiv \begin{pmatrix} \partial_i \bar{D}_{\bar{j}} \bar{s}(z) & \partial_i D_j s(z) \\ \bar{\partial}_{\bar{i}} \bar{D}_{\bar{j}} \bar{s}(z) & \bar{\partial}_{\bar{i}} D_j s(z) \end{pmatrix} \quad [20]$$

(note that $\partial Ds = DDs$ at a critical point). One can then compute this density along the same lines. The holomorphy of $s$ implies that $\partial_i \bar{D}_{\bar{j}} s = \omega_{i\bar{j}} s$, which is one simplification. Other geometric simplifications follow from the fact that eqn [19] depends only on $s$ and a finite number of its derivatives at the point $z$.

For the attractor problem, using the identity

$$D_i D_j s = \mathcal{F}_{ijk} \omega^{k\bar{k}} \bar{D}_{\bar{k}} s = 0$$

from special geometry of Calabi–Yau 3-folds, the Hessian becomes trivial, and $\det H = |s|^{2n}$. One thus finds (Denef and Douglas 2004) that the asymptotic density of attractor points with large $|Z| \le Z_{\max}$ in a region $R$ is

$$\mathcal{N}(R, |Z| \le Z_{\max}) \sim \frac{2^{n+1}}{(n+1)\pi^n} Z_{\max}^{n+1} \cdot \text{vol}(R)$$

where $\text{vol}(R) = \int_R \omega^n / n!$ is the volume of $R$ in the Weil–Peterson metric. The total volume is known to be finite for Calabi–Yau 3-fold moduli spaces, and thus so is the number of attractor points under this bound.

The flux vacuum problem is complicated by the fact that $DDs$ is nonzero and thus the determinant of the Hessian does not take a definite sign, and implementing the absolute value in eqn [19] is nontrivial. The result (Douglas, *et al.* 2004) is

$$\mu(z) \sim \frac{1}{b_3! \sqrt{\det \Lambda(z)}} \int_{\mathcal{H}(z) \times \mathbb{C}} |\det(HH^* - |x|^2 \cdot \mathbf{1})| \times e^{H^t \Lambda(z)^{-1} H - |x|^2} dH\, dx$$

where $\mathcal{H}(z)$ is the subspace of Hessian matrices eqn [20] obtainable from periods at the point $z$, and $\Lambda(z)$ is a covariance matrix computable from the period data.

A simpler lower bound for the number of solutions can be obtained by instead computing the index density

$$\mu_I(z) = \mathbb{E}\left[\delta^{(n)}(D_i s)\delta^{(n)}(\bar{D}_i \bar{s}) \det_{1\le i,j\le 2n} H_{ij}\right] \qquad [21]$$

so-called because it weighs the vacua with a Morse–Witten sign factor. This admits a simple explicit formula (Ashok and Douglas 2004),

$$I_{\text{vac}}(R, L \le L_{\max}) \sim \frac{(2\pi L_{\max})^{b_3}}{\pi^{n+1} b_3!} \int_R \det(\mathcal{R} + \omega \cdot 1) \qquad [22]$$

where $\mathcal{R}$ is the $(n+1)\times(n+1)$-dimensional matrix of curvature 2-forms for the Weil–Peterson metric.

One might have guessed this density by the following reasoning. If $s$ had been a single-valued section on a compact $\mathcal{M}_c$ (it is not), topological arguments determine the total index to be $[c_{n+1}(\mathcal{L}\otimes T^*\mathcal{M})]$, and this is the simplest density constructed solely from the metric and curvatures in the same cohomology class.

It is not in general known whether this integral over Calabi–Yau moduli space is finite, though this is true in examples studied so far. One can also control $|W|^2$ as well as other observables, and one finds that the distribution of $|W|^2$ among flux vacua is to a good approximation uniform. Considering explicit examples, the prefactor in eqn [22] is of order $10^{100}$–$10^{300}$, so assuming that this factor dominates the integral, we have justified the Bousso–Polchinski solution to the cosmological constant problem in these models.

The finite $L$ corrections to these formulas can be estimated using van der Corput techniques, and are suppressed by better than the naive $L^{-1/2}$ or $|Z|^{-1}$ one might have expected. However the asymptotic formulas for the numbers of flux vacuum break down in certain limits of moduli space, such as the large complex structure limit. This is because eqn [18] is an indefinite quadratic form, and the fact that it bounds the number of solutions at all is somewhat subtle. These points are discussed at length in (Douglas *et al.* 2005).

Similar results have been obtained for a wide variety of flux vacuum counting problems, with constraints on the value of the effective potential at the minimum, on the masses of scalar fields, on scales of supersymmetry breaking, and so on. And in principle, this is just the tip of an iceberg, as the study of more or less any class of superstring vacua leads to similar questions of counting and distribution, less well understood at present. Some of these are discussed in Douglas (2003), Acharya *et al.* (2005), Denef and Douglas (2005), Blumenhagen *et al.* (2005).

# Random Dynamical Systems

**V Araújo**, Universidade do Porto, Porto, Portugal

## Introduction

The concept of random dynamical system is a comparatively recent development combining ideas and methods from the well-developed areas of probability theory and dynamical systems.

Let us consider a mathematical model of some physical process given by the iterates $T_0^k = T_0 \circ \overset{k}{\cdots} \circ T_0$, $k \geq 1$, of a smooth transformation $T_0 : M \circlearrowleft$ of a manifold into itself. A realization of the process with initial condition $x_0$ is modeled by the sequence $(T_0^k(x_0))_{k\geq 1}$, the orbit of $x_0$.

Due to our inaccurate knowledge of the particular physical system or due to computational or theoretical limitations (e.g., lack of sufficient computational power, inefficient algorithms, or insufficiently developed mathematical or physical theory), the mathematical models never correspond exactly to the phenomenon they are meant to model. Moreover, when considering practical systems, we cannot avoid either external noise or measurement or inaccuracy errors, so every realistic mathematical model should allow for small errors along orbits not to disturb the long-term behavior too much. To be able to cope with unavoidable uncertainty about the "correct" parameter values, observed initial states and even the specific mathematical formulation involved, let randomness be embedded within the model to begin with.

This article presents the most basic classes of models, defines the general concept, and presents some developments and examples of applications.

## Dynamics with Noise

To model random perturbations of a transformation $T_0$, we may consider a transition from the image $T_0(x)$ to some point according to a given probability law, obtaining a Markov chain, or, if $T_0$ depends on a parameter $p$, we may choose $p$ at random at each iteration, which also can be seen as a Markov chain but whose transitions are strongly correlated.

### Random Noise

Given $T_0 : M \circlearrowleft$ and a family $\{p(\cdot \mid x) : x \in M\}$ of probability measures on $M$ such that the support of $p(\cdot \mid x)$ is close to $T_0(x)$, the random orbits are sequences $(x_k)_{k\geq 1}$ where each $x_{k+1}$ is a random variable with law $p(\cdot \mid x_k)$. This is a Markov chain with state space $M$ and transition probabilities $\{p(\cdot \mid x)\}_{x\in M}$. To extend the concept of invariant measure of a transformation to this setting, a probability measure $\mu$ is said to be "stationary" if $\mu(A) = \int p(A \mid x)\, d\mu(x)$ for every measurable (Borel) subset $A$. This can be conveniently translated by saying that the skew-product measure $\mu \times p^{\mathbb{N}}$ on $M \times M^{\mathbb{N}}$ given by

$$\begin{aligned} &d(\mu \times p^{\mathbb{N}})(x_0, x_1, \ldots, x_n, \ldots) \\ &\quad = d\mu(x_0) p(dx_1 \mid x_0) \cdots p(dx_{n+1} \mid x_n) \cdots \end{aligned}$$

is invariant by the shift map $\mathcal{S} : M \times M^{\mathbb{N}} \circlearrowleft$ on the space of orbits. Hence, we may use the ergodic theorem and get that time averages of all continuous observables $\varphi : M \to \mathbb{R}$, that is, writing $\underline{x} = (x_k)_{k\geq 0}$ and

$$\begin{aligned} \tilde{\varphi}(\underline{x}) &= \lim_{n\to+\infty} \frac{1}{n} \sum_{k=0}^{n-1} \varphi(x_k) \\ &= \lim_{n\to+\infty} \frac{1}{n} \sum_{k=0}^{n-1} \varphi(\pi_0(\mathcal{S}^k(\underline{x}))) \end{aligned}$$

exist for $\mu \times p^{\mathbb{N}}$-almost all sequences $\underline{x}$, where $\pi_0 : M \times M^{\mathbb{N}} \to M$ is the natural projection on the first coordinate. It is well known that stationary measures always exist if the transition probabilities $p(\cdot \mid x)$ depend continuously on $x$.

A function $\varphi : M \to \mathbb{R}$ is invariant if $\varphi(x) = \int \varphi(z) p(dz \mid x)$ for $\mu$-almost every $x$. We then say that $\mu$ is ergodic if every invariant function is constant $\mu$-almost everywhere. Using the ergodic theorem again, if $\mu$ is ergodic, then $\tilde{\varphi} = \int \varphi\, d\mu$, $\mu$-almost everywhere.

Stationary measures are the building blocks for more sophisticated analysis involving, for example, asymptotic sojourn times, Lyapunov exponents, decay of correlations, entropy and/or dimensions, exit/entrance times from/to subsets of $M$, to name just a few frequent notions of dynamical and probabilistic/statistical nature.

**Example 1** (Random jumps). Given $\epsilon > 0$ and $T_0 : M \to M$, let us define

$$p^{\epsilon}(A \mid x) = \frac{m(A \cap B(T_0(x), \epsilon))}{m(B(T_0(x), \epsilon))}$$

where $m$ denotes some choice of Riemannian volume form on $M$. Then $p^{\epsilon}; (\cdot \mid x)$ is the normalized volume restricted to the $\epsilon$-neighborhood of $T_0(x)$.

This defines a family of transition probabilities allowing the points to "jump" from $T_0(x)$ to any point in the $\epsilon$-neighborhood of $T_0(x)$ following a uniform distribution law.

### Random Maps

Alternatively, we may choose maps $T_1, T_2, \ldots, T_k$ independently at random near $T_0$ according to a probability law $\nu$ on the space $T(M)$ of maps, whose support is close to $T_0$ in some topology, and consider sequences $x_k = T_k \circ \cdots \circ T_1(x_0)$ obtained through random iteration, $k \geq 1$, $x_0 \in M$.

This is again a Markov chain whose transition probabilities are given for any $x \in M$ by

$$p(A \mid x) = \nu(\{T \in T(M)\colon T(x) \in A\})$$

so this model may be reduced to the first one. However, in the random-maps setting, we may associate, with each random orbit, a sequence of maps which are iterated, enabling us to use "robust properties" of the transformation $T_0$ (i.e., properties which are known to hold for $T_0$ and for every nearby map $T$) to derive properties of the random orbits.

Under some regularity conditions on the map $x \mapsto p(A \mid x)$ for every Borel subset $A$, it is possible to represent random noise by random maps on suitably chosen spaces of transformations. In fact, the transition probability measures obtained in the random-maps setting exhibit strong spatial correlation: $p(\cdot \mid x)$ is close to $p(\cdot \mid y)$ as $x$ is near $y$.

If we have a parametrized family $T\colon \mathcal{U} \times M \to M$ of maps, we can specify the law $\nu$ by giving a probability $\theta$ on $\mathcal{U}$. Then with every sequence $T_1, \ldots, T_k, \ldots$ of maps of the given family, we associate a sequence $\omega_1, \ldots, \omega_k, \ldots$ of parameters in $\mathcal{U}$ since

$$T_k \circ \cdots \circ T_1 = T_{\omega_k} \circ \cdots \circ T_{\omega_1} = T^k_{\omega_1, \ldots, \omega_k}$$

for all $k \geq 1$, where we write $T_\omega(x) = T(\omega, x)$. In this setting, the shift map $\mathcal{S}$ becomes a skew-product transformation

$$\mathcal{S} : M \times \mathcal{U}^{\mathbb{N}} \circlearrowleft \quad (x, \underline{\omega}) \mapsto (T_{\omega_1}(x), \sigma(\underline{\omega}))$$

to which many of the standard methods of dynamical systems and ergodic theory can be applied, yielding stronger results that can be interpreted in random terms.

**Example 2** (Parametric noise). Let $T : P \times M \to M$ be a smooth map where $P$, $M$ are finite-dimensional Riemannian manifolds. We fix $p_0 \in P$, denote by $m$ some choice of Riemannian volume form on $P$, set $T_w(x) = T(w, x)$, and for every $\epsilon > 0$ write $\theta_\epsilon = (m(B(p_0, \epsilon))^{-1} \cdot (m \mid B(p_0, \epsilon))$, the normalized restriction of $m$ to the $\epsilon$-neighborhood of $p_0$. Then $(T_w)_{w \in P}$, together with $\theta_\epsilon$, defines a random perturbation of $T_{p_0}$, for every small enough $\epsilon > 0$.

**Example 3** (Global additive perturbations). Let $M$ be a homogeneous space, that is, a compact connected Lie group admitting an invariant Riemannian metric. Fixing a neighborhood $\mathcal{U}$ of the identity $e \in M$, we can define a map $T : \mathcal{U} \times M \to M$, $(u, x) \mapsto L_u(T_0(x))$, where $L_u(x) = u \cdot x$ is the left translation associated with $u \in M$. The invariance of the metric means that left (and also right) translations are isometries, hence fixing $u \in \mathcal{U}$ and taking any $(x, v) \in TM$, we get

$$\begin{aligned} \|DT_u(x) \cdot v\| &= \|DL_u(T_0(x))(DT_0(x) \cdot v)\| \\ &= \|DT_0(x) \cdot v\| \end{aligned}$$

In the particular case of $M = \mathbb{T}^d$, the $d$-dimensional torus, we have $T_u(x) = T_0(x) + u$, and this simplest case suggests the name "additive random perturbations" for random perturbations defined using families of maps of this type.

For the probability measure on $\mathcal{U}$, we may take $\theta_\epsilon$, any probability measure supported in the $\epsilon$-neighborhood of $e$ and absolutely continuous with respect to the Riemannian metric on $M$, for any $\epsilon > 0$ small enough.

**Example 4** (Local additive perturbations). If $M = \mathbb{R}^d$ and $U_0$ is a bounded open subset of $M$ strictly invariant under a diffeomorphism $T_0$, that is, closure $(T_0(U_0)) \subset U_0$, then we can define an isometric random perturbation setting:

(i) $V = T_0(U_0)$ (so that closure $(V) =$ closure $(T_0(U_0)) \subset U_0$);
(ii) $G \simeq \mathbb{R}^d$ the group of translations of $\mathbb{R}^d$; and
(iii) $\mathcal{V}$ a small enough neighborhood of 0 in $G$.

Then for $v \in \mathcal{V}$ and $x \in V$, we set $T_v(x) = x + v$, with the standard notation for vector addition, and clearly $T_v$ is an isometry. For $\theta_\epsilon$, we may take any probability measure on the $\epsilon$-neighborhood of 0, supported in $\mathcal{V}$ and absolutely continuous with respect to the volume in $\mathbb{R}^d$, for every small enough $\epsilon > 0$.

### Random Perturbations of Flows

In the continuous-time case, the basic model to start with is an ordinary differential equation $dX_t = f(t, X_t)dt$, where $f\colon [0, +\infty) \to \mathcal{X}(M)$ and $\mathcal{X}(M)$ is the family of vector fields in $M$. We embed randomness in the differential equation

basically through "diffusion," the perturbation is given by white noise or Brownian motion "added" to the ordinary solution.

In this setting, assuming for simplicity that $M = \mathbb{R}^n$, the random orbits are solutions of stochastic differential equations

$$\begin{aligned} \mathrm{d}X_t &= f(t, X_t)\mathrm{d}t + \epsilon \cdot \sigma(t, X_t)\mathrm{d}W_t, \\ & 0 \le t \le T,\ X_0 = Z \end{aligned}$$

where $Z$ is a random variable, $\epsilon, T > 0$ and both $f : [0, T] \times \mathbb{R}^n \to \mathbb{R}^n$ and $\sigma : [0, T] \times \mathbb{R}^n \to \mathcal{L}(\mathbb{R}^k, \mathbb{R}^n)$ are measurable functions. The space of linear maps $\mathbb{R}^k \to \mathbb{R}^n$ is written on $\mathcal{L}(\mathbb{R}^k, \mathbb{R}^n)$ and $W_t$ is the white-noise process on $\mathbb{R}^k$. The solution of this equation is a stochastic process:

$$X : \mathbb{R} \times \Omega \to M \quad (t, \omega) \mapsto X_t(\omega)$$

for some (abstract) probability space $\Omega$, given by

$$X_t = Z + \int_0^T f(s, X_s)\mathrm{d}s + \int_0^T \epsilon \cdot \sigma(s, X_s)\mathrm{d}W_s$$

where the last term is a stochastic integral in the sense of Itô. Under reasonable conditions on $f$ and $\sigma$, there exists a unique solution with continuous paths, that is,

$$[0, +\infty) \ni t \mapsto X_t(\omega)$$

is continuous for almost all $\omega \in \Omega$ (in general these paths are nowhere differentiable).

Setting $Z = \delta_{x_0}$, the probability measure concentrated on the point $x_0$, the initial point of the path is $x_0$ with probability 1. We write $X_t(\omega)x_0$ for paths of this type. Hence, $x \mapsto X_t(\omega)x$ defines a map $X_t(\omega) : M\circlearrowleft$ which can be shown to be a homeomorphism and even diffeomorphisms under suitable conditions on $f$ and $\sigma$. These maps satisfy a cocycle property

$$\begin{aligned} X_0(\omega) &= \mathrm{Id}_M \quad \text{(identity map of } M\text{)} \\ X_{t+s}(\omega) &= X_t(\theta(s)(\omega)) \circ X_s(\omega) \end{aligned}$$

for $s, t \ge 0$ and $\omega \in \Omega$, for a family of measure-preserving transformations $\theta(s) : (\Omega, \mathbb{P})\circlearrowleft$ on a suitably chosen probability space $(\Omega, \mathbb{P})$. This enables us to write the solution of this kind of equations also as a skew product.

### The Abstract Framework

The illustrative particular cases presented can all be written in skew-product form as follows.

Let $(\Omega, \mathbb{P})$ be a given probability space, which will be the model for the noise, and let $\mathbb{T}$ be time, which usually means $\mathbb{Z}_+, \mathbb{Z}$ (discrete, resp. invertible system) or $\mathbb{R}_+, \mathbb{R}$ (continuous, resp. invertible system). A random dynamical system is a skew product

$$\mathcal{S}_t : \Omega \times M\circlearrowleft, (\omega, x) \mapsto (\theta(t)(\omega), \varphi(t, \omega)(x))$$

for all $t \in \mathbb{T}$, where $\theta : \mathbb{T} \times \Omega \to \Omega$ is a family of measure-preserving maps $\theta(t) : (\Omega, \mathbb{P})\circlearrowleft$ and $\varphi : \mathbb{T} \times \Omega \times M \to M$ is a family of maps $\varphi(t, \omega) : M\circlearrowleft$ satisfying the cocycle property: for $s, t \in \mathbb{T}$, $\omega \in \Omega$,

$$\begin{aligned} \varphi(0, \omega) &= \mathrm{Id}_M \\ \varphi(t + s, \omega) &= \varphi(t, \theta(s)(\omega)) \circ \varphi(s, \omega) \end{aligned}$$

In this general setting an invariant measure for the random dynamical system is any probability measure $\mu$ on $\Omega \times M$ which is $\mathcal{S}_t$-invariant for all $t \in \mathbb{T}$ and whose marginal is $\mathbb{P}$, that is, $\mu(\mathcal{S}_t^{-1}(U)) = \mu(U)$ and $\mu(\pi_\Omega^{-1}(U)) = \mathbb{P}(U)$ for every measurable $U \subset \Omega \times M$, respectively, with $\pi_\Omega : \Omega \times M \to \Omega$ the natural projection.

**Example 5** In the setting of the previous examples of random perturbations of maps, the product measure $\eta = \mathbb{P} \times \mu$ on $\Omega \times M$, with $\Omega = \mathcal{U}^{\mathbb{N}}$, $\mathbb{P} = \theta_\epsilon^{\mathbb{N}}$ and $\mu$ any stationary measure, is clearly invariant. However, not all invariant measures are product measures of this type.

Naturally an invariant measure is ergodic if every $\mathcal{S}_t$-invariant function is $\mu$-almost everywhere constant. That is, if $\psi : \Omega \times M \to \mathbb{R}$ satisfies $\psi \circ \mathcal{S}_t = \psi$ $\mu$-almost everywhere for every $t \in \mathbb{T}$, then $\psi$ is $\mu$-almost everywhere constant.

## Applications

The well-established applications of both probability or stochastic differential equations (solution of boundary value problems, optimal stopping, stochastic control etc.) and dynamical systems (all kinds of models of physical, economic or biological phenomena, solutions of differential equations, control systems etc.) will not be presented here. Instead, this section focuses on topics where the subject sheds new light on these areas.

### Products of Random Matrices and the Multiplicative Ergodic Theorem

The following celebrated result on products of random matrices has far-reaching applications on dynamical systems theory.

Let $(X_n)_{n\ge0}$ be a sequence of independent and identically distributed random variables on the probability space $(\Omega, P)$ with values in $\mathcal{L}(\mathbb{R}^k, \mathbb{R}^k)$ such that $E(\log^+ \|X_1\|) < +\infty$, where $\log^+ x = \max\{0, \log x\}$ and $\|\cdot\|$ is a given norm on

$\mathcal{L}(\mathbb{R}^k, \mathbb{R}^k)$. Writing $\varphi_n(\omega) = X_n(\omega) \circ \cdots \circ X_1(\omega)$ for all $n \geq 1$ and $\omega \in \Omega$ we obtain a cocycle. If we set

$$B = \left\{ (\omega, y) \in \Omega \times \mathbb{R}^k : \lim_{n \to +\infty} \frac{1}{n} \log \|\varphi_n(\omega) y\| \right.$$
$$\left. \text{exists and is finite or is } -\infty \right\},$$
$$\Omega' = \{\omega \in \Omega : (\omega, y) \in B \text{ for all } y \in \mathbb{R}^k\}$$

then $\Omega'$ contains a subset $\Omega''$ of full probability and there exist random variables (which might take the value $-\infty$) $\lambda_1 \geq \lambda_2 \geq \cdots \geq \lambda_k$ with the following properties.

1. Let $I = \{k+1 = i_1 > i_2 > \cdots > i_{l+1} = 1\}$ be any $(l+1)$-tuple of integers and then we define

   $$\Omega_I = \{\omega \in \Omega'' : \lambda_i(\omega) = \lambda_j(\omega), i_h > i, j \geq i_{h+1},$$
   $$\text{and } \lambda_{i_h}(\omega) > \lambda_{i_{h+1}}(\omega) \text{ for all } 1 < h < l\}$$

   the set of elements where the sequence $\lambda_i$ jumps exactly at the indexes in $I$. Then for $\omega \in \Omega_I, 1 < h \leq l$,

   $$\Sigma_{I,h}(\omega) = \left\{ y \in \mathbb{R}^k : \lim_{n \to +\infty} \frac{1}{n} \log \|\varphi_n(\omega)\| \leq \lambda_{i_h}(\omega) \right\}$$

   is a vector subspace with dimension $i_{h-1} - 1$.
2. Setting $\Sigma_{I,k+1}(\omega) = \{0\}$, then

   $$\lim_{n \to +\infty} \frac{1}{n} \log \|\varphi_n(\omega)\| = \lambda_{i_h}(\omega)$$

   for every $y \in \Sigma_{I,h}(\omega) \backslash \Sigma_{I,h+1}(\omega)$.
3. For all $\omega \in \Omega''$ there exists the matrix

   $$A(\omega) = \lim_{n \to +\infty} [(\varphi_n(\omega))^* \varphi_n(\omega)]^{1/2n}$$

   whose eigenvalues form the set $\{e^{\lambda_i} : i = 1, \ldots, k\}$.

The values of $\lambda_i$ are the random Lyapunov characteristics and the corresponding subspaces are analogous to random eigenspaces. If the sequence $(X_n)_{n \geq 0}$ is ergodic, then the Lyapunov characteristics become nonrandom constants, but the Lyapunov subspaces are still random.

We can easily deduce the multiplicative ergodic theorem for measure-preserving differentiable maps $(T_0, \mu)$ on manifolds $M$ from this result. For simplicity, we assume that $M \subset \mathbb{R}^k$ and set $p(A \mid x) = \delta_{T_0(x)}(A) = 1$ if $T_0(x) \in A$ and 0 otherwise. Then the measure $\mu \times p^{\mathbb{N}}$ on $M \times M^{\mathbb{N}}$ is $\sigma$-invariant (as defined earlier) and we have that $\pi_0 \circ \sigma = T_0 \circ \pi_0$, where $\pi_0 : M^{\mathbb{N}} \to M$ is the projection on the first coordinate, and also $(\pi_0)_*(\mu \times p^{\mathbb{N}}) = \mu$. Then, setting for $n \geq 1$

$$X : M \to \mathcal{L}(\mathbb{R}^k, \mathbb{R}^k) \quad \text{and} \quad X_n = X \circ \pi_0 \circ \sigma^n$$
$$x \mapsto DT_0(x)$$

we obtain a stationary sequence to which we can apply the previous result, obtaining the existence of Lyapunov exponents and of Lyapunov subspaces on a full measure subset for any $C^1$ measure-preserving dynamical system.

By a standard extension of the previous setup, we obtain a random version of the multiplicative ergodic theorem. We take a family of skew-product maps $\mathcal{S}_t : \Omega \times M \circlearrowleft$ as in the section "The abstract framework" with an invariant probability measure $\mu$ and such that $\varphi(t, \omega) : M \circlearrowleft$ is (for simplicity) a local diffeomorphism. We then consider the stationary family

$$X_t : \Omega \to \mathcal{L}(TM),\ \omega \mapsto D\varphi(t, \omega) : TM \circlearrowleft \quad t \in \mathbb{T}$$

where $D\varphi(t, \omega)$ is the tangent map to $\varphi(t, \omega)$. This is a cocycle since for all $t, s \in \mathbb{T}$, $\omega \in \Omega$ we have

$$X(s+t, \omega) = X(s, \theta(t)\omega) \circ X(t, \omega)$$

If we assume that

$$\sup_{0 \leq t \leq 1} \sup_{x \in M} \left( \log^+ \|D\varphi(t, \omega)(x)\| \right) \in L^1(\Omega, \mathbb{P})$$

where $\|\cdot\|$ denotes the norm on the corresponding space of linear maps given by the induced norm (from the Riemannian metric) on the appropriate tangent spaces, then we obtain a sequence of random variables (which might take the value $-\infty$) $\lambda_1 \geq \lambda_2 \geq \cdots \geq \lambda_k$, with $k$ being the dimension of $M$, such that

$$\lim_{t \to +\infty} \frac{1}{t} \log \|X_t(\omega, x) y\| = \lambda_i(\omega, x)$$

for every $y \in E_i \omega, x) = \Sigma_i(\omega, x) \setminus \Sigma_{i+1}(\omega, x)$ and $i = 1, \ldots, k+1$, where $(\Sigma_i(\omega, x))_i$ is a sequence of vector subspaces in $T_x M$ as before, measurable with respect to $(\omega, x)$. In this setting, the subspaces $E_i(\omega, x)$ and the Lyapunov exponents are invariant, that is, for all $t \in \mathbb{T}$ and $\mu$-almost every $(\omega, x) \in \Omega \times M$, we have

$$\lambda_i(\mathcal{S}_t(\omega, x)) = \lambda_i(\omega, x) \quad \text{and} \quad E_i(\mathcal{S}_t(\omega, x)) = E_i(\omega, x)$$

The dependence of Lyapunov exponents on the map $T_0$ has been a fruitful and central research program in dynamical systems for decades extending to the present day. The random multiplicative ergodic theorem sets the stage for the study of the stability of Lyapunov exponents under random perturbations.

### Stochastic Stability of Physical Measures

The development of the theory of dynamical systems has shown that models involving expressions as simple as quadratic polynomials (as the logistic family or Hénon attractor), or autonomous ordinary

differential equations with a hyperbolic singularity of saddle type, as the Lorenz flow, exhibit sensitive dependence on initial conditions, a common feature of chaotic dynamics: small initial differences are rapidly augmented as time passes, causing two trajectories originally coming from practically indistinguishable points to behave in a completely different manner after a short while. Long-term predictions based on such models are unfeasible, since it is not possible to both specify initial conditions with arbitrary accuracy and numerically calculate with arbitrary precision.

**Physical measures** Inspired by an analogous situation of unpredictability faced in the field of statistical mechanics/thermodynamics, researchers focused on the statistics of the data provided by the time averages of some observable (a continuous function on the manifold) of the system. Time averages are guaranteed to exist for a positive-volume subset of initial states (also called an observable subset) on the mathematical model if the transformation, or the flow associated with the ordinary differential equation, admits a smooth invariant measure (a density) or a physical measure.
